There are certain hospitals in this country in which for many years necropsies have been performed in nearly all fatal cases. Such hospitals, however, are usually special hospitals of one sort or another. Comparatively few institutions that offer an apprenticeship in general practice have done so well. This fact, already has received comment from time to time, and efforts have been made toward improving the situation. For example, all hospitals now desiring approval by the American Medical Association for the training of residents must examine post mortem at least 15 per cent of their fatal cases. This ruling is a logical one, stressing as it does adequate training in pathology as an important qualification for a good residency, and the belief that on the whole the percentage of necropsies obtained in any hospital forms a very good index of the professional efficiency of the institution.

There are various methods that can be employed to obtain permission to make pathologic examinations in an increasing number of cases: public education is one of the most important. People must learn what a post-mortem examination is and why it is important. Articles for the layman, such as the one called "I want a Postmortem Examination Made When I Die," by Dr. Emil Bogen,² or the one by Dr. Oscar T. Schultz,³ "Tales That Dead Men Tell," have played an important part in public education of this character. Since physicians must set the pace in matters of this sort, the example of a man like Dr. W. S. Thayer is most inspiring. In the *Boston Herald* for December 15, 1932, there appeared an Associated Press article under the caption "Dr. Thayer Wills Body to Science." This article quoted Dr. Thayer's will as beginning:

I direct that on my death a necropsy be performed upon my body for the purpose of scientific study at the earliest possible moment after my death, preferably by my dear friend William G. MacCallum.

I should like especially to have the condition of my coronary arteries and heart muscle carefully explored.

Especially do I desire that my friend Dr. Adolph Meyer may, if he desires, have every opportunity to study my brain. The interest which may attach to this lies in the circumstance that I have had for about fourteen years, since a resection of my nasal septum, a complete anosmia.

After a complete necropsy, after which any parts of my body which may be useful may be preserved, I direct that the remains be cremated and the ashes buried at Sleepy Hollow graveyard at Concord, Mass.

Such an example is bound to affect the public mind. I hope many physicians will follow it.

From the Medical Clinic of the Peter Bent Brigham Hospital.
Read before the Section on Practice of Medicine at the Eighty-Fourth Annual Session of the American Medical Association, Milwaukee, June 16, 1933.

3. Schultz, O. T.: Tales that Dead Men Tell, *Hygeia* 7: 1201-1204 (Dec.) 1929.

Cooperation with undertakers and funeral directors, too, is an important step in increasing a hospital's autopsy percentage. Ten years ago, Krumbhaar⁴ described the necessity for such cooperation and showed how, in the Philadelphia General Hospital, by this and other steps, the necropsy percentages were increased rapidly from 10 to over 50. In 1925, the New England Hospital Association listened to a very stimulating address on "Requirements for Cooperation Between Hospitals and Funeral Directors" by Mr. Arthur H. Chandler,⁵ president of the Massachusetts Funeral Directors' Association, and, as judged by the ensuing discussion, this paper had a far-reaching effect on the hospitals in New England.

Fundamentally, however, the necropsy percentages of any hospital depend on the staff. For ten years I have had the privilege of being associated with the Peter Bent Brigham Hospital in Boston. During this decade our pathologists have examined 66 per cent of all patients dying in the hospital. This is one of the few general hospitals in the country with such a record for accomplishment of thorough work. It is not amiss, therefore, to describe how the record is maintained.

What Dr. Harvey Cushing⁶ has termed "the personality of a hospital" has much to do with the activities of the pathologic laboratory. Since the Peter Bent Brigham Hospital opened, it has been the tradition for the resident, visiting and nursing staff to treat each patient as though he or she owned the place. We have put ourselves out to make our guests feel at home, to become well acquainted with them and with their friends and relatives, to be sympathetic with their idiosyncrasies and to understand thoroughly not only their diseases but also—and sometimes this is much more important—their social, economic and psychologic problems.

It also has become a tradition with us to explain to patients and their relatives the necessity for whatever procedure is indicated; to tell them what we hope to accomplish by treatment and to be as patient as possible with those who are distraught or prone to misunderstand. This is carried out by frequent interviews with the patients in the wards. Each day, too, after ward rounds, the senior house officers assemble at the front of the hospital to talk to the friends and relatives of the patients. Here all questions are answered and the personal relationship is established that exists between a practicing physician and the families of his patients. And, finally, if treatment has failed and death has occurred, the senior house officer in charge of the ward in which the fatality has taken place asks the nearest relative or friend for permission to carry on a pathologic examination. He, as a well educated physician should, tells the friends or relatives of deceased patients what has happened and why further examination is important; and he assures them that such an examination is not in the least disfiguring but merely a necessary operation to make sure that everything possible in treatment has been done. In the majority of cases, as our records show, no great objection is encountered.

The examination is conducted expertly and with the same regard for technic and care that is displayed by all good surgeons. A careful record of the observations is made, and, at last, a letter describing the sig-

nificance of the observations in regard to the individual case is sent with a word of condolence to the patient's relatives and family physician.

This general course of procedure in completing the final study of our cases has been effectual for so many years and in the hands of so many different interns that I am fully convinced of its efficacy. An intern who treats his patients and their relatives considerately and well can generally, forever after, get them to do anything he wishes.

THE CABOT CLINIC

Just as it is important for members of the hospital staff who are engaged in training interns to encourage a complete and careful clinical study of each case, so is it equally important for them to make sure that the pathologic material of the hospital is used to best advantage for educational purposes. This can be accomplished in various ways.

More than twenty-five years ago Dr. Richard Cabot introduced in the Harvard Medical School an interesting and popular teaching exercise which he still maintains. Every other week he comes to the Peter Bent Brigham Hospital and meets in the amphitheater a group of students and staff. He is given an abstracted case record of a certain patient whom he has never seen and of whose case he knows nothing. He reads the record aloud, comments as he sees fit on the history and the physical and laboratory examinations, inspects such roentgenograms as he wishes to look at, reads the "follow-up" notes and finally makes a diagnosis. He explains why he arrives at his diagnosis in this particular case, discusses, on the way, differential diagnosis, the physical signs or laboratory data which are essential or misleading, and the significance, in his experience, of this or that point. Having made a diagnosis, he asks the pathologist for the actual observations. These are given in detail and are often accompanied by gross and microscopic demonstrations. Thus, the correctness of Dr. Cabot's diagnosis is established or refuted beyond peradventure. Dr. Cabot aims to make diagnoses that are unequivocal and definite, and he never hedges; he makes an earnest attempt to correlate clinical and pathologic observations to improve not only his own diagnostic acumen but also that of his audience.

I have always found this exercise most stimulating. It has been fitted to hospitals elsewhere, as Dr. Steinberg⁷ of Toledo has shown, but its success, in Boston at least, depends on Dr. Cabot's personality. To carry on the exercise properly, the clinician should be pungent and witty, have a positive way of stating things, should know nothing about the case before the time of discussion, and should be entirely fearless and unashamed to be found wrong by a keen pathologist.

THE MAYO CLINIC STAFF CONFERENCE

When I was working in Rochester, Minn., the clinical-pathologic staff conferences of the Mayo Clinic were equally valuable and interesting. The staff met each Wednesday evening and each member was supplied with a typewritten summary of all fatal cases of the previous week. A very short abstract of each case was given with a note on the diagnosis, treatment and pathologic observations. Each case was then discussed in detail by the pathologist and the importance of the various pathologic observations was described. The

pathologic interest of the cases was not so much stressed, however, as was the possibility of devising new methods of diagnosis or treatment to prevent the future occurrence of similar cases. Thus, for example, in that particular period of time an undue number of patients with thyroid disease and with jaundice appeared to be doing badly. As a result, Dr. Henry Plummer before long introduced the use of compound solution of iodine (Lugol's solution), and the thyroid fatalities disappeared, and Dr. Waltman Walters began studying blood coagulation and liver function experimentally and in jaundiced patients, with the result that methods were soon developed by which cases of this type were prepared scientifically for operation and rendered good instead of poor surgical risks.

This experience in the Mayo Clinic has made a deep impression on my mind, demonstrating as it does the possibilities of team play in the advancement of medical knowledge. I have often thought that large hospitals, especially large municipal hospitals with a quick "turn-over," might do well to establish similar conferences for the visiting and resident staffs. It is very important to know the type of case that is being admitted to such a hospital at any given season of the year, whether in general disease is severe or mild, which type of disease produces the fatalities that occur and what are the major problems. This information can be obtained and made generally available only by staff conferences of the Mayo Clinic type. If such conferences are attempted, however, the spirit of self-sacrificing team play must be fostered. The staff conferences must be well attended. There must be no backbiting nor unfair criticism. Every one must make an honest effort to improve the work of the hospital, concentrating material for investigation, when necessary, and giving those with a bent for clinical investigation all possible opportunity, support and encouragement.

THE PETER BENT BRIGHAM HOSPITAL CONFERENCES

Still another valuable method for making use of the pathologic material is employed at the Peter Bent Brigham Hospital. One day a week for an hour there is an x-ray conference at which the roentgenologist demonstrates the particularly interesting films of the week. A brief history of each case is given and the roentgen observations are correlated with the clinical examinations. Cases that have been examined by the pathologic department are utilized to particular advantage; gross and microscopic appearances are compared with those of the roentgenogram, and the advancement of any disease is traced as clearly as possible by serial films. Finally, there is an exhibition of tissues that have been removed by the surgeons, or of abnormalities discovered at necropsy by the pathologists. This is a very important exercise. It is attended by the entire staff and links together firmly the combined activities of the clinical, radiologic and pathologic staffs of the hospital.

One day a week, too, we have a more formal clinical-pathologic conference. Here, completely studied cases are discussed. Case histories and clinical examinations are compared with pathologic observations, and the life history of disease in a given case is described from beginning to end. The exercise is a popular one, well liked by students and staff. I know of no better method of teaching applied pathology to a group of clinically minded interns and students.

PUBLISHED CASE REPORTS

Finally, the hospital teaching staff must remember that one of its important duties is to train men to write medical papers properly. Professor Christian, with us, has always made it a point to encourage each one of his interns to carry out some piece of original work as part of his training. Since interesting cases worthy of record are constantly under observation and followed up, many interns add to the literature by reporting one or more of the carefully and completely studied cases that have been observed. In writing such a paper, the intern learns how to assemble literature and thus how to use a library; how to compile a bibliography, and, most important of all, the fact that medical writing is difficult and laborious. Such an experience is a valuable feature of effective intern training and, if carried on elsewhere, will do much to help American medical literature. For several years, the Alleghany County Medical Society of Pennsylvania⁸ has tried an interesting experiment along this line. Each year the society offers a prize of \$50 for the best case report submitted by interns of any approved hospital in the county. In judging the material submitted, brevity, general interest of the case, completeness of detail and literary style of the composition each receive due consideration. No doubt, the possibility of winning such a prize improves the work of the interns of the hospitals in Alleghany County to a perceptible degree.

These, in brief, are some of the ways in which the pathologic work of hospitals in which interns are trained can be utilized for teaching purposes. No doubt there are many other ways, equally valuable, to accomplish this purpose. Each institution must develop the method best suited to itself. To make such teaching of greatest value, however, enthusiasm on the part of the teaching staff is essential. A great deal can be accomplished to improve the scheme of graduate-teaching in hospitals approved for interns if each practitioner who is on such a hospital staff remembers Dr. Cushing's advice:

Example has much to do with the perpetuation of tradition, especially where there is a succession of hero-worshipping and imitative juniors; and if a hospital's personality is, as I believe it to be, its chief asset, the thought should quicken the sense of responsibility of everyone. He who is willing to do something more than follow a prescribed routine and who merges himself most with the active indoor life of the institution, giving even at personal sacrifice the most time to the attainment of this end, is certain to be the best and longest remembered.

Agnesis of the Corpus Callosum.—Since 1812, eighty-two cases of agnesis of the corpus callosum have been reported, in fifty-one (62 per cent) of which it was complete and in thirty-one (38 per cent) partial. Agnesis of the corpus callosum is usually associated with other anomalies of the brain, such as polygyria, embryonic arrangement of sulci, absence of olfactory nerves and partial separation of the frontal lobes. The age of distribution of agnesis ranges from birth to 73 years of age, the majority of patients being in the first decade of life. The mentality of the patients varies from idiocy to mediocre intelligence, corresponding somewhat with the associated anomalies of the brain. The etiology of this condition is unknown, although many speculations have been suggested.—Barker, R. C., and Graves, G. O.: Partial Agnesis of the Corpus Callosum, *Arch. Neurol. & Psychiat.* 29:1054 (May) 1933.

THE RÔLE OF DIIODOTYROSINE IN HYPERTHYROIDISM

A COMPARISON OF THE THERAPEUTIC EFFECT OF
DIIODOTYROSINE WITH INORGANIC IODINE

ALEXANDER B. GUTMAN, M.D.

LAWRENCE W. SLOAN, M.D.

ETHEL BENEDICT GUTMAN
AND

WALTER W. PALMER, M.D.

NEW YORK

In a number of publications which appeared recently,¹ particularly in the German literature, it was reported that the administration of diiodotyrosine to patients with hyperthyroidism causes a striking amelioration of symptoms and a sharp fall in the basal metabolic

need of thyroidectomy could be obviated in less severe cases.¹¹ These authors regard diiodotyrosine as the medication of choice in the management of hyperthyroidism. However, although a controlled comparison of the effects of diiodotyrosine with the response to more commonly used iodine compounds would seem to be indicated by the therapeutic importance and theoretical interest of these observations, no such study has been made, so far as we know. A record of our experience with diiodotyrosine in the preoperative management of patients with hyperthyroidism as compared with our results with compound solution of iodine and sodium iodide may therefore be of interest.

The therapeutic effect of diiodotyrosine is also of more general interest, since diiodotyrosine is now known to be one of the constituent amino-acids of thyroglobulin.² Its significance in the economy of the thyroid gland, particularly in the development of hyper-

rate. The response to diiodotyrosine was found to be more marked than that expected with compound solution of iodine (Lugol's solution) and is believed to be not an iodine effect but a specific diiodotyrosine response *sui generis*. Remission was obtained with diiodotyrosine in cases refractory to iodides,^{1e} and the

thyroidism, has long been a matter of conjecture. Harington and Barger³ regarded diiodotyrosine as an intermediate in the synthesis of thyroxine, formed, probably, "by the coupling of two molecules of diiodotyrosine with the loss of one side chain." Although never verified experimentally, this suggestion has been widely accepted as a reasonable working hypothesis. A more significant rôle has been ascribed to diiodotyrosine recently by Abelin,⁴ who suggests that the physiologic activity of the thyroid hormone is the resultant of the antagonistic effects of thyroxine and diiodotyrosine, normally in equilibrium. This balance is destroyed in

pathologic states of the thyroid gland; hyperthyroidism being associated with a preponderance of thyroxine, myxedema with an excess of diiodotyrosine. The favorable influence of diiodotyrosine in hyperthyroidism is therefore regarded as the result of the restoration of normal equilibrium between thyroxine and diiodotyrosine in the diiodotyrosine-deficient gland.⁵ The evidence for this view is based on the following observations: 1. The decrease in liver glycogen caused by feeding thyroid to rats is less marked if diiodotyrosine is given simultaneously in appropriate doses.⁴ 2. The elevation of the basal metabolic rate caused by feeding thyroid to rats is decreased by added diiodotyrosine.⁴ Iodides are ineffective.⁶

The studies reported here were made on a group of thirty unselected bed patients who showed definite clinical and metabolic evidence of hyperthyroidism. The results are summarized in table 1. In five cases the

cal evaluation according to the severity of symptoms and signs. In all but six cases there was a gain in weight during the first week of medication averaging about 2 pounds (900 Gm.) per patient. The largest gain was 6 pounds (2,700 Gm.). The average gain in weight during the second week was slightly less. The basal pulse rate showed a definite and satisfactory drop in all but six cases, in which the initial basal pulse rate was low and remained essentially unchanged. In two cases a slight rash appeared. As not infrequently observed with compound solution of iodine and sodium iodide, the clinical improvement of some patients seemed more satisfactory than the basal metabolic determination would indicate, particularly during the second week of treatment.

The postoperative course of these patients did not differ notably from those prepared for operation with inorganic iodine. A routine histologic examination

thyroid gland was nodular; in the remainder, diffusely enlarged. With three exceptions, to be discussed later, none of the patients had received iodine prior to admission. A careful clinical estimation of the hyperthyroid state was made and the basal metabolic rate determined on admission and again after two or more days of bed rest with phenobarbital as the only medication. The administration of diiodotyrosine was then begun, the usual dose being 100 mg. a day (containing approximately as much iodine as in 0.5 cc. of compound solution of iodine). A clinical and metabolic check-up was again made after one and two weeks of medication. Partial thyroidectomy was performed shortly thereafter, and portions of the resected gland were examined histologically and chemically. The clinical impression of the response to diiodotyrosine was checked by a numeri-

cal evaluation according to the severity of symptoms and signs. The changes being those associated with iodine-treated hyperthyroid glands:^{1b} hyperplasia, cuboidal and columnar acinous epithelial cells, focal collections of lymphocytes and accumulation of colloid, which frequently showed vacuolization.

The response to diiodotyrosine of three cases previously treated with inorganic iodine is of particular interest with respect to the specificity of the diiodotyrosine effect. In each instance, the response to iodides and to diiodotyrosine seemed to be very similar:

CASE 23.—An American girl, aged 17 years, presenting a classic picture of exophthalmic goiter, had been treated with inorganic iodine for two weeks relatively early in the course of the disease and gave a clear history of improvement. About six months later she was admitted to the hospital following an exacerbation of symptoms with a basal metabolic rate of +35, which dropped to +9 in seven days. Operation was postponed, but she was given compound solution of iodine in intermittent

doses and her progress followed in the clinic. The response was fair at first, but the symptoms became more severe about ten months later. At that time diiodotyrosine was given and for a period of about two and a half months there was definite improvement, the basal metabolic rate dropping from $+58$ to $+29$. Then, as previously on inorganic iodine, unmistakable signs of "escape" began to develop, the basal metabolic rate mounting to $+61$ in less than a month. Diiodotyrosine was discontinued at that point, the basal metabolic rate thereafter mounting further to $+83$. Diiodotyrosine was then given preparatory to operation, the basal metabolic rate dropping to $+45$.

CASE 24.—A Negro woman, aged 38, had been similarly treated with inorganic iodine relatively early in the disease, with a good effect at first for about two months. Signs of "escape" then began to develop. She was admitted to the hospital with a basal metabolic rate of $+53$ and obviously very toxic. She had not received iodine for two weeks at the time of admission. After a third week without iodine, compound solution of iodine was given for nine days, the basal metabolic rate changing very little ($+46$). Clinically, she appeared somewhat improved. Diiodotyrosine was then started and continued for twelve days, after which the basal metabolic rate was $+48$ and there was no obvious improvement in her condition. She was still in a very toxic state at the time a partial hemithyroidectomy was performed and died two days after operation with all the signs and symptoms of severe acute thyrotoxicosis.

CASE 25.—An American housewife, aged 62, presented all the stigmas of exophthalmic goiter of moderate severity with a moderately large gland but with a basal metabolic rate of only $+21$ on admission to the hospital. She was given sodium iodide for ten days without clinical improvement and the basal metabolic rate was then found to be $+28$. Diiodotyrosine was administered for ten days, at the end of which time the rate was $+32$, with no definite clinical improvement.

In confirmation of the earlier reports,¹ our results indicate that administration of diiodotyrosine to patients with hyperthyroidism usually results in clinical remission and a fall in the basal metabolic rate. While the response was often very satisfactory, it was our general clinical impression that remission was not more striking than that noted after compound solution of iodine or sodium iodide. This impression was fortified by the results of a comparison of the fall in basal metabolism after diiodotyrosine in this series with that obtained with compound solution of iodine or sodium iodide in 185 unselected bed patients showing definite clinical and metabolic evidence of hyperthyroidism (table 2). In thirty-five of these cases, the thyroid gland was nodular; in the remainder, diffusely enlarged. Forty-five patients received sodium iodide before operation (usually 0.1 Gm. daily), while the remainder received compound solution of iodine (usually 1 cc. daily), the response to the two medications being essentially the same in this series.⁷ The patients are grouped according to the level of the basal metabolic rate as determined not earlier than the third day of hospitalization, before iodine medication was begun. The response indicated was obtained after from seven to fourteen (average ten) days of treatment with iodine, with eighteen exceptions. The average fall in the basal metabolic rate in the several groups corresponds in general with the careful studies reported by clinics as widely separated geographically as Boston,⁸ Chicago,⁹

Baltimore,¹⁰ Vienna¹¹ and Breslau.¹² Comparison of these results with the decrease in the basal metabolic rate following administration of diiodotyrosine (as shown in table 1, and the articles cited in footnote 1) does not warrant the conclusion that the response to diiodotyrosine is more marked than might have been anticipated with compound solution of iodine or sodium iodide.

The resected thyroid glands of our patients prepared with diiodotyrosine were analyzed for total iodine by a slightly modified Kendall method¹³ and for thyroxine iodine by the method of Leland and Foster.¹⁴ The results in this series (table 1) fall within the wide range of variation previously observed in a larger group in which compound solution of iodine had been used before operation.¹⁵ This obtains also for the thyroxine iodine per cent of thyroglobulin iodine, as indicated in the accompanying chart. Analysis of 120 thyroid glands of patients with hyperthyroidism, including many severe cases, has not provided us with any instance in which hyperthyroidism was associated with an increased thyroxine iodine percentage of thyroglobulin iodine definitely above the normal maximum.¹⁶ On the contrary, all the available chemical data¹⁷ point to a decrease in thyroxine iodine percentage of thyroglobulin iodine in hyperthyroidism. The mean thyroxine iodine per-

Scatter diagram to show the relationship between increasing thyroglobulin iodine percentage and the ratio of thyroxine iodine to thyroglobulin iodine in seventy-two diffuse and eighteen nodular hyperthyroid glands from patients given inorganic iodine; and twenty-five diffuse and five nodular glands after diiodotyrosine. The major trend is indicated by lines drawn to include the areas containing the majority of points. The solid dots represent patients with toxic diffuse goiters given compound solution of iodine; hollow dots, patients with toxic nodular goiters given compound solution of iodine; plus signs, patients with toxic goiters given diiodotyrosine.

centage of thyroglobulin iodine in thirty-eight hyperthyroid glands containing less than 0.1 per cent of total iodine in the dry gland was found to be 11.4. A similar decrease was also observed in degenerated nontoxic nodular glands.¹⁵ The cause of the decrease in thyroxine iodine percentage of thyroglobulin iodine is not known. It has been suggested¹⁵ that too rapid discharge of thyroid hormone into the circulating fluid in hyperthyroidism, or a deficiency of some essential agent in degenerated nontoxic glands might play a part in the inadequate formation of thyroxine from intermediate

iodine compounds such as diiodotyrosine. But, as pointed out by Wilson and Kendall,¹⁷ these changes in the thyroid gland are probably secondary and do not play a determining causal rôle in the course of hyperthyroidism.

It has been shown that when gram doses of diiodotyrosine are fed to rabbits, some diiodotyrosine is absorbed intact,¹⁸ as indicated by the recovery of diiodotyrosine and 3,5-diiodo-4-hydroxyphenyllactic acid in the urine.¹³ When fed in such enormous doses, only about 10 per cent of the total iodine excreted was found to be in inorganic form. It is not known what proportion of diiodotyrosine is broken down when given in therapeutic doses to patients. It is not impossible that, when administered in small quantities, no diiodotyrosine is absorbed as such and the effects observed in hyperthyroidism are due to inorganic iodine split off in the alimentary tract. For this reason, an attempt was made to estimate diiodotyrosine as the free amino-acid in the thyroid glands of our patients given diiodotyrosine. The glands, dried at 70 C. for from twenty-four to forty-eight hours, were extracted with tenth normal sulphuric acid,¹⁹ in which diiodotyrosine is soluble and relatively stable. The extract was then ultrafiltered and the ultrafiltrate examined for inorganic iodine.¹³ More than half of the ultrafilterable iodine could be accounted for as iodides, in most instances, but an appreciable fraction gave a silver precipitate which was acid soluble, reacting like diiodotyrosine (table 1). A mean of 94 per cent of ultrafilterable iodine was recovered as iodides from six thyroid glands of patients given compound solution of iodine. This is within the limit of error of recovery in known potassium iodide solutions.

CONCLUSIONS

We are more impressed with the similarities than by the differences between the response of hyperthyroid patients to diiodotyrosine and to other iodine compounds. The effects are indistinguishable as to time of onset of remission, the period required for maximum response, the duration of remission, the exacerbation when medication is discontinued, the response when again administered,¹ the ultimate development of a refractory state, the success of intermittent dosage in mild cases,¹ and the characteristic clinical, metabolic, histologic and chemical changes common to the two. The conclusion that the effects of diiodotyrosine and of inorganic iodine are essentially the same appears justified. It has been suggested⁴ that the effects of iodine in hyperthyroidism are due to the influence of diiodotyrosine that is formed. Ignorance of the intermediary iodine metabolism of the thyroid gland makes it impossible to prove or disprove this assumption. Diiodotyrosine has not been conclusively shown to have any physiologic activity that could be regarded as antagonistic to thyroxine. The lowering of the basal metabolic rate of animals fed thyroid gland by added diiodotyrosine was not observed by Kommerell¹⁹ in dogs or in this laboratory in guinea-pigs.²⁰ Diiodotyrosine does not lower the basal metabolism of normal animals, as might be expected of a substance having an

effect antagonistic to thyroxine. One might expect, furthermore, that administration of thyroxine in the form of thyroid gland, which also contains a large proportion of diiodotyrosine, would not produce as great an effect on the metabolism as an equivalent amount of thyroxine in the form of the free amino-acid. That this is not the case is well established. It should be pointed out that the only definite physiologic activity which diiodotyrosine has been shown to possess is the acceleration of metamorphosis in amphibia, in which respect it acts like thyroxine.

SUMMARY

1. Thirty patients with hyperthyroidism were prepared for thyroidectomy by administration of diiodotyrosine. The reports of earlier workers that diiodotyrosine induces clinical remission and a fall in the basal metabolic rate were confirmed.

2. The degree and characteristics of the clinical and metabolic response were essentially similar to those obtained with compound solution of iodine and sodium iodide. The total iodine and thyroxine contents of the resected thyroid glands were found to fall within the range of variation of glands obtained from patients given inorganic iodine.

3. No evidence was obtained to justify the impression that the effect of diiodotyrosine in hyperthyroidism is specifically different from that of other forms of iodine.

DERMATITIS PRODUCED BY COSMETICS (LA GERARDINE)

LESTER HOLLANDER, M.D.

PITTSBURGH

Dermatitis produced by cosmetics through direct contact is becoming a more frequently established and recognized condition, but the specific agent responsible for this eruption has to be ferreted out of an almost endless number of these so-called beautifying preparations.

As the eruption may develop either immediately after the use of a new preparation as a result of specific hypersensitivity or of chemical irritation, or only after a long period of use, as a result of sensibilization, created through frequent and constant use, difficulty arises in finding the cause. A subconscious defensive attitude on the part of the patient when the subject of cosmetics is broached adds further hindrance.

It may be profitable to mention what arouses one's suspicion of a dermatitis produced by contact with cosmetics:

1. Location of the eruption.
2. Sudden appearance.
3. Intense subjective symptoms (burning and itching).
4. Time element.
5. Type of skin eruption.

These points need further elucidation:

1. *Location.*—The area in which the eruption originally began is of the greatest importance and must be carefully elicited. As a general rule, only the exposed surfaces become involved, but in severe cases, through scratching, distant parts may become secondarily affected.

From the Pittsburgh Skin and Cancer Foundation.

18. Oswald, A.: Ueber den Abbau des Dijodotyrosins im tierischen Organismus, *Ztschr. f. physiol. Chem.* 65:141, 1910. Foster and Gutman.²³

19. Kommerell, B.: Zur Frage der Wirkung des Dijodotyrosins auf den thyreotoxischen Stoffwechsel, *Arch. f. exper. Path. u. Pharmacol.* 165:169, 1932.

20. The normal oxygen consumption of three guinea-pigs (94.1, 91.7 and 95.0 cc. per square meter per minute) was increased 24, 47.3 and 38.3 per cent by feeding thyroid. After ten days on the same daily dosage of thyroid + 50 mg. of diiodotyrosine, the oxygen consumption remained 38.4, 50.3 and 39.7 per cent, respectively, above the initial value. The determinations were made in a modified Benedict closed circuit apparatus by Dr. J. P. Leland, to whom we are greatly indebted.

Dependent on the location of the commencement of the eruption, the following causative factors may be suspected:

Scalp: Hair tonics and hair dyes. (Usually only chemical irritants contained in hair tonics cause a dermatitis in the scalp, such as tincture of capsicum or of cantharides.)

Forehead: Hair lotions, hair dyes, tissue creams.

Eyelids: Hair tonics, hair dyes, massage creams, eye washes, face powder, nasal sprays.

Nose: Nasal sprays.

Circumoral Area: Tooth powders, tooth pastes, mouth washes, lip rouge.

Face: Face creams, face powder, hair tonics, hair dyes, hair waving preparations, soap, depilatories.

Retro-Auricular Area: Perfume, hair tonics.

Neck: Perfume, hair dyes, hair waving preparations, hair tonics, massage creams (especially lemon creams).

Axillae: Deodorants, depilatories, perfume.

Nipples and Navel: Perfume.

Under the Breasts: Powder, soap.

Nails: Nail paints, manicuring aids.

Groin and Anal Region: Menstrual pads, toilet paper, deodorants hair dyes.

Legs: Depilatories, soaps.

Interdigital Areas and Soles: Dusting (foot) powders.

2. *Sudden Appearance.*—Usually the eruption appears without prodromal symptoms. If it is due to a strong chemical in the preparation, the objective symptoms of redness and swelling occur rapidly; if due to hypersensitivity, the symptoms will usually be much milder.

3. *Intense Subjective Symptoms.*—In most instances the itching and burning are extremely out of proportion to the amount of involvement. Especially is this true of the symptom of itching. There is an intense desire on the part of the patient to rub open the affected areas.

4. *The Time Element.*—Both the time of the appearance and the time of greatest intensity of the symptoms are important. Dermatitis produced by strong chemicals will occur in direct ratio to the application, while the intensity of the eruption in all cases will have a definite periodicity associated with the application of the cosmetic. One must bear in mind that the cosmetic applied to the scalp will cause the symptoms during the night and on arising, because very frequently the condition is spread from the scalp to the more sensitive areas of the face and neck through contact with the bed linen.

When the eruption is due to a perfume in the preparation, sunlight is usually required to bring it out, and therefore both the subjective and the objective symptoms will arise after this secondary exposure. When it is due to a cream, it invariably starts within a half hour after the application. When it is due to a powder (this is usually a sensitivity to orris root, which is frequently a component part of face powder), the time of occurrence is usually after the patient gets warm and, in order to get rid of the perspiration and sebaceous fatty excretion on her face, repowders with a good deal of vigor.

5. The type of skin eruption varies from a simple erythema to a marked excoriation and even loss of epidermal structure. Frequently, however, it is ill defined and bilateral but not symmetrical.

The patient need not be the one using the irritant. Contact dermatitis may arise from husband, wife or any close associate.

The type of eruption produced by the various cosmetics may be summarized in a general way in the following manner:

Creams usually produce a fine vesicular eruption on an inflammatory base, which is pale pink. The more vigorous the massage and the finer the texture of the skin, the more marked is the resultant clinical picture.

Powders and rouge produce an erythema and a slight amount of scaling not unlike an erythematous type of lupus erythematosus.

Tooth cleansing preparations produce a dry scaling hyperemia of the lips and may show slight vesiculation and cracking on the mucous surfaces.

Hair preparations produce an edema and redness of the upper eyelids which soon increases in severity and results in a fissuration of the transverse fold, minute vesicles on the forehead along the hair line and vesicular dermatitis of the ears.

Perfumes produce elongated, red, edematous, plaque-like lesions, brought out or intensified by sunlight; a dark brown persistent pigmentation replaces the red-den patch after a time.

Nail paints and manicuring aids produce a scaling and breaking of the nail plates and occasionally an inflammation of the nail fold.

Deodorants and depilatories produce an indolent folliculitis which sooner or later becomes suppurative and spreads by contiguity.

The art of history taking is nowhere more difficult, because of the patient's elusive and evasive replies. However, one must ascertain the following:

1. The name, make and kind of all the cosmetics used. Specific questions should be asked about powders, rouges, massage creams, vanishing and cleansing creams, skin foods, tonics, washes, hair preparations, wave-setting fluids, lip sticks, eyebrow pencils and the like.

2. The frequency and the time of their use.

3. The onset and duration of the eruption.

4. The time of greatest intensity. The latter I found to be of inestimable value, especially when the periodicity of the eruption's greatest intensity may be ascertained.

Both the direct and the indirect method should be used to prove the specific cosmetic responsible for the eruption. This is accomplished as follows:

First, by skin testing: A small amount of the suspected cosmetic is placed in apposition with the skin of the forearm and kept there with an impervious dressing for from twenty-four to forty-eight hours. Since at times a broken skin surface is necessary to produce the dermatitis, a second patch is applied over a superficially scarified area. As a control, an unaffected individual is used. The test will be considered positive if an erythema or a vesicular erythema appears and persists for twenty-four hours at the site of the patch test. If a cream is suspected, it must be massaged into the area tested. An exacerbation of the original symptoms may frequently result after the patch test has been applied.

Secondly, the elimination of the cosmetic should be followed by the disappearance of the symptoms. When the cosmetic suspected has been used for the hair, it is necessary to have a thorough shampoo. After all the symptoms have cleared, reapplication of the cosmetic gives a recurrence of the symptoms.

Three cases of circumscribed dermatitis came under my observation within the last few months which illustrate some of these points mentioned. All three were

caused by the preparation "La Gerardine," which is used for producing "natural" waves in the hair.

REPORT OF CASES

CASE 1.—Mrs. F. B. I., aged 37, an American housewife, consulted me, March 22, 1933, for an intensely itchy eruption which involved her neck, anteriorly and laterally. The lesions consisted of a number of discrete, pinpoint to pea-sized, ill defined macules and vesicopapules. The latter appeared on an elevated, erythematous base, not unlike a lesion produced by an insect bite. The itching was constant; it was most intense three or four hours after retiring and on awakening. The condition was of five or six weeks' duration.

The sudden onset, the limitation of involvement, the lack of symmetry (though bilateral) and the periodicity of intensity all suggested a contact dermatitis.

Thorough questioning as to cosmetics for the skin and hair, the wearing of new furs or clothes, the recent dry cleaning of these, and contact with plants, vegetable oils, perfumes and the like led nowhere.

A local preparation of calamine was prescribed, which seemed to stop the subjective symptoms, but the lesions persisted.

Three weeks later the nape of the neck became involved also, and the itching of the entire neck became intolerable. This time I insisted that the patient describe in minute detail everything she did in the way of her toilet, including what was done for her at the hair dressers. It was then that the use of a hair waving preparation called "La Gerardine" was mentioned. The disconcerting thing about this was the fact that she had been using the preparation for the last three years. Having had patients who developed sensibilization after prolonged use of a substance before, I instituted the following treatment:

A thorough shampoo of the hair was given. There was an almost instant relief from the itching, and the lesions disappeared in about three days.

Reapplication of "La Gerardine," after a period of a week's freedom, reproduced both the subjective and the objective symptoms; a thorough shampoo again cleared the dermatitis.

CASE 2.—Miss A. W., aged 30, a beautician, consulted me, Feb. 10, 1933, for a small patch of dermatitis over the left zygomatic area and a few ill defined circumscribed areas of intensely itchy plaque-like erythematous lesions on the sides of her neck.

One year previously I treated the patient for a nickel dermatitis of her neck and wrist (she was then wearing eye glasses on a metal chain and a metal encased wristwatch), and I assumed that this was a return of the condition, though the patient insisted that she had not come in contact with any metal.

One-fourth unit of roentgen ray was given, and I asked the patient to refrain from the use of all cosmetics. Though there was some improvement for a time, the condition kept on recurring. After the causative agent in case 1 was determined, I found that this patient, too, was using "La Gerardine" on her hair.

A thorough shampoo, a change of the bed linen and the discontinuation of "La Gerardine" promptly cleared up the skin. Reapplication of this preparation caused a recurrence of the eruption, which again yielded to the treatment.

CASE 3.—Mrs. E. P., aged 29, a housewife, complained of an acute eruption on her face, which had developed six days before examination. There were about eighty millet-sized to pea-sized lesions covering the face and neck anteriorly and laterally. Each lesion appeared as a discrete erythema with minute vesiculation. In most of them the epidermis had scaled off, leaving a somewhat shiny base. The eruption was extremely itchy.

Eight days before after a shampoo of the hair, the patient began to use "La Gerardine" to put a "natural" wave in her hair. Since that day she had been spraying this preparation on her hair with an atomizer, according to the directions on the circular with this preparation.

Shampoo of the hair, change of pillow cases and discontinuation of the use of "La Gerardine" was followed by almost instantaneous clearing of the eruption.

FUNDAMENTALS OF ASPHYXIA

YANDELL HENDERSON, PH.D.

NEW HAVEN, CONN.

Asphyxia is the most frequent and the most important of all pathologic processes. This is true because respiration—the exchange of oxygen and carbon dioxide and the production of energy—is the most fundamental process of life. Any disturbance of the circulation, any alteration of the cells of any tissue almost inevitably involves an alteration of the respiratory activity of one or more organs, or of the body as a whole. A large part of all the structural abnormalities that the pathologist studies involve perversions of tissue respiration. This is true, for instance, of cancer cells. There is good evidence, also, that not only such temporary psychic phenomena as unreasonableness in aviators and mountaineers, but even catatonic lethargy and other symptoms of insanity are dependent on impairment of the respiration of the brain.

Evidently asphyxia is something much broader than the acute conditions that are being discussed today. It is not only carbon monoxide poisoning, asphyxia of the new-born, the effects of hemorrhage and anemia, or the state of a patient after prolonged anesthesia; it is the state that develops in one way or another in the majority of all human beings as death from disease approaches. Unless one is burned alive, the tissues of one's body always die of asphyxia.

STAGES OF ASPHYXIA

What then is asphyxia? Primarily it is a state or series of states induced by an oxygen supply short of tissue needs. But deficiency of oxygen is only the initial cause and first stage of asphyxia. Life is not like a candle that on extinction can be immediately relighted. Recovery from asphyxia in an untreated patient is often extremely slow, indicating that certain conditions and processes, far more complex than mere deficiency of oxygen, have to be slowly and with difficulty reversed. If asphyxia of a little less than fatal intensity is prolonged, it may in rare cases render a man permanently an idiot as completely as if his cerebrum had been removed. Tissue degeneration, once started, is not immediately reversed by even the most ample supply of oxygen.

The problem of asphyxia puts before us, then, first and foremost the question: What is the significant element secondary to oxygen deficiency that lack of oxygen induces? What is the critical factor in the second stage of asphyxia? The answer to this question is perhaps one of the most extraordinary that science has ever given. It is simply this: The critical element in the second stage of asphyxia is deficiency of carbon dioxide. Beyond this second stage there are a series of other stages leading to autolysis, fatty degeneration, and necrosis.

THE DISCOVERY OF ACAPNIA

The initial observations that led me to this conception of the second stage of asphyxia were made twenty-five or thirty years ago and were published as studies on acapnia.¹ Acapnia means deficiency of carbon dioxide.

From the Laboratory of Applied Physiology, Yale University.

Read before the Society for the Prevention of Asphyxial Death at the New York Academy of Medicine, New York, May 24, 1933.

1. Henderson, Yandell: Acapnia as a Factor in Shock, *Brit. M. J.* 2: 1812, 1906; Fatal Apnea and the Shock Problem, *Bull. Johns Hopkins Hosp.* 21: 235 (Aug.) 1910; Acapnia and Shock, *Am. J. Physiol.* 21: 126 (Feb.) 1908; 23: 345 (Feb.) 1909; 24: 66 (April) 1909; 25: 310 and 385 (Feb.) 1910; 26: 260 (June) 1910; 27: 152 (Nov.) 1910. Henderson, Yandell, and Harvey, S. C.: *Ibid* 46: 533 (Aug.) 1918.

Unfortunately, I gave the word an accessory significance: I regarded it as the result of simple overbreathing. I see now that the overbreathing itself is secondary to deficiency of oxygen somewhere in the body. This deficiency induces the liberation of some substance which acts on respiration and thus induces overbreathing. I shall, therefore, in the future give the second stage of asphyxia another name. I shall call it "acarbica." I define acarbica as the asphyxial diminution in the bicarbonates of the blood.

The conception of acapnia, crude as it was, has yet been useful. By it anesthetists were led to use rebreathing. From this practice they have learned to avoid the stage of excitement, overbreathing, and excessive elimination of carbon dioxide. They thus avoid inducing the condition of simple acute acapnia and failure of respiration. Today a competent anesthetist conserves the carbon dioxide store of the body. As a result, very few patients now die from respiratory failure on the operating table, an occurrence once common.

The idea that the carbon dioxide store of the body should be conserved, or sometimes even increased, seemed at first to be opposed to one of the great fundamental discoveries of science. A hundred and forty years ago, Lavoisier discovered that the body consumes oxygen and produces and excretes carbon dioxide. Carbon dioxide was therefore generally classed with other excreta. To administer it to a patient seemed as illogical as to employ urine as a therapeutic agent. Furthermore, measures to keep carbon dioxide in the body were regarded as essentially equivalent to keeping oxygen out. Even today, the dictionaries, including medical dictionaries, define asphyxia not only as deficiency of oxygen, which it is, but also as excess of carbon dioxide, which it is not.

THE ACID-BASE BALANCE OF THE BLOOD, AND SO-CALLED ACIDOSIS

No sooner was this difficulty overcome than a new and greater difficulty arose. Toward the end of the last century the great Swedish scientist Arrhenius introduced into chemistry the idea that salts, acids and alkalis in solution are separated into their component elements and act as ions. From this idea the conception developed that in all solutions the acid and alkaline elements interact to maintain what is now called the hydrogen ion concentration of the solution: the quantity now expressed by the symbol p_H . This conception was introduced into physiology by L. J. Henderson,² who showed that in the balance of acids and alkalis in the blood the acid is chiefly carbonic acid and the alkaline factor chiefly bicarbonates. Van Slyke³ called these bicarbonates the "alkaline reserve." For their measurement he invented the useful modification of the mercury pump that is now in universal use. These were great contributions; but they have also lent support to a misconception of long standing,⁴ namely, that all the conditions called "acidosis" involve intoxication by acid.

Intoxication by acid would, of course, partially neutralize the bicarbonates of the blood and thus diminish the so-called alkaline reserve. Accordingly, when it was found that the amount of the bicarbonates in the blood—that is, the amount of carbon dioxide that can be got out of the blood—is diminished, it appeared that

theory and observation, laboratory and clinic, were in complete agreement. Nothing could be clearer, more logical or more satisfying than this conception. It is now taught as gospel truth to every medical student. Let any clinician go to any biochemist with a question in regard to the topics discussed in this paper and the biochemist will state this conception as one of the most important and most certain of the principles of his science.⁵

The only trouble is that this inference from physico-chemical theory, when put to the test on living men and animals, proves in certain crucial features to be flatly contradicted by facts. I shall mention three such tests.

TESTS FOR ACIDOSIS

First, there is the obvious test consisting in the administration of alkalis to patients with so-called acidosis. When the acid-base equilibrium of the blood was first presented to physiologists and clinicians as a fundamental feature of the living system, it was recognized that, according to this conception, acidosis should be relieved by the administration of alkalis. This therapy has in fact been widely tried.

In diabetic acidosis, before the discovery of insulin, sufficient alkali was often administered to restore the normal bicarbonate content of the blood; yet the patients died. In some conditions the administration of alkali has even proved to be injurious. I tried it on a patient in one of the classic forms of so-called acidosis: that induced by carbon monoxide asphyxia. The effect fell just short of immediate death. I warn against administering alkali to asphyxiated new-born babies, although they also have what is now called acidosis. The facts that I shall give presently make it exceedingly probable that the baby would die.

The second test is one that a number of critics have emphasized on theoretical grounds but have neglected to put to practical test, either experimental or clinical. On the other hand, I have applied this test both experimentally and clinically with results that refute the critics' inferences from theory. According to theory, the principal acid of the blood, in fact the only free acid, is carbonic acid; that is, carbon dioxide in solution. Any condition of what is now called acidosis—the condition that I call acarbica—especially when the normal alkalinity, or p_H , of the blood is also diminished, is therefore interpreted as involving at least a relative excess of carbon dioxide. From this it follows, as critics have pointed out, that the administration of carbon dioxide must "intensify the acidosis." The inference is that "intensification of acidosis" should be distinctly injurious to the patient. The logic is almost perfect. It is only the facts that perversely refuse to correspond.

RESUSCITATION BY INHALATION OF CARBON DIOXIDE

Many years ago, my colleague Dr. H. W. Haggard and I decided that in spite of the prevailing theory we would try out the therapeutic possibilities of carbon dioxide inhalation on two classes of patients: (1) the victims of carbon monoxide asphyxia, and (2) patients who came from the surgical operating room in the deep

postanesthetic depression that was then common. Both of these classes of patients have very definitely what is now generally called acidosis. Cannon⁶ observed it in wounded soldiers during the war. The administration of carbon dioxide to patients in postanesthetic depression met therefore with the objection that the administration of carbon dioxide must "intensify acidosis."⁷

Fortunately, we could also justify the inhalation of carbon dioxide on grounds that others would accept. We avoided discussion of the problem of acidosis lest it stir up controversy and retard the introduction of measures for the saving of life. We used as our argument the fact, demonstrated by the elder Haldane⁸ and his co-workers, that carbon dioxide stimulates respiration. We stressed only the fact that increase of breathing hastens the elimination of carbon monoxide, ether and other volatile substances from the blood. We did not stress the fact, which is really much more important, that carbon dioxide inhalation hastens recovery of normal conditions after asphyxia or anesthesia,⁹ even when there is no foreign substance like carbon monoxide, anesthetics or other volatile substances to be eliminated.

Today, carbon dioxide, diluted in oxygen or air, is everywhere the accepted therapy for carbon monoxide asphyxia.¹⁰ The rescue crews of practically all American fire and police departments and gas and electric light companies are equipped with inhalators for the administration of carbon dioxide diluted with oxygen. There are more than 3,500 inhalators in use, and it is conservatively estimated that more than 50,000 cases of carbon monoxide poisoning, drowning and other forms of asphyxia are treated by this means annually. Many hundreds of lives have been saved; and as yet there is no evidence whatever in any single case of any such effect as would be involved in an "intensification of acidosis."

As regards the use of carbon dioxide in connection with anesthesia, the cases that have been treated are numbered by hundreds of thousands. The use of carbon dioxide in connection with surgical anesthesia is one of the most widely employed accessories of the modern surgical operating room. I do not mean to assert that carbon dioxide should be administered to every patient; but in many cases it is absolutely of life-saving value. It does far more than merely stimulate breathing. It is the dilatation of the thorax and increase of the vital capacity by better tonus rather than the increase of breathing that overcomes atelectasis.¹¹ Carbon dioxide is in fact the most widely active hormone, or chemical regulator, in the body.

The observations that Haggard, Coburn and I¹² made on the cases that we studied at the initiation of this use of carbon dioxide showed that, during anesthesia of the badly administered type then common and after surgical operations, there was a very marked decrease of the alkali bicarbonates of the blood. This is the feature that has led others to conclude that such patients suffer from acidosis. What we found was that, under inhalation of carbon dioxide, the normal amount of alkali bicarbonates in the blood is quickly restored. The circulation improves correspondingly and the patient is thus not only freed from excess of ether but largely restored to normality; Porter¹³ also observed this on shocked soldiers during the war.

ALLEGED ACIDOSIS IN ASPHYXIA NEONATORUM

One of the most important and now most widely applied uses of carbon dioxide is in the resuscitation of asphyxiated new-born babies.¹⁴ Resuscitation of these cases by means of carbon dioxide diluted in oxygen may fairly be described as a close imitation of nature's own method. It is oxygen that keeps what is called the respiratory center alive and capable of activity. It is the carbon dioxide of the blood that stimulates the center to activity. These are the main facts of respiration in the adult, and they are equally true of the new-born baby. The inhalational method of resuscitating the still-born affords as perfect a demonstration of the physiology of respiration as any that has ever been performed in a laboratory.^{14a} There is ample clinical testimony that, in a large proportion of all nonbreathing or poorly breathing infants, natural respiration develops quickly after the lungs are dilated with a sufficient percentage of carbon dioxide mixed with oxygen.

Yet, objection has been raised on the basis of biochemical theory.¹⁵ Investigation has shown that in still-born babies the blood has all the characteristic

features of so-called acidosis. The bicarbonates are low; the p_H is shifted in the acid direction, and there is a considerable increase of lactic acid. This is exactly what should have been expected. On the basis of these facts, the inference has been drawn that "the use of carbon dioxide as a resuscitating agent in asphyxia neonatorum is not only superfluous but may even be harmful in that it tends to aggravate an already existing acidosis." This theoretical objection to the treatment is not supported by any clinical test. It is not denied that the inhalation of carbon dioxide in proper dilution makes the baby breathe.

I have not investigated the blood changes in asphyxia neonatorum, and no one has investigated the return of normality in the blood in these cases under the inhalational treatment. I have merely collected and presented the evidence, which seems to me decisive, that asphyxia neonatorum is in all essential features identical with the other forms of asphyxia that I have studied intensively for more than twenty years. In all these forms of asphyxia, the administration of carbon dioxide is as important for remedial purposes as is oxygen itself. In fact, in many forms of asphyxia it is probable that carbon dioxide diluted with air is more effective than oxygen without carbon dioxide and almost as effective as carbon dioxide mixed with oxygen.

I shall return to the subject of asphyxia of the newborn a little later on. I want first to report the third test, which shows that so-called acidosis, at least when it results from lack of oxygen, is not acid poisoning.

ACIDOSIS WITHOUT ACID

In my laboratory during the past few years we have carried out experiments on asphyxia¹⁶ which show that inferences drawn from physical chemistry and applied directly to the problems of life and disease without adequate tests on living creatures may lead one far from the truth. Physiology and biochemistry have thus gone far astray in regard to the acid-base equilibrium of the blood and have led clinicians after them.

In our experiments, dogs were subjected to a progressively diminishing supply of oxygen until asphyxia and death resulted. Overbreathing occurred under these conditions in all cases. The carbon dioxide content of the blood was thus diminished and a progressive compensatory acarbica developed; that is, the content of bicarbonates in the blood diminished. Along with these developments, the present conception would have led one to expect a progressive increase in the amount of lactic acid in the blood, beginning even with the first slight decrease in the oxygen supply. But in fact in no case was there any increase of lactic acid in the blood until the oxygen had fallen to an asphyxial level and the animal was approaching death. Even then, the formation of lactic acid is best explained not as a form of intoxication but as a last desperate attempt of the living system to protect itself. It certainly is not a condition that can properly be defined as acid intoxication; for animals dying of asphyxia live longer if the atmosphere contains carbon dioxide.

We have carried proof still further.¹⁷ There is now a compound, monoiodoacetic acid, which has the extraordinary property of depriving the tissues of the powers to produce lactic acid. We have first administered this drug and have then asphyxiated the animals. As a result, all the signs of so-called acidosis, particu-

larly the acarbica, developed exactly as in undrugged animals; but without the formation of any lactic acid whatever.

THE H-ION CONCENTRATION OF THE BLOOD

From current theory it is often inferred that the balance of acids and bases in the body is determined merely by the relative amounts of these elements in the diet. Similarly, any alteration of the normal faint alkalinity of the blood is now often assumed to be due to the addition of alkali or acid to the blood. This would be true of nearly every other solution with which a chemist deals. But the living body manages otherwise; it regulates itself. I am not now speaking of the absolute amount of bicarbonate in the blood, but of the H-ion concentration, or p_H ; that is, the balance between bicarbonate and carbonic acid. When that balance is altered from the normal, the cause is really physiologic and not merely chemical. It is rarely due to abnormal nutrition or metabolism. It is generally due to an alteration of respiration because of an increase or decrease of the sensitivity of the respiratory center.

Perhaps the body is merely a chemical machine; but it rarely carries out its processes in the simple ways that chemists expect.

Even a slight depression of respiration increases the amount of carbon dioxide retained in the body and alters the blood in the direction of acidity. A slight increase of the sensitivity of the center increases the elimination of carbon dioxide and renders the blood more alkaline. From the standpoint of physical chemistry, an increase of H-ions (low p_H) means, of course, a relative excess of acid. But the acid that is in excess is merely carbonic acid; that is, carbon dioxide. What an alteration of the p_H of the blood really tells us is not whether the balance of acids and alkalis in the body is abnormal; it tells us rather that the sensitivity of the respiratory center is abnormally high or low. Alkalosis and acidosis, in the sense of high or low p_H , express disturbance of respiration. Only slight excess or decrease of breathing is needed to raise or lower the p_H greatly; and the excess or decrease depends on the sensitivity of the center. The p_H of the blood is really an index of the state of the respiratory center.

During the development of asphyxia, first an alkaline and then an acid shift occurs in the blood. Under slight oxygen deficiency in the first stage of asphyxia, the increased respiration overventilates the blood. The loss of carbonic acid leaves the blood relatively alkaline, and a compensatory decrease of bicarbonates occurs. Anoxemia thus leads to acapnia, and acapnia to acarbica. Later, under extreme anoxia, respiration is depressed; there is a relative excess of carbonic acid, and the blood is shifted in the acid direction.

The simplest explanation of these occurrences is that the supply of oxygen is the principal factor controlling the sensitivity of the respiratory center. A slight deficiency of oxygen causes the appearance in the blood of some substance that increases the sensitivity. Extreme deficiency, on the contrary, diminishes the sensitivity, so that an abnormally strong stimulus is required to excite activity. But neither oxygen nor oxygen deficiency, slight or intense, ever acts as a stimulus to the center. The stimulus is afforded by carbon dioxide acting through the p_H of the blood. The amount required depends on the sensitivity at the time. This conception applies to all forms of asphyxia, including the victims of drowning and still-born babies. They do not breathe in spite of a more than normal pressure of carbon

16. Henderson, Yandell, and Radloff, E. M.: The Chemical Control of Breathing, as Shown in the Acid Base Balance of the Blood, Under Progressive Decrease of Oxygen. *Am. J. Physiol.* 101: 647 (Sept.) 1932.
17. Henderson, Yandell, and Greenberg, L. A.: To be published.

dioxide and a very low p_{H} . The reason is that the sensitivity of the respiratory center has been depressed by anoxia. A much stronger stimulus than normal is required: it may be 7 per cent of carbon dioxide or 10 or 15 per cent. I know of one baby that at first responded to nothing less than 20 per cent and was thus resuscitated. Once respiration is started, and oxygen is thus supplied, the sensitivity of the respiratory center is gradually restored. As the sensitivity returns, less and less stimulus is needed, until finally the baby, or the victim of drowning or of carbon monoxide, again breathes with no more than the normal stimulus of 5 per cent of carbon dioxide in the air of the lungs.

SIMILARITIES AND DIFFERENCES BETWEEN ACIDOSIS AND ACARBIA

The most striking example of real acid poisoning is afforded by the experiments of J. B. S. Haldane¹⁸ on himself. He swallowed enough ammonium chloride to induce a true acidosis. The ammonium was converted into urea; and the hydrochloric acid that remained displaced carbon dioxide from the bicarbonates of the blood and diminished their amount. Breathlessness even on slight exertion and other symptoms of low blood alkali developed.

What appeared to be the same condition was induced in J. S. Haldane (father of J. B. S.) and myself when we spent five weeks together on top of Pike's Peak¹⁹ in the summer of 1911. In full acclimatization to such altitudes the bicarbonates of the blood are diminished and there is breathlessness on exertion. In these and other superficial features, the conditions defined by the Haldanes, father and son, were alike. But, fundamentally, these conditions were entirely different. In the one case a considerable part of the alkalis of the blood had been neutralized by acid. In the other, no appreciable amount of alkali had been lost; it was merely out of use. It was occult but ready to return to use whenever the conditions, particularly the pressures of oxygen and carbon dioxide, recalled it on our return to sea level.

In support of this distinction there are experiments that Haggard and I performed on dogs.⁹ We injected dilute hydrochloric acid into a vein until the blood alkali was diminished and respiration was increased: effects superficially like those induced by asphyxia. We then administered carbon dioxide both to such acidotic animals and to those which we had subjected to asphyxia. The former were unable to tolerate such treatment; the latter were quickly restored to health by it. It is the recall of the normal amount of alkali to the blood by inhalation of carbon dioxide and the accompanying functional recovery that constitute the chief benefit of inhalational therapy in asphyxia and related conditions. The increase of breathing is merely an accessory benefit.

The control of the amount of alkali in use in the circulating fluid of the body by the pressure and amount of carbon dioxide in solution appears to be one of the fundamental biologic reactions in all living things. It is now found by Thornton²⁰ to occur in plants essentially as I have found it in animals and men. Exposure of

plants to atmospheres containing increasing amounts of carbon dioxide causes the juices to become correspondingly not more acid but more alkaline. The p_{H} rises and the alkalis are increased. That this reaction is biologic is shown by the fact that the presence of oxygen is also essential; in the absence of oxygen the p_{H} is lowered under merely chemical forces. Perhaps the study of plants will contribute to a fuller understanding of this reaction so vital to the health of man.

The importance of the normal relation of oxygen, carbon dioxide and blood alkali is most significantly illustrated by mountain sickness and acclimatization to altitude. Under diminished pressure of oxygen, respiration generally increases rather slowly. The carbon dioxide and alkali of the blood are for a time out of their normal relation to oxygen, and mountain sickness occurs. When acclimatization is established and health returns, it is found that the carbon dioxide and alkali have been diminished to nearly the same percentage of their sea level value as is the oxygen pressure in the lungs. The conditions in mountain sickness are essentially like those of a man recovering from alcoholic intoxication; which is also a condition misinterpreted as acidosis.²¹ It is probable that all the conditions now called acidosis, which arise from asphyxia, general or local, or those which are related to asphyxia, such as anesthesia and crushing injuries, are in reality not acid poisoning but acarbica.

THE CLINICAL USE OF CARBON DIOXIDE

There is not space to deal here with the details of the technic of inhalational therapy. But it is important, at least, to point out that carbon dioxide may be administered according to two distinct plans: In one, a mixture of a certain percentage of carbon dioxide (formerly 5, now generally 7 per cent) in oxygen is used, and every patient breathes exactly this percentage regardless of his special condition and needs. In the other plan, a mixture of from 20 to 30 per cent of carbon dioxide in oxygen, or even pure carbon dioxide, is used. It is administered through an open mask so that air is inhaled and mixed with it. The amount of carbon dioxide is adjusted to the special requirements of the particular patient.

The first of these methods is suitable for the use of laymen, such as the members of the rescue crews of city gas companies, and the police and fire departments. It is vitally important that the victims of carbon monoxide asphyxia shall be treated at the earliest possible moment and generally before a physician arrives.

The second method is generally preferable in hospitals, particularly in connection with anesthesia. It is also very much cheaper. For most of the new-born babies that do not breathe spontaneously, or breathe poorly, mixtures of from 7 to 10 per cent of carbon dioxide in oxygen are sufficient. But in extreme cases, higher percentages of carbon dioxide are required and should be administered by an anesthetist accustomed to using apparatus that will supply controlled percentages. In such cases and in the prevention of postoperative pulmonary complications in adults, the amount of carbon dioxide should be adjusted according to the reactions of the patient. It is not enough, as some physicians, surgeons and even clinical investigators have done, to say to a nurse, "Give the patient carbon dioxide," without further specific directions or supervision.

CONCLUSIONS

One of the fundamental conditions of health is the balance maintained by respiration between the pressure of oxygen and the amount of carbon dioxide in the body. Oxygen deficiency is the initial cause and first stage of asphyxia, out of which develops the second stage characterized by carbon dioxide deficiency and a compensatory decrease of the bicarbonates of the blood without considerable loss of alkali from the body.

The therapy that nature itself indicates to combat asphyxia and related conditions is therefore not only the restoration of an ample supply of oxygen but also the restoration of the normal amount of carbon dioxide. Carbon dioxide, then, recalls the normal amount of alkali into use and, with the return of the normal relations of oxygen, carbon dioxide, and blood alkali, the chief elements in the living system, the circulation, respiration, muscle tonus and mind, again become normal.

The facts that the clinical use of carbon dioxide has established force this alternative: either acidosis is a matter of small importance and intensification of acidosis does a patient no harm whatever, or many of the conditions now called "acidosis" are etiologically not acid poisoning.

HORMONE DIAGNOSIS OF VIABILITY OF PREGNANCY

FRANK SPIELMAN, M.D.
MORRIS A. GOLDBERGER, M.D.
AND
ROBERT T. FRANK, M.D.
NEW YORK

The clinical diagnosis of viability of a pregnancy, especially in the early months, is usually difficult. Both the Aschheim-Zondek¹ and the Friedman² pregnancy tests may be of considerable help in determining life or death of the fetus. As Wilson and Corner,³ Wladika⁴ and Spielman⁵ have demonstrated, these two reactions depend on the presence or absence of viable chorionic villi. With the complete death of the chorionic tissue, the tests become negative. The prepituitary hormone is the substance which here plays the important rôle.

Besides the prepituitary, the female sex hormone is also considerably increased in pregnancy from the second month on. As early as 1926, we⁶ called attention to the importance of female sex hormone studies in pathologic pregnancy. In order to determine a possible interrelationship between life or death of a fetus and both of these hormones, studies of the hormones were instituted in cases in which missed abortion was suspected or expected.⁷ An exceptional opportunity to

study these cases was afforded by the fact that the method of choice in therapeutic abortion at the Mount Sinai Hospital, when indications are absolute and permanent, is radiotherapy. Two classes of cases were studied: first, those in which irradiation had been done and, second, those in which missed abortion was suspected on clinical grounds.

TECHNIC

The female sex hormone studies were made on the blood by the Frank-Golddberger method,⁸ 40 cc. being used for each determination, at intervals usually varying from one week to one month after irradiation was performed. Simultaneously, the Aschheim-Zondek or Friedman test was carried out on the urine. In the majority of cases, the Friedman test, which has superseded the Aschheim-Zondek reaction in our laboratories, was employed. The reaction obtained by the two tests in each case was compared with special reference to the period at which it became negative, indicating disappearance of the hormones. Subsequent expulsion of the fetus or continued viability clinically or by roentgen examination served as a check on the reliability of the results.

RESULTS

The total number of cases studied comprised thirty-three, of which twenty-three represented x-ray abortions and ten, other conditions. The tables show the essential features, both clinical and laboratory.

X-Ray Abortions.—Of the twenty-three x-ray abortions (table 1), in eleven the female sex hormone test became negative at periods varying from seven to twenty-nine days following irradiation, in one after forty-nine days, and in another after seventy-seven days. In the latter two it is to be noted that in the one no determination was made for thirty days, and in the other the negative result obtained after seventy-seven days was the only test performed. All of these patients passed dead fetuses spontaneously. Of the other ten x-ray abortions, the female sex hormone test was negative in five, either at the time roentgen treatment was instituted or immediately afterward. All these patients also aborted dead fetuses spontaneously. The remaining five cases in this group were positive. Four of the patients subsequently showed live growing fetuses necessitating operative removal, and the fifth patient, who later passed a dead fetus, showed first a strongly positive and later a weakly positive reaction.

The pregnancy test in these twenty-three cases varied considerably. Ten either were negative at the time of the first examination or became negative later; nine remained positive even on repeated examination, and in four cases the test was not done. It is to be noted here that, of the ten "positives" which subsequently became "negatives," in six the negative reaction occurred at a much later date than the "negatives" obtained by the female sex hormone test. Of the nine cases that remained positive, six showed the reaction a short time before abortion took place. In one case (P. K.) a blood anterior pituitary hormone determination by a method described by us⁸ showed a positive result.

Other Cases.—There were ten cases studied which were not x-ray abortions (table 2). The results obtained here have shed considerable light on the hormonal processes involved. In eight of the ten, missed abortion

dead fetuses subsequently in two, the examination of the curettings in another, and, in the fourth case, the removal of a dead abdominal pregnancy at operation. The fifth "negative" turned out at laparotomy to be an old ectopic pregnancy. There were five "positives" and, of these, one patient went on to term, two subsequently passed live fetuses, and the last two "positives" occurred in the cases of retained placenta.

allowed to go to term, two patients who later showed dead fetuses (R. S. and J. S.), and the last occurred in one of the cases of retained placenta. The one "negative" was in a case of proved missed abortion.

COMMENT

These results may be summarized as follows: The female sex hormone test was performed in thirty-one

cases in which missed abortion was suspected or expected, and in two cases of retained placenta. A negative reaction was obtained when the fetus was dead (twenty-three cases), and a positive reaction when the fetus was alive (eight cases). The five "negatives" seen at the time of, or immediately after, roentgen treatment to induce abortion must be interpreted as indicating that the fetuses were dead at the time of irradiation, an assumption not at all illogical when the fact that there were present serious medical conditions which indicated induction of abortion is taken into consideration. The conclusion to be reached is obvious: the female sex hormone blood determination may be used as an early and reliable clinical indicator of whether the fetus is alive or dead.

The summarized results of the pregnancy tests show that repeated examinations were performed in twenty-four cases. Eleven of these were or became negative when the female sex hormone test also was negative, but as has been already mentioned, in the majority, a negative pregnancy reaction was obtained at a much

(A. L. and L. F.), placentas were retained. In both, the female sex hormone tests were positive and subsequently the structures passed were found to be in a fresh state and recently separated from the uterine wall. The explanation for the rapid disappearance of the female sex hormone, as compared to the prepituitary in missed abortion, apparently lies in the fact that the increase of the former both in the placenta and in the blood in pregnancy is not nearly as great as the increase of the latter. Consequently, injury to the placenta results in rapid diminution of the quantity of female sex hormone to a nondemonstrable level. The prepituitary-like hormone, however, present in much greater quantities, takes much longer to disappear. Also, the presence of viable chorionic villi, as has been demonstrated,⁹ supplies sufficient hormone, in spite of fetal death, to give persistently positive tests.

SUMMARY AND CONCLUSIONS

1. Thirty-three pregnancy cases in which missed abortion was suspected or expected were studied from

TABLE 2.—Other Cases

| Name R. S. | Last Menstrual Period | Diagnosis | Size of Uterus | Female Sex Hormone | Pregnancy Test | Aborted | Summary |
|---------------|-----------------------------|------------------------|--------------------------------------|-----------------------|-------------------|--------------------------------|---|
| | 5/28/30 | Toxemia of pregnancy | 7 months; no fetal heart heard | 1/20/31—Neg. | 1/20/31 | Dead fetus | Toxemia with 7 mos. gravidity; F. S. H. neg.; preg. test pos.; passed dead fetus spontaneously |
| M. R. | 9/18/27 | Inevitable miscarriage | 5 months | 12/17/27—Pos. | Not done | 12/18/27 | Passed live fetus |
| E. R. | | Ectopic pregnancy | | 3/ 9/27—Neg. | Not done | Ectopic (old), at operation | Ectopic preg.; microscopically old villi seen; F. S. H. neg. |
| I. N. | 3/12/26 | Missed abortion | 3 months | 11/10/26—Neg. | Not done | 12/10/26 | Uterus remained 3 mos. in size after 7 mos. amenorrhea; passed dead 3 mos. fetus; F. S. H. neg. |
| A. B. | 7/17/30 | Missed abortion | 10 weeks | 3/ 3/31—Neg. | 3/3/31—Neg. | 3/9/31 curetted | Uterus remained 3 mos. in size after 8 mos. amenorrhea; F. S. H. and preg. tests neg.; on curettage old preg. found |
| B. B. | 8/ 6/30 | Threatened abortion | 3½ months | 12/18/30—Pos. | Not done | 12/20/30 | F. S. H. pos.; passed live fetus |
| J. S. | 4/ 7/29 | Abdominal pregnancy | 5 months' fetus by x-ray | 9/23/29—Neg. | 9/23/29—Pos. | 10/14/29 operated | Dead abdominal preg.; F. S. H. pos.; urine preg. test negative |
| A. L. | 7/27/26 | Retained placenta | Term | 5/26/27—Pos. | Not done | 5/27/27 placenta passed | F. S. H. pos.; retained placenta, fresh when passed 1 day after test |
| L. F. | | Retained placenta | 4 months | 3/26/21—Pos. | 3/26/31—Pos. | 3/27/31 | Retained placenta at 4 mos.; passed fresh placenta 1 day after test was done |
| L. G. | 6/15/32 | Preg. +; fibroids | 3 months | 11/18/32—Pos. | 11/18/32—Pos. | Went on to term | Seen in follow-up, 12/7/32; felt live; uterus corresponds to 6 mos.; F. S. H. and A-Z. pos.; patient went to term |

later date. In ten cases, positive urine pregnancy reactions persisted when the female sex hormone determinations were negative. In all of these, dead fetuses were subsequently found. Three cases showing positive pregnancy tests checked with similar positive female sex hormone tests. All of these showed live fetuses. It is to be emphasized that never was a negative urine pregnancy reaction obtained when the fetus was alive, but on the other hand in about 50 per cent of cases positive reactions were present in spite of the death of the fetus. The conclusion to be reached is that when a dead fetus is suspected the pregnancy test is of great value in cases that show a negative response, but a positive reaction is of no value since it may mean either a live or a dead fetus. As can be seen, the pregnancy test is not nearly as sensitive an indicator of the presence or absence of a dead fetus as the female sex hormone blood determination.

The modus operandi in both reactions is of considerable interest. The rapid disappearance of the female sex hormone and, to a lesser extent, of the prepituitary-like hormone in cases of missed abortion draws attention to the production center of these two hormones, the placenta. In two of the patients studied

the hormonal aspect in order to determine the relationship between the female sex hormone of the blood and the prepituitary hormone of the urine on the one hand, and fetal life or death on the other.

2. The Frank-Goldberger method was used in the blood studies, and either the Aschheim-Zondek or the Friedman test in the urine studies.

3. A negative female sex hormone reaction was obtained when the fetus was dead (twenty-three cases) and a positive reaction when the fetus was alive (eight cases). The results here were 100 per cent correct.

4. A negative pregnancy reaction was obtained when the fetus was dead in eleven cases, and ten cases gave positive reactions in spite of dead fetuses (approximately 50 per cent correct).

5. The female sex hormone blood determination has proved itself in our small series an absolute indicator of whether a fetus is alive or dead. The urine pregnancy test is of value only when the reaction is negative.

6. The presence or absence of the hormones depends on the degree of involution of the placenta and its attachment to the uterine wall.

METHYLENE BLUE SOLUTIONS IN
POTASSIUM CYANIDE
POISONING

REPORT ON CASES 2 AND 3

J. C. GEIGER, M.D.
Director of Public Health
SAN FRANCISCO

Attention has recently been drawn to the apparently successful treatment of a case of cyanide poisoning by the use of a 1 per cent methylene blue solution in water, injected intravenously.¹

REPORT OF CASES

CASE 2.—H. L., a white man, aged about 25, swallowed two number 0 capsules of potassium cyanide in an attempt at suicide; he stated this fact to an official of the Y. M. C. A. in the lobby of that organization's hotel and immediately collapsed. A call was placed with the Central Emergency Hospital for an ambulance. These events occurred between 4:35 and 4:40 p. m., May 18, 1933.

The patient was brought into the Central Emergency Hospital and placed on the table in the treatment room at 4:45 p. m., in an unconscious state, marked cyanosis, body rigid, with clonic spasm of the voluntary musculature, pupils dilated and inactive to light, respirations 12 per minute, of stertorous character, pulse feeble at a rate of about 160 per minute. The odor of cyanide was evident from the respired air.

Respiration ceased during the preparation of the methylene blue solution, and artificial respiration was administered and continued during the injection of methylene blue, which was given by Dr. R. J. Millzner, assistant surgeon. Improvement was evident, with a decrease in the depth of the cyanosis, a lowering of the pulse rate and a partial return to consciousness. Gastric lavage with warm water was begun and continued through 2½ gallons. The odor of cyanide was present in the washings, which contained no food particles. Normal spontaneous respiration returned at the rate of 10 per minute, shortly increasing to 28 per minute. The pulse rate was of better quality, at a rate of from 132 to 144 per minute. With these signs of improvement, but also because of the fact that it was quite definite that a comparatively large amount of cyanide had been taken (two number 0 capsules), a second injection of methylene blue was begun at 5:08 p. m. This was followed by a momentary return of cyanosis and an elevation of the pulse rate from 132 to 144. Carbon dioxide oxygen (carbogen) was given. Return to complete consciousness was rapid, with clearing of cyanosis, normal respiration, and stabilized pulse rate of about 112 to 128 per minute. The patient vomited a greenish tinged fluid, during which there was some distress. An attempt to pass a stomach tube for lavage with sodium thiosulphate solution resulted in placing only about 200 cc. of the solution, and this probably accounts for the emesis.

There was no further discomfort or complication during the forty-eight hour stay in the hospital. Methylene blue was first noticed in the urine at 7 p. m., approximately two hours after the first injection. There was no elevation of temperature above 98.8 F.; the pulse rate dropped gradually to a level of from 78 to 86, and respirations returned to 20 and 18 per minute.

A specimen of blood was obtained a short period after the second injection of methylene blue, in an effort to learn of the possibilities of the formation of methemoglobin. Laboratory study failed to reveal the presence of this substance.

Approximately 0.0416 Gm. of cyanide was found in the washings from the stomach. If the patient swallowed two number 0 capsules, he must have absorbed approximately 1.1 Gm., or 16.4 grains, of the poison.

CASE 3.—E. M., a white man, aged 57, at 9:30 p. m., May 30, ate a banana which had been split and between the two halves of which he had allegedly placed enough potassium cyanide to equal a heaping teaspoonful. On repeated questioning of the

patient after recovery, the statement as to the approximate amount of cyanide consumed with the banana was confirmed. The potassium cyanide was taken from a quarter-pound can purchased in a local drug store. From the contents of the can, which was found in the patient's pocket, this amount could be considered substantially correct. Therefore, the quantity consumed by actual weight was approximately 100 grains (6.5 Gm.).

Since the condition of the patient on arrival in the Park Emergency Hospital was such that washing of the stomach contents was not resorted to, the extraordinary amount stated to have been consumed must have been absorbed.

The patient was brought into the hospital at 9:47 p. m., seventeen minutes after taking the poison. On arrival in the hospital, there was marked cyanosis and complete unconsciousness; the pupils were dilated; breathing was extremely difficult and rapid, with a barely perceptible pulse, and a typical odor of cyanide on the breath. Respiration was becoming increasingly labored when the first methylene blue solution was administered at 9:55. A second injection, making 100 cc. in all, was given at 10:30. Between the two injections the patient became conscious, complained severely of pain in the calves of both legs, and talked rationally.

Other than an elevation of temperature to 99.5 F. for only a short while, recovery has been apparently complete.

A specimen of blood, obtained after the second injection of methylene blue, on examination was negative for methemoglobin.

These cases demonstrate three important facts:

1. Methylene blue, intravenously, is useful, definitely beneficial and successful in the treatment of cyanide poisoning.

2. The dye can be used in quantities up to 100 cc. of a 1 per cent solution (1 Gm. of the dye) within a period of one-half hour without untoward symptoms.

3. The use of methylene blue, even to the extent of 100 cc. of the 1 per cent solution (1 Gm. of the dye) did not produce measurable quantities of methemoglobin in the blood of these particular cases.

SALMONELLA SUIPESTIFER INFECTIONS
IN MAN

FURTHER OBSERVATIONS

ANN G. KUTTNER, M.D.

AND

H. D. ZEPP, A.B.

BALTIMORE

In recent years, an increasing number of sporadic cases of *Salmonella suipestifer* infections in man,¹ not associated with outbreaks of food poisoning, have been reported in all parts of the world. In the great majority of instances, the source of the infection has remained undetermined, and no definite relationship to infected pigs or pork could be established.

These cases have presented an extremely varied clinical picture: in some the signs and symptoms suggested bronchopneumonia, in others typhoid. In some

instances *Salmonella suipestifer* infection was found as a postoperative complication, and in children pyarthrosis has been reported by several observers.² The diagnosis was made by blood culture in all the cases except those of arthritis. In the latter, *Salmonella suipestifer* was grown from the pus aspirated from the affected joint. In one instance this organism has been isolated from the spinal fluid of a case of chronic meningitis.³ In 1932 we reported from the Harriet Lane Home, Johns Hopkins Hospital, a series of seven cases of *Salmonella suipestifer* septicemia in children varying in age from 7 months to 6 years.³ Four of the patients were admitted with a preliminary diagnosis of typhoid, one had bronchopneumonia, one had congenital syphilis, and one had had an abdominal operation. The organism was isolated by blood culture in every instance. The disease was relatively mild. None of the children developed complications, and all of them made good recoveries.

During the course of 1932-1933, we have observed four more cases of *Salmonella suipestifer* infection: three in children and one in an adult. The clinical observations in these cases differed greatly from those previously described by us, and in one of them death occurred. It seemed of interest, therefore, to report these cases in detail in order to emphasize the increasing prevalence of this infection in Baltimore, and the varied clinical picture it may assume.

REPORT OF CASES

CASE 1.—L. E., a Negress, aged 28, living in Baltimore, was admitted to the nose and throat service, Aug. 29, 1932, with a diagnosis of nasal polypi, chronic ethmoiditis, bilateral chronic maxillary sinusitis and chronic tonsillitis. The patient had been suffering from sore throat for several months but had no other complaints. On physical examination she was found to have a few scattered râles at the left base but was considered in good condition for general anesthesia. August 30, a bilateral nasal ethmoid and sphenoid operation was performed. The patient stood the operation well and had no fever. September 1, a bilateral radical antrum was done. Pus was obtained from the left antrum, which on culture showed alpha streptococci.

The patient developed fever following operation, ranging from 102 to 103 F. She had no complaint except headache. Physical examination was negative except for coarse râles at the left base. White blood cells numbered 7,600; polymorphonuclears, 64 per cent; lymphocytes, 36 per cent. The urine showed from 5 to 15 white blood cells in a high power field in the centrifuged specimen.

September 4, the white blood count was still 6,400, with the temperature ranging from 103 to 105. Some frequency of urination was noted. A catheterized specimen of urine showed from 3 to 5 white blood cells per high power field. Urine culture yielded *Staphylococcus aureus*.

September 6, the patient complained of dysuria and began to cough.

September 7, the percussion note at the left base was impaired and the temperature was still high. The patient was transferred to the medical service. Blood cultures taken September 3 and 4 were both positive for *Salmonella suipestifer*, group II. There was no brachycardia. There were no rose spots. The tip of the spleen was barely palpable on one occasion. The patient's temperature remained hectic from the 1st to the 13th, when it gradually became normal. The cough continued. Dysuria and frequency persisted.

September 9, a catheterized specimen of urine showed 100 white blood cells per high power field. Urine cultures, September 8 and 12, showed almost pure cultures of *Salmonella suipestifer*. Roentgen examination revealed the left base hazy, probably because of thickened pleura; the lungs otherwise were clear. Cultures from the sinuses, nose, throat and stool were negative for *Salmonella suipestifer*.

September 15, serum agglutinations were negative for typhoid, paratyphoid A and paratyphoid B. They were positive for *Salmonella suipestifer*, group II, 1:80. They were positive for a homologous organism, 1:160. The Wassermann reaction was negative. The white blood count was consistently low, from 9,350 to 4,700. As the pyuria cleared, the dysuria disappeared. Urine cultures became negative for *suipestifer*. Blood cultures, September 12, were negative. Renal function was normal. Serum obtained October 12 agglutinated the homologous strain in a dilution of 1:160 and a known porcine strain of *suipestifer* (group II) in a dilution of 1:640. The patient was discharged, October 12, six weeks after admission.

The final diagnoses were: 1. Chronic pansinusitis. 2. Septicemia, *Salmonella suipestifer*. 3. Cystitis, *Salmonella suipestifer*. 4. Questionable bronchopneumonia, left base.

CASE 2.—R. G., a Negro boy, aged 2 years, living in Baltimore, was admitted Jan. 16, 1933, with a diagnosis of bronchopneumonia. The patient's past history was negative. He became ill suddenly, Dec. 28, 1932, nineteen days before admission, with cough, fever and rapid, grunting respirations. A doctor was called, who made a diagnosis of pneumonia. A public health nurse visited him daily, until the day of admission. He remained very sick during the nineteen days prior to admission with a temperature fluctuating from 105 to normal. His cough continued, and he vomited occasionally.

On admission, the temperature was 102, respiration 32, pulse 96. The patient was acutely ill, anemic and malnourished and was in marked respiratory distress. He was unable to breathe except in an upright position. Respirations were shallow and grunting, with dilatation of the alae nasae. The sclerae were slightly icteric, and there was slight cyanosis. There were no rose spots. The tonsils were enlarged; the pharynx was edematous. Both lung bases were dull to percussion; the breath sounds were suppressed and tubular in character. Fine and coarse râles were heard. Both apexes were relatively clear. Fluoroscopic examination showed patchy consolidation at both bases. The heart was enlarged to the right; the sounds were of fair quality, with no murmurs. The abdomen was not distended. The liver was enlarged 4 cm. below the costal margin. The tip of the spleen could be just felt. There was no swelling or tenderness of the extremities. Neurologic examination was negative.

On admission, the red blood cells numbered 2,150,000; hemoglobin was 35 per cent; white blood cells, 17,400. The differential count showed: polymorphonuclears, 42 per cent; lymphocytes, 52 per cent. There were no sickle cells. Platelets, numbered 150,000. The bleeding time was not prolonged. Examination of the urine was negative, except for a trace of diacetic acid. Throat culture revealed type III pneumococcus. The Wassermann reaction was negative.

Because of the signs of heart failure, the patient was given digitalis, with some improvement. Three days after admission, January 19, he received a small transfusion, without any reaction. The following day he seemed slightly better, the heart had decreased in size, and the temperature was 100.4. A second transfusion was performed on the twenty-first. The following day he vomited coffee ground material, the stools and sputum were streaked with blood, the urine was grossly bloody, and his gums were bleeding. There were petechiae on the hard palate.

January 22, the red blood cells numbered 3,800,000; hemoglobin was 50 per cent; white blood cells numbered 7,500; reticulocytes, 18 per cent. The bleeding time was twenty-seven minutes, the clotting time four and one-half minutes. Platelets were completely absent. Blood cultures taken January 16, 18 and 19, were all positive for *Salmonella suipestifer*, group II. Serum obtained on the 23rd showed no agglutinins for *Salmonella suipestifer*. The patient was given three more transfusions but the bleeding continued, and the patient died,

3. Kuttner, A. G., and Zepp, H. D.: Paratyphoid-Like Fever in Children Due to the *Salmonella suipestifer* Group, *Bull. Johns Hopkins Hosp.* 51: 373, 1932.

4. This case is included through the courtesy of the medical department.

January 25, nine days after admission. Stool obtained on the 25th was positive for suipestifer, group II. Postmortem blood culture was positive for suipestifer, group II. Postmortem lung puncture yielded *Bacillus influenzae* and pneumococcus, type III, negative for suipestifer. The postmortem spinal fluid was sterile.

Autopsy revealed purpura with hemorrhage into the tonsils, lymph nodes, pericardium, endocardium, kidneys, pelves of the kidneys, ureters, spleen, bladder, suprarenals, testes, stomach and intestine.

The lungs, on gross examination, had a thick, fibrinous exudate over both bases. Both lower lobes felt solid, and on section areas of denser consolidation surrounded all the small bronchioles.

Microscopic examination showed the bronchi filled with exudate, consisting mainly of polymorphonuclears and fibrin. The walls of the bronchioles were thickened and infiltrated with mononuclears. The alveoli in many places were filled with edema fluid, some polymorphonuclears and fibrin. The typical picture of interstitial bronchopneumonia was presented, characteristic of pneumonias caused by viruses. In spite of careful search, no inclusion bodies were found. Two postmortem lung punctures showed pneumococcus, type III, and influenza bacilli, but no *Salmonella* suipestifer, in spite of the fact that this organism was present in the blood. No evidence was obtained, therefore, that *Salmonella* suipestifer was the etiologic agent responsible for the pneumonia.

Focal necroses in the liver resembled those found in typhoid.

Aside from hemorrhages, no lesions were found in the intestine.

CASE 3.—J. S., a Negro boy, aged 19 months, living in Baltimore, was admitted, Feb. 21, 1933, with a diagnosis of pyarthrosis. The family and past histories were negative.

The patient was well until February 7, two weeks before admission, when he lost his appetite and did not appear to be doing well. February 15, six days before admission, he bumped his left knee and complained that it hurt, although the mother could not see any swelling or redness. The following day, February 16, the knee began to swell and the patient felt feverish. He limped for two days until February 18, three days before admission, when he refused to stand on his left leg. The fever continued. He was seen in the dispensary two days before admission, February 19, when he had a temperature of 103. He was found to have pharyngitis. The soft tissue of the left thigh and knee were swollen and tender. The impression at that time was that the condition was cellulitis. He failed to improve, and the fever continued. The patient was brought to the dispensary, February 21, and 10 cc. of greenish purulent pus was aspirated from the left knee joint. He was admitted on the same day.

On admission, the temperature was 103.6. The patient was well nourished, irritable and alert, and did not appear particularly sick. He lay with his left knee slightly flexed and externally rotated. Physical examination revealed enlargement of the cervical lymph nodes, the tonsils and pharynx injected and edematous, and a slight mucopurulent posterior nasal discharge. The heart was not enlarged; the rate was rapid. The liver and spleen were not felt. The left knee was diffusely swollen, hot, and tender on palpation and passive movement. There was fluctuation within the joint.

Laboratory examination revealed: hemoglobin, 75 per cent; white blood cells, 28,040; polymorphonuclears, 64 per cent; platelets, abundant. The urine was normal. The Wassermann reaction was negative. Blood culture on the day of admission was sterile. Culture from the pus aspirated from the left knee yielded *Salmonella* suipestifer, group II.

The knee was aspirated every day from the 21st to the 25th, inclusive, from 3 to 10 cc. being obtained. The knee was put in traction on the 23d, two days after admission. The patient's temperature was lower, the second week in the hospital, but it was still necessary to aspirate the knee every other day, sometimes as much as 20 cc. of purulent material being obtained. The patient had a pharyngitis during most of his stay in the hospital, but two throat cultures failed to show either suipestifer or beta streptococci. All the cultures made from the pus aspirated from the joint showed *Salmonella* suipestifer until

March 17, twenty-five days after admission, when the culture was negative. No further aspirations were done after this date, the swelling subsided gradually, and passive exercise was started, March 25. Traction was discontinued, March 28. There was only slight limitation of extension and the patient was able to bear weight on his leg fairly well, although he had a marked limp. Two roentgenograms failed to show any damage to the bones. The patient's serum agglutinated the homologous organism in a dilution of 1:160. The stool was negative for suipestifer. As in the majority of the other cases of *Salmonella* suipestifer infection, no source of infection was found. No other member of the family was sick and there were no butchers or farm workers in the family. The mother's serum failed to agglutinate the organism isolated from the patient.

The patient was discharged, April 9, after seven weeks in the hospital. Serum obtained one month after discharge, May 6, agglutinated the homologous and other strains of *Salmonella* suipestifer, group II, in a dilution of 1:160.

CASE 4.—F. W., a white girl, aged 5 weeks, living in Fullerton, Md., was admitted, April 8, 1933, with a diagnosis of arthritis. There was no history of syphilis or gonorrhea. The patient was breast fed. The mother gave a history of having had a breast abscess, which was healed at the time of admission. The patient had nursed from the infected breast, but the nature of the infection was not known. The patient had been entirely well until ten days before admission, March 29, when

Subluxation of right shoulder; evidence of fluid in joint; osteomyelitis of right humerus.

the mother noticed that the infant was not moving her right arm and cried when it was touched. The patient had no fever and did not seem sick. No swelling was noted, until the day before admission, April 7, when the mother noticed that the right shoulder joint was swollen but not hot or red.

On admission the patient was well nourished and the infant did not appear acutely ill, temperature was normal. She did not move her right arm and cried when it was handled. There was no general glandular enlargement; the epitrochlears were not felt. The eyes were normal. The pharynx was slightly red. The heart and lungs were normal. The spleen was easily palpable. There was no vaginal discharge. The right shoulder joint was swollen; there was slight local heat but no redness. The other joints were normal.

Laboratory examination revealed red blood cells, 3,900,000; hemoglobin, 94 per cent; white blood cells, 22,600; polymorphonuclears, 46 per cent; lymphocytes, 64 per cent. Platelets were abundant. The urine was normal.

Attempts to aspirate the joint the day of admission failed. The patient remained afebrile and took her feedings well. A roentgenogram of the right shoulder, April 10, showed fluid in the joint and an area of destruction at the upper end of the humerus. Blood cultures taken, April 10 and 13, were negative.

April 13, the shoulder was again aspirated and 0.5 cc. of thick pus obtained. A smear showed gram-negative bacilli. A culture yielded *Salmonella* suipestifer, group II. Serum obtained from the patient on the same date failed to agglutinate typhoid, paratyphoid A and B or *Alcaligenes melitensis*; agglutination with *Salmonella* suipestifer, group II, was positive in a dilution of 1:320.

Repeated stool and urine cultures have been negative for *Salmonella suipestifer*. The patient's shoulder was immobilized for three weeks. The swelling has decreased and the patient is improving gradually.

The serum of the patient's parents was tested for agglutinins for *Salmonella suipestifer*. The father's serum was negative, but the mother agglutinated the organism isolated from the patient in a dilution of 1:80. The family live in the country but do not keep pigs.

BACTERIOLOGY

The cultures isolated from these patients were gram-negative motile bacilli that fermented dextrose, mannite, maltose, rhamnose and xylose with the production of gas and failed to ferment lactose, saccharose, arabinose, trehalose and inositol. They all produced blackening on lead acetate mediums. These organisms were not agglutinated or agglutinated only in low dilutions by paratyphoid B serum but agglutinated well in serums produced by the injection into rabbits of group II *Salmonella suipestifer* of human and porcine origin. They failed to agglutinate in immune serum produced by the injection of the specific phase of *Salmonella suipestifer*, group I. These cultures were identical with *Salmonella suipestifer*, group II, cultures isolated by us³ in 1932. The virulence of the cultures was tested by injecting 0.01 and 0.001 of a twenty-four hour broth culture subcutaneously into rabbits. All the cultures proved to be virulent, killing rabbits in from six to fifteen days.

COMMENT

Four more cases of *Salmonella suipestifer* infection in man have been reported: one in an adult and three in children. The adult developed a *suipestifer* septicemia and cystitis, following a radical antrum operation. Two of the children had arthritis and one of them showed osteomyelitis. The other child developed a *suipestifer* septicemia accompanied by severe purpura, during the course of bronchopneumonia. No complications such as arthritis, osteomyelitis, cystitis and purpura were observed in the group of cases reported by us³ in 1932. It is of interest that this organism, *Salmonella suipestifer*, group II, can produce arthritis and osteomyelitis unaccompanied by fever (case 4). Nabarro and his associates⁴ described a similar case in England in an infant, aged 8 months, due to *Salmonella suipestifer*, group I.

Purpura has been observed as a rare complication in paratyphoid B fever.⁵ In none of the cases of *suipestifer* infection in man that we have been able to find in the literature has severe purpura with complete disappearance of platelets been described (case 2). Since purpura is a common symptom of pigs infected with the hog cholera virus, it was thought possible, in view of the interstitial bronchopneumonia found at autopsy, that in this patient *Salmonella suipestifer* might have been associated with the virus of hog cholera. Unfortunately, no experiments to determine the presence of the virus were undertaken. On the other hand, it is entirely possible that the purpuric manifestations were merely the result of a severe infection in a debilitated child and that some virus other than that of hog cholera was responsible for the pathologic picture in the lung. None of the other cases showed any evidence of purpura, and their platelet counts were entirely normal.

Three of the patients live in Baltimore; one lives in the country. In no instance was any association with infected pigs established, and none of the cases had

any contact with each other. There was no history of a similar illness in any other member of the family, although the mother of one of the patients agglutinated the organism isolated from her daughter.

The organisms isolated from these four cases all belong to group II, *Salmonella suipestifer*, although group I is generally considered the American type, most commonly associated with hog cholera in this country. In recent years, however, group II has been associated with increasing frequency from infected pigs in the United States.⁶ In 1932 our observations were similar: six of the seven cases reported belonged to group II.

MENINGOCOCCIC MENINGITIS IN INFANCY

REPORT OF CASE

ALAN BROWN, M.D. (Tor.), F.R.C.P. (CAN.)
AND
NELLES SILVERTHORNE, M.B. (Tor.)
TORONTO

This report embodies the observations of meningococcic septicemia with meningitis in a 22-day old infant with a diagnosis correctly made within twenty-four hours of the onset, immediate, adequate serum therapy given by the most desired routes, and early recovery. Very few cases reported in the literature at this early age have been found. A case has been reported by McLean and Caffey¹ in a 23-day old infant. An individual may be susceptible at any age, since the youngest patient in whom the condition has been recorded is the present one, and the oldest is a woman of 61 years.² Holt and Howland,³ in their textbook, state that "the youngest case we have seen was in an infant 5 weeks old." These authors also remark that 12 per cent of patients were under 1 year. Ker⁴ points out that 14 per cent of his patients were under 1 year of age.

REPORT OF CASE

History.—J. R., a girl baby, aged 22 days, admitted to the hospital, May 15, and discharged, May 29, 1933, was sent into the hospital by one of us (A. B.) with a diagnosis of meningitis, which was made by observing carefully the few physical signs that were present.

Fever, vomiting, irritability and anorexia had been present for from twelve to twenty-four hours. There were six contacts, all adults, two of them with head colds. Otherwise the family history was negative. The child had been delivered with forceps but had been perfectly normal since birth. She had nursed since birth and no other feeding had been necessary. The baby was apparently quite healthy until the day before admission, when she became feverish and drowsy. She nursed poorly and vomited once on the day of admission.

Examination.—The infant was well nourished and developed. She was quite drowsy and was irritable on being disturbed. The anterior fontanel was tense, with a feeling of increased pressure yet not definitely bulging. Occasional quick lateral nystagmoid movements of the eyes were noted. No rash or petechiae were seen. Examination did not reveal the slightest sign of nuchal rigidity. Kernig's sign was positive bilaterally, although this is not always reliable in a new-born infant as a diagnostic criterion of meningitis. Otherwise, the physical examination was negative.

5. Jameson, H. P., and Signy, A.: A Case of Paratyphoid B Infection with Purpura and Specific Bronchopneumonia, Arch. Dis. Childhood 3: 238 (Oct.) 1928.

Lumbar puncture revealed a high cell count and many intracellular and extracellular gram-negative diplococci. Some were seen as a single coccus.

A provisional diagnosis of meningococcic meningitis was made.

Progress.—The temperature on admission was 105 F., varying around 100 to 103 for eight days and finally falling by lysis to normal toward the day of discharge. The baby seemed much the same as on the first day of hospitalization, when on May 18, three days later, general improvement was noticed, as manifested by a better appetite, less irritability and noticing the surroundings. The condition remained much the same until May 22, when a definite neck rigidity was noticed. From this time on the baby gradually improved until all observations were negative on the day of discharge. It will be seen in the table that the cerebrospinal fluid taken at lumbar puncture was sterile for the first time on the ninth day following hospitalization.

The white blood cell count was 14,300, with 76 per cent polymorphonuclear leukocytes. Hemoglobin was 80 per cent. The urine was normal. The intracutaneous tuberculin test was negative. Blood culture and a nasopharyngeal swab was positive for meningococci on admission.

Treatment.—On the first day of admission, within half an hour, specific antimeningococcic serum was administered, which on later test proved to agglutinate in high titer the infecting meningococcus. This serum was given intravenously on the first and third days of hospitalization in approximately 70 cc. of 5 per cent dextrose in physiologic solution of sodium chloride. Usually when intravenous therapy is given, the con-

* I.V., Intravenously; I.T., Intrathecally.

tinuous intravenous drip method is employed, with serum administered in dextrose and saline solution.⁵ In this case the infant was too young, so that ordinary intravenous therapy was given. Daily lumbar puncture was performed, with drainage of spinal fluid and administration of antimeningococcic serum.

COMMENT

We believe that early diagnosis, together with more intensive and adequate serum therapy by early use of the intravenous and intrathecal routes will materially reduce the mortality rate in this disease. It is currently believed that there is a great tendency for a block to occur at the base of the brain in very young infants and that cisternal and ventricular punctures may be necessary. We should like to emphasize the fact that, by the use of continuous intravenous therapy with serum, or, in very young infants, the ordinary administration of intravenous fluid, with serum, one tends to increase the amount and flow of cerebrospinal fluid.

SUMMARY AND CONCLUSIONS

1. A 22-day old infant had meningococcic septicemia with meningitis.
2. Sterilization of the spinal fluid occurred nine days after onset.
3. The infant was discharged from the hospital cured in fifteen days.
4. The intravenous route was used on the first and third days for the administration of antimeningococcic serum. The intrathecal route was used daily.

THE FORM OF THE STOOL AS A CRITERION OF LAXATION

GEORGE R. COWGILL, Ph.D.
WILLIAM E. ANDERSON, M.A.
AND
ALBERT J. SULLIVAN, M.D.
NEW HAVEN, CONN.

It has been well established that one of the important functions of the large intestine is to dehydrate the food residues received from the small bowel in preparation for elimination by the act of defecation. Burnett¹ has made this the basis of a test for what he calls intestinal indigestion and has suggested that the ability to form a hard stool made up of numerous smaller parts called *fecal units* indicates that the large intestine is in excellent condition; cases were described in which the shape of the stool was changed by dietary means from a "soft and formless" type to a "unit basis" with concomitant improvement of health. He also reported on the rate of passage of food residues through the alimentary tract, his method being to study the time required for practically all of a 50 cc. quantity of millet seed to be eliminated. As a result of such tests, Burnett was led to believe that the normal intestinal rate is from 62 to 130 hours, a period much longer than is generally accepted. This point of view was favored by Alvarez and Freedlander,² who studied the time required for the passage of glass beads. The numerous experiments of Hoelzel,³ however, who used not only millet seeds and glass beads but also gold, silver and rubber balls, steel ball bearings and other materials, have helped to explain these unusual results of Burnett and of Alvarez and Freedlander. Hoelzel wrote that "rates of passage more or less proportional to the specific gravity of the test materials were found, the heavier materials passing slower than light materials." Concerning Burnett's use of millet seed, Hoelzel stated that the ingestion of a 50 cc. quantity actually delayed intestinal passage about twelve hours and that "Burnett's method therefore is misleading rather than advantageous."

During the past few years we have had the opportunity of studying the value of bran as a laxative for men and have made observations not only on normal individuals⁴ but on a group of patients⁵ as well. In

our study the men subsisted on carefully controlled diets of a known roughage content, all the foods being analyzed for crude fiber. The total fiber content of the food was taken as a measure of the amount of roughage ingested. Charcoal and carmine were the only materials other than the foods taken in these experiments, and they were ingested only in small quantities sufficient to mark the residues from the meals eaten at the beginning and end of experimental periods of at least seven days' duration. We feel, therefore, that our observations were made under conditions in which the influence of any inert or non-nutritive foreign substance was practically negligible. In other words, the laxative performances exhibited by our human subjects were almost entirely attributable to the foods and test substances ingested.

Reference has already been made to the unusually long periods of passage of food residues through the alimentary tract reported by Burnett and Alvarez. It seems pertinent, therefore, to call attention to the results obtained in our investigations in which laxation was studied in twenty men over periods of from at least a month to as many as sixty-two days.⁶ Our

Fig. 1.—Specimen passed by E. W. S. while subsisting on the basal diet only. This is an example of the hard, fecal-unit type of stool. Record of subjective impressions describes it as "very painful and difficult."

observations support the more general view held by gastro-enterologists, roentgenologists and others that, under "normal" laxative conditions, interpreted subjectively as "satisfactory," food residues require from about sixteen to twenty-four hours to traverse the alimentary tract.

In the course of our work we became impressed with the importance of purely subjective criteria of laxation; namely (a) the ease with which defecation takes place, and (b) the presence or absence of a sense of complete emptying at the time the dejecta are passed. Our records indicate that the passage of stools of the definitely fecal-unit type, described by Burnett, is a disagreeable, often painful, process and is associated subjectively by the individual with constipation. Figure 1 illustrates this. The fecal-unit type of stool is also the type observed clinically in cases of spastic constipation and mucous colitis and is produced by hospital patients subsisting on liquid or "soft" diets; its small hard character is probably due to a too prolonged dehydrating action of the colon on too small an amount of indigestible food residue.

Our series of photographs contain many illustrations of the different types of stools described by Burnett. The records of subjective impressions show that a fairly large, sausage-shaped stool, with few or no markings indicative of so-called haustral contractions, is usually easy to pass and its elimination is generally

Fig. 2.—Specimen passed by M. L. P. while ingesting the basal diet plus a processed bran product. The large, sausage-shaped stool was characteristic of this dietary regimen. Records of subjective impressions report "an easy, satisfying movement."

accompanied by a sense that emptying is complete and is followed by a feeling of well being. Likewise, a large bulky "formless" stool, such as is obtained when wheat bran or milled bran products are ingested in appropriate amounts, gives no difficulty whatever during the act of defecation. Figures 2 and 3 show such stools observed in the course of our study.

Occasionally the stool showed both a fecal-unit part and a sausage-shaped portion. Figure 4 is an example of this. The records of subjective impressions made

Fig. 3.—Specimen passed by F. B. W. while subsisting on the basal diet plus about an ounce daily of wheat bran, which had been treated with weak acid in order to remove phytin. This is an example of what might be called the semiformed or a formless stool, which was characteristic of this dietary regimen. The record of subjective impressions describes it as "a most satisfactory movement."

at the time these stools were passed contain such remarks as "a large stool, satisfying but hard to start," "a fairly easy movement, first part tending to be scybulous," and others similar in nature. This type of stool is very likely to appear when the individual

6. Cowgill and Anderson.⁴ Cowgill and Sullivan.⁵

changes from a low-roughage diet to a high-roughage regimen; presumably, the increased intake of roughage stimulates intestinal motility, and the food residues from the new meal reach the rectum in time to be passed along with the scybalous masses formed by the residues from the low-roughage regimen. In all probability, the presence of the extra roughage serves to increase the stimulus for defecation. A similar phenomenon is that observed when a patient whose bowels are constipated has been given a barium meal as part of a roentgenologic examination. The scybalous masses characteristic of the constipation are eliminated just ahead of the roughage of the barium meal.

The feeling that emptying is complete may be related to the size of the stool, the easy passage of a large amount of material nearly always being interpreted subjectively as a "satisfying movement." There seems little doubt that the pain accompanying the elimination of fecal-unit stools is due to the hardness of the fecal masses and their size. It seems obvious that the passage of any hard object approximating at all the diameter of a moderately distended anal ring should be more painful than the passage of an object of the

Fig. 4.—Specimen passed by P. S. while receiving the basal diet plus a processed bran product. This stool represents a combination of the fecal-unit type and the sausage type. The record of subjective impressions made at the time this specimen was passed describes it as a "satisfactory movement except for the first part, which is scybalous."

same size but of softer and therefore more pliable consistency.

In view of these observations, we suggest that clinicians who are treating cases of constipation give due attention to the matter of securing an easy passage of dejecta together with a satisfying sense that all fecal material has been eliminated. We have not seen this point emphasized in the literature but are convinced from our observations, made under carefully controlled dietary conditions, that it is important.

In stating his belief that defecation at least once a day is not necessary for every so-called normal individual, Alvarez⁷ writes that he has seen many persons who defecate not more than once every three or more days, and this without definite deleterious effects. We are naturally led to inquire as to how painful each defecation may be in such an individual when it does finally occur. One of the patients in the group reported in our second paper⁵ was in the habit of defecating about once every three days, but the difficulty with which each elimination took place was sufficient to

cause him to inquire as to how he might be treated for what he regarded as definite constipation.

What may appear to the clinician as absence of stasis may still be regarded as definite "constipation" by the patient. For example, the clinician may look on movements occurring once a day as evidence that material can pass through the alimentary tract without obstruction and does pass through in what appears to be a reasonable time. The patient, on the other hand, may consider that his bowels are constipated because the dejecta are of very solid consistency and difficult to pass; such a patient will not be satisfied that his constipation has been "cured" until he can accomplish the act of defecation comfortably and completely.

We suggest that, so far as the form of the stool is to be taken as a criterion of the state of laxation prevailing in the individual, the fecal-unit type described by Burnett be regarded as one extreme indicative of constipation—or, rather, indicative of lack of sufficient indigestible material to allow formation of a stool suitable for a completely satisfactory defecation—with a formless watery stool as the opposite extreme; and that for an appropriate objective of his therapy the clinician should aim at the production of a fairly large sausage-shaped stool having few or no markings indicative of haustral contractions.

Clinical Notes, Suggestions and New Instruments

VITAMIN D IN THE TREATMENT OF ACNE VULGARIS

ABRAHAM DOKTORSKY, B.S., AND S. S. PLATT, B.S.
CHICAGO

It is known that cases of acne vulgaris are improved temporarily by treatment with ultraviolet rays. The present work was based on the supposition that the activation of ergosterol in the skin by ultraviolet rays is the prime factor for this temporary relief in acne. We therefore attempted to alleviate acne by the direct ingestion of vitamin D in the form of viosterol.

We ourselves were our first patients, since both of us have this condition. We started with a dosage of 10 drops a day of Mead's viosterol in oil 250 D and increased this during a period of two weeks to 20 drops a day. After continuing for a period of one month we observed by actual count of pustules a decrease of about 75 or 80 per cent. We considered these results satisfactory enough to warrant experimentation on a larger number of subjects.

The subjects chosen for the experiment were thirty-five men and women from the University of Chicago, ranging in age from 17 to 30. All were started on the same dosage that we had taken; later it was increased to 20 drops a day. After a period of from four to five weeks we found a 70 to 80 per cent improvement in 90 per cent of the cases. In the remaining subjects, a 40 to 50 per cent improvement was observed. These results are based on actual counts of the pustules on the chest, face and back. In all the subjects the blood calcium remained normal. As a control we discontinued the treatment for two weeks with ten different subjects picked at random from this group and found a great increase in the number of pustules over that found during the period of treatment. On the other hand, those who continued the treatment showed a sustained improvement.

This preliminary communication is published with the hope that this form of treatment will be given further trial by the general practitioner and dermatologist. The work was done under the supervision of Dr. A. B. Luckhardt.

HEMOSTATIC SCALP CLIP

ALFRED W. ADSON, M.D., ROCHESTER, MINN.
AND
EDGAR F. FINCHER, JR., M.D., ATLANTA, GA.

The time-consuming procedure of opening and closing in craniotomy has not been improved to the same degree as have diagnostic methods and surgical treatment of cerebral neoplasms. Many methods for the control of hemorrhage from the scalp have been employed, but still there remains ample opportunity for additional aids.

The scalp tourniquet was not practicable, for it was difficult to hold it in place during the operation, and it could not always be placed so as to control the hemorrhage. The running lock stitch served its place for hemostasis, but again it was unsatis-

Fig. 1.—a, scalp clip holder; b, clip holder, illustrating jaws.

factory, for it required additional time to sew it in place; often it failed to control hemorrhage, and more often it devitalized the cut edge of the scalp.

The scalp clamps, if properly applied, controlled the bleeding from the cut edges of the scalp, but they frequently crushed the edges of the scalp, besides cluttering the wound with forceps. The pedicle clamp had a place in the hemostatic armamentarium, but it too is soon to be discarded, since it requires additional time to apply, and hemorrhage occasionally occurs from the internal surface of the bone flap following its removal.

Fig. 2.—a, loading clips in holder from racks; b, position of clip held in holder, and c, position of clip when compressed.

Fig. 3.—a and a', scalp clip before and after reshaping; b, reshaping forceps; and c, scalp clip reshaped and held in place while teeth are adjusted with pointed forceps.

Fig. 4.—a, application of clips to scalp for hemostatic purposes; and b, removal of clip with pointed forceps preliminary to suture of galea with interrupted silk sutures.

The application of pointed forceps to the galea has been almost universally used, and would be the ideal method for hemostasis of the scalp were it not for the fact that the wound is filled with instruments which are constantly in the way. The end forceps of a group often pull loose from the galea, and occasionally the weight of the forceps pulls the scalp loose from the bone flap.

The perplexing problems of hemostasis and the loss of time in opening and closing wounds in the cranium stimulated one of us (Adson) to devise a hemostatic scalp clip. The technic of application and reshaping of the clip for future use was developed by both of us. The Mischel skin clip had been used, but we found it too narrow and not large enough to include

all the layers of scalp, especially if the scalp had been infiltrated with a local anesthetic. Swift called Adson's attention to the Willus Andrews clip, which was made from a flat, circular ring of german silver. The ring was bent at an angle to form a staple, with two sets of two teeth opposite each other for the purpose of fixing the position of the staple-like clip. These clips were used, but we soon learned that they were too large to be accurately placed in the corners of the wound. The application of the clip with Ochsner forceps was an awkward procedure, but no accompanying holder had been provided. The V shape, where the ring was bent at the diameter of the circle, had a tendency to compress the margin of the scalp too tightly if the clip was compressed sufficiently to remain in place. The clip could be used again many times, but there was no special arrangement for reshaping the clips to a standard opening.

We were convinced that a clip could be made that would control bleeding from the scalp without traumatizing the galea or skin, that could be applied more quickly than pointed forceps, that would remain in place until removed, and that would avoid the necessity of filling the wound with instruments. Following is the description of the scalp clip, the holder, the rack for clips and the reshapers:

The clip is stamped, from a copper alloy, in the shape of an open rectangle 22 by 12 mm., with the band measuring 3 mm. wide and 0.3 mm. thick. This is then shaped into an open U, with teeth at each corner opposing one another. The opening of the clip is standardized by the reshapers, in order that it may always be open enough to include the galea and the full thickness of the skin. The straight lines of the clips allow one to apply them side by side, avoiding hemorrhage between clips.

The clip holder (fig. 1) is equipped with jaws that hold the clip in readiness for use, with two posts situated behind the clip to permit the operator to apply force in adjusting the clip to the scalp. The metal plates in the jaws are of such thickness as to compress the edges of the clip evenly into a U shape without producing more pressure in one place than in another (fig. 2 c). The U shape prevents the injury to the edge of the scalp that commonly occurred when V-shaped clips were used. Removal of the clips from the rack, with relative positions of open and closed clips, held in the holder, may be noted in

figure 2. In loading the holder, the forceps portion is closed sufficiently to lock the ratchet, after which a nurse takes the instrument between her thumb and first finger, holds it just above the box joint, and slides the clip holder onto the clip, which is resting on the rack. The clips must be properly shaped (fig. 3 a and b) in order to facilitate the speed of application. Two or three holders are necessary to avoid delay. The method of applying the clips and their removal just preceding the suture of the galea may be noted in figure 4. The scalp is compressed laterally to the incision during the application of the clips just as it is when pointed forceps are used.

The hemostatic scalp clip has controlled bleeding, shortened the time of operation, reduced the number of instruments in the wound, and avoided trauma and sloughing of the edges of the scalp.

SUBMUCOUS LIPOMA OF THE CECUM

H. R. DeLUCA, M.D., BRIDGEPORT, CONN., AND PHILIP HENSTELL, M.D.,
NEW HAVEN, CONN.

This case is presented because of its infrequent occurrence. F. R., a white woman, aged 45, admitted to St. Vincent's Hospital, Bridgeport, Conn., April 10, 1932, complained of sharp pains in the epigastrium which were intermittent, belching of gas, nausea, and a sour taste in the mouth. She stated that she had never vomited.

She had been operated on fifteen years before for a ruptured ectopic pregnancy. Recovery was good. Eighteen years before, she had had malaria. Otherwise her past history was negative.

The present condition began about four months before admission with a dull ache in the epigastrium and a sour taste in the mouth. This ache gradually became worse and finally sharp pain was experienced which was intermittent in character. Although at first the pain was confined to the epigastrium, it later radiated to the lower right quadrant. The pain had no definite relation to food; however, she felt nauseated whenever the pain was present but never vomited. About two months before admission, she noticed a lump in the upper right quadrant just beneath the skin. About that time the pain seemed to subside for a few days but then returned with increased severity. The day before admission the pains became so severe that she was told that she had an acute appendicitis.

On admission, the patient looked very ill and complained of the severe pain in the epigastrium, which radiated to both sides of the lower part of the abdomen. She was nauseated and had a sour taste in her mouth. The temperature was 99.8 F. by rectum, the pulse was 88 and respirations were 22. On examination, the head and neck were essentially normal, as well as the chest, heart and lungs. The blood pressure was 156 systolic, 88 diastolic. The abdomen was round, obese and soft with no rigidity; there was tenderness in the lower part on both sides, but particularly in the lower right quadrant. The scar from the operation of fifteen years before was visible in the lower midabdomen. In the upper right quadrant of the abdomen was felt a mass about the size of a small orange, which was smooth and firm and moved with deep inspiration; it was not tender and appeared to be attached to the under surface of the liver. The extremities and the skin were normal.

Laboratory examinations showed: hemoglobin, 35 per cent; red blood cells, 1,850,000; white blood cells, 7,200; polymorphonuclears, 82 per cent; small mononuclears, 12 per cent; large mononuclears, 6 per cent. Analysis of the urine was negative; of the feces, negative for blood.

Because of the results of clinical and laboratory examination, operation was postponed for further study of the case. Cystoscopy and pyelograms showed normal kidneys, ureters and bladder. A cholecystogram showed a normal gallbladder. Roentgen examination of the colon by a barium enema revealed no obstruction to the passage of the barium until it reached the first portion of the transverse colon, where it stopped at a dilatation of the bowel. After one hour a small amount entered the hepatic flexure, where there appeared to be marked infiltration of the wall and canalization with dilatation of the transverse colon. The opinion of the roentgenologist was that there existed a malignant growth causing an obstruction.

Although up to admission the patient had never vomited and had been having good bowel movements with the aid of laxatives, she had no bowel movements in the hospital and began to vomit small amounts of green fluid three days after admission. Colonic irrigations were given with poor results. Her breath took on a foul odor. She began to complain of severe pains all over the abdomen and in the upper part of the back. The temperature, pulse and respirations rose slightly. She received daily subcutaneous infusions of saline solution and dextrose until the operation. The preoperative diagnosis was carcinoma of the ascending and transverse colon.

Operation was performed nine days after admission by Drs. William Verdi and Daniel Banks. The incision was made on the right side of the abdomen. The cecum was found high up on the right, and a large mass was palpated in the wall near the ileocecal valve. The appendix was normal. No metastases were found. The cecum, the ascending colon and a part of the transverse colon were resected in one piece and then the ileum was anastomosed to the transverse colon. Postoperative diagnosis was carcinoma of the cecum and the ascending colon.

Pathologic examination revealed a large mass 2 inches (5 cm.) in diameter in the cecum arising in the wall just above the ileocecal valve and occluding the lumen. The mass was composed of fatty tissue and was covered by mucosa. No enlarged lymph glands were found. Microscopic examination of the tissue from this mass showed a loosely combined connective tissue interspersed with lipid tissue, and necrosis was present. The mucosa covering showed signs of pressure atrophy. No malignant growth was found. The pathologic diagnosis was submucous lipoma of the cecum.

The patient made an uneventful recovery and was discharged, May 8, twenty-eight days after admission, fully recovered. The blood count, on discharge, showed hemoglobin 65 per cent and red blood cells 2,000,000.

COMMENT

Of the 181 cases of lipoma of the gastro-intestinal tract reported by Comfort¹ in 1931, only 16 were in the cecum alone; of these 16, 12 were with symptoms and 4 without symptoms. The symptoms present usually consisted of appendicitis or even obstruction. Consequently, the two conditions most usually confused with cecal lipoma are appendicitis and carcinoma. The case presented gave features simulating both conditions, and at times both conditions were suspected. However, the true nature of the lesion was not established until the specimen was seen by the pathologist; but rarely, if ever, is a correct diagnosis made before operation. To confuse submucous lipoma of the cecum with appendicitis is not a very serious mistake, but the confusion arising out of the fact that a malignant growth is suspected often leads to a large amount of unnecessary surgery and the subjection of the patient to an unwarranted risk.

The case presented illustrates all the characteristic features of a lipoma of the cecum. With an understanding of the physiology of this region, it is no wonder that the early symptoms of which the patient complained were those simulating appendicitis. The epigastric pain with later radiation to the lower right quadrant led to the diagnosis of appendicitis, with admission to the hospital for this complaint. The presence of a mass in the upper right quadrant of the abdomen with the negative laboratory data soon pointed away from this diagnosis. A barium enema was then given because malignancy was suspected on the basis of the mass. Conditions found on roentgen examination as a result of the enema were characteristic of intestinal obstruction due to a tumor in this region. The picture, however, was still further confused by the abnormally high cecum, which was up under the liver. Soon after the enema was given, symptoms of intestinal obstruction, with vomiting, increase in the vital signs and the aggravation of the pain in the abdomen developed. However, the signs of obstruction were by no means of a severe grade. The combination of a history of appendicitis with the subsequent development of the signs of intestinal obstruction might be taken as the clinical picture of an obstructive lesion of the cecum. It is to be differentiated from appendicitis by the negative examinations other than the abdominal pain and the appearance of intestinal obstruction. It is to be differentiated from a malignant growth of the cecum by the fact that malignancy does not yield a history of epigastric pain radiating to the lower right quadrant. By this complex of symptoms the clinical picture of benign lesions of the cecum, even though rare, may be perhaps split off from the large group of conditions that yield symptoms referable to this region and be diagnosed more frequently.

Another interesting feature of this case was the relatively severe grade of secondary anemia that was present. The hemoglobin on admission was 35 per cent and the red blood count 1,850,000. It is well recognized among clinicians that lesions involving the ileocecal region have a marked tendency to the production of severe secondary anemia. The explanation of this fact, however, has not received the attention it deserves. Coon of the Mayo Clinic, in a study of malignant growths in this region, came to the conclusion that the degree of anemia present correlated with the degree of intestinal obstruction. This is evidently not so, as in the case presented there was no obstruction of any great importance either in the history or during the course of the patient's illness in the hospital. The

1. Comfort, M. W.: *Submucous Lipomata of the Gastro-Intestinal Tract, Surg., Gynec. & Obst.* 52: 101-118 (Jan.) 1931.

cause of this type of anemia must lie in a functional disturbance in this region; but the physiology of the region is as much a mystery as the fact that these patients should develop a severe secondary anemia at all.

47 Kensington Street.

ARTERIOVENOUS FISTULA OF THE LEFT INTERNAL CAROTID ARTERY AND JUGULAR VEIN

D. R. McINTYRE, M.D., SHREVEPORT, LA.

R. H., a white man, aged 54, an American lawyer, consulted me, March 6, 1933, complaining of a blowing, pumping, steam-like noise in the left ear, together with extreme nervousness, anxiety, headache and easy fatigue.

The noise in his left ear began in February, 1928, with a sudden onset while he was at ease reading in his library. Having just recovered from otitis media in the right ear, he first thought that possibly a like condition was making its appearance in the left ear. He consulted an ear specialist but a pathologic condition was not found. There had been no noticeable change in the noise heard, but he had progressively become more uneasy about his condition until he had reached the stage bordering on a nervous breakdown.

The patient was well developed and fairly well nourished. On examination there was some swelling on the left side, and the external veins of the face on that side appeared congested; palpation revealed nothing. There was no abnormal pulsation but on auscultation a blowing, pumping, hissing-like noise, very similar to that heard over an aneurysm, could be heard extending upward from below the tip of the mastoid process to the top and right side of his head. The blood pressure at the first examination was 180 systolic, 90 diastolic; the heart appeared normal. There was no history of syphilis; the blood and urine were normal. The patient was instructed how to promote collateral circulation through the circle of Willis and also advised concerning rest and diet so as to lower his blood pressure. In March, at the first examination, he could stand for the circulation to cease by pressure over the left internal carotid less than ten second. By repeated and frequent efforts, after three months, he is now able to withhold the circulation by pressure more than three minutes, and he appears to be much improved physically as well as mentally. The blood pressure is now 135 systolic, 85 diastolic.

This case is reported because of the extreme rarity of an arteriovenous fistula, especially in this region; also, because there is no history to account for its occurrence. If the collateral circulation continues to improve, ligation of the carotid artery will be done.

528 Ricou-Brewster Building.

CONGENITAL STENOSIS OF THE PYLORUS: TWO CASES

CHARLES E. TRIBBLE, M.D., NEW HAVEN, CONN.

I am placing on record a report of multiple cases of pyloric stenosis occurring in the same family. Other instances of this occurrence have been reported by Freund,¹ Grissen,² Heubner,³ Rosenhaupt,⁴ Ibrahim,⁵ Still,⁶ Finkelstein,⁷ Richter,⁸ Sauer,⁹ Davis,¹⁰ Moore¹¹ and Caulfield.¹²

There are three children in the family which came under my observation. The patients were the first and last born; the second child passed through infancy without any gastro-

intestinal trouble. The first child came under observation in the New Haven Hospital at the age of 8 weeks. He had been vomiting for five weeks. In the hospital, projectile vomiting occurred after all feedings, peristaltic waves were visible over the stomach, and a hard rounded mass was palpable just to the right of the epigastrium. A Fredet-Rammstedt operation was performed at the end of the third hospital week; recovery was satisfactory. Now, at the age of 5 years, the boy is in excellent health.

The third child vomited frequently during the first five weeks of life; at first, the vomiting was not projectile but later it became so and the patient was admitted to the New Haven Hospital at the age of 5 weeks. On examination, large, slow peristaltic waves were seen over the stomach, and there was a rounded tumor at the location of the pylorus. At the end of ten days a pyloroplasty was performed. The child did well and at the age of 6 months is a fat active baby, free of any gastro-intestinal symptoms.

Special Articles

REPORT OF THE AMERICAN COMMITTEE ON OPTICS AND VISUAL PHYSIOLOGY

The work of this committee is seriously hindered by the difficulty of getting its members together for adequate discussion of the subjects brought to its attention. A meeting has been held in connection with the annual meeting of each of the national organizations that have joined in forming the committee. But these meetings, held in different parts of the country, cannot be attended by all the members and can secure only inadequate time for their discussions.

At the meeting held in connection with the meeting of the American Ophthalmological Society in Washington, May 9, 1933, certain suggestions with reference to lenses were discussed and were placed before the American Ophthalmological Society in the following report:

1. A great number of claims made by the manufacturers advertising various patented and copyrighted lenses, accepted by reputable lay and scientific journals, are absurd.

For the protection of the patient, therefore, it is the duty of the ophthalmologist to be well enough acquainted with the fundamental facts specifically to state in each prescription the exact coflexure of the lenses; in the case of the presbyope, whether two pairs of glasses, or bifocals, are desired, and the particular style or type of bifocals, and the shade and color of tinted glasses, so that the designation can be made in a scientific manner and not by trade names.

When tinted glasses are necessary for certain purposes, London Smoke Nos. 1, 2 and 3 are better than many that are said by their makers to perform miracles. Too much ado has been made about "glare." The "soft light" of a cathedral is a poor light for ordinary purposes.

2. The committee recommends that the scope of the Council on Pharmacy and Chemistry of the American Medical Association be extended to include spectacle lenses, instruments, appliances or drugs pertaining to ophthalmology; if it cannot be otherwise arranged, that this council be given authority to designate the person or persons to pass on the merits of such articles.

The cooperation promised last year, on behalf of the Council on Physical Therapy of the American Medical Association, does not seem adequate to meet the situation with regard to the prescription and advertising of lenses. Lenses, like medicines, may be of secret composition and be sold and advertised under copyrighted names, conditions that favor deceit and fraud that essentially constitute quackery. An appeal from this section should have weight with the Council on Pharmacy and Chemistry.

From the Department of Psychology of the University of Michigan, those who have undertaken the study of visual acuity have been able only in the last year to perfect their apparatus

From the Department of Pediatrics, Yale University School of Medicine, and the Pediatric Service of the New Haven Hospital and Dispensary.

and work out methods of study. With this progress they hope at an early date to report important scientific results.

The National Society for the Prevention of Blindness calls attention to the effort of the Committee on Central Statistics of the Blind to prepare a Table for the Uniform Grouping of the Blind by Amount of Visual Perception. They have proposed four groups for the blind:

1. "Totally blind," including from no light perception to 2/200.
2. "Motion and form perception," from 2/200 to 5/200.
3. "Traveling sight," from 5/200 to 10/200.
4. "Ability to read large letters," from 10/200 to 20/200.

And "borderline cases," vision of 20/200 or better.

Your committee feels that such grouping could not help the understanding of the disability of blindness and that the matter should receive careful consideration from ophthalmologists in general, before any such plan of grouping is promulgated.

For the Committee,

EDWARD JACKSON, Chairman.

REPORT OF COMMITTEE ON COMPENSATION TABLES FOR EYE INJURIES

Your committee has continued its activities during the last year and is pleased to report increasing use of the method advocated by it for determining the visual efficiency of an individual following industrial injury or occupational disease of the eyes.

In reply to a letter of inquiry directed to the International Association of Industrial Accident Boards and Commissions of the U. S. A., as to the uniformity of methods for evaluating visual efficiency following ocular injuries or occupational diseases, and as to how many boards and commissions utilized the American Medical Association committee's methods, the secretary replied (in part):

"Except in states where compensation for specific injuries is written into the statutes, I think all the states compute partial permanent (disability) on a percentage of total permanent (disability), and this would apply to eye injuries as far as I know.

"Economic blindness is construed as total permanent disability by a majority of the industrial commissions; in fact, by all of them, so far as I know, unless specific weighting is written into their statute.

"There has not only been a tendency to adopt the recommendation made by the Section on Ophthalmology of the American Medical Association in determining visual efficiency, but, so far as I know, it has in practice been adopted by every state where a specific weighting is not written into the statute."

CORRESPONDENCE WITH WORKMEN'S COMPENSATION BOARDS

On March 28 and 29, 1932, the Bureau of Legal Medicine and Legislation, American Medical Association, sent fifty-three letters to the several workmen's compensation boards in the United States. Each board was asked to state whether the method approved by the American Medical Association for the appraisal of visual efficiency had been adopted by it, and, if so, the date of adoption. Each board was asked for criticisms and suggestions with respect to the method, based on the board's experience with it. Twenty-six replies were received. The following is an analysis of these replies:

Officially Adopted

| | |
|---------------------|----------------|
| Arizona..... | Nov. 3, 1925 |
| North Carolina..... | Jan. 1, 1931 |
| Tennessee..... | June 1, 1928 |
| Washington..... | March 17, 1931 |

From the state of Kansas a rating sheet was received that indicated that that state used the standards set forth on page 3 of the American Medical Association's pamphlet "Appraisal of Loss of Visual Efficiency," but correspondence indicates that Dr. Gradle found variations between the Kansas method and the American Medical Association's method.

Use but Have Not Officially Adopted

Maine, Texas and Vermont. Hawaii uses a part of the American Medical Association's method, but the laws of the

territory make the adoption of the method in its entirety impracticable.

Use Similar Methods

Colorado, Ohio and West Virginia

Approve

Wyoming. There is no statement, however, whether the workmen's compensation board does or does not use the method.

Disapprove

Do Not Use

California

Alabama
Connecticut
Idaho
Indiana
Iowa
Michigan

Minnesota
New Hampshire
New Jersey
New York
North Dakota
Utah

COMMENTS

The following comments received from the several states may help throw light on the extent to which the American Medical Association's method is in use and some of the reasons why it is not more extensively used:

Alabama and New Hampshire have no industrial commissions. In Michigan the laws make the adoption of the American Medical Association's method impracticable.

New York uses a radically different method, and correspondence suggests that the American Medical Association's method is not approved.

New Jersey reported that it was unfamiliar with the American Medical Association's method, and it requested information concerning the method.

Idaho and Minnesota stated that they did not use the American Medical Association's method, but did not state what method they did use.

Connecticut and North Dakota rely on the Snellen tests.

Indiana and Iowa have no particular method but go on the testimony of physicians.

Utah uses the Chapman table.

On April 26 and 27, 1932, the Bureau of Legal Medicine and Legislation sent to thirty-seven insurance companies likely to be interested in the appraisal of the loss of visual efficiency letters inquiring whether these companies had adopted the American Medical Association's method and asking for criticisms and suggestions of that method, if it had been adopted. Replies were received from eleven companies. Of these eleven companies, the following favored the American Medical Association's method:

Aetna Casualty and Surety Company.
General Accident and Assurance Corporation, Ltd.
London Guarantee and Accident Company.
Lumbermen's Mutual Casualty Company.
Maryland Casualty Company.
Metropolitan Casualty Insurance Company.
National Life and Accident Insurance Company.
Union Indemnity Company.

The Travelers Insurance Company reported that it found the Snellen test more widely adopted.

The American Mutual Liability Insurance Company adopts the methods of the various state industrial commissions.

The Lloyd Casualty Company was unwilling to express an opinion.

Through the untiring efforts of one of the members of the committee, Dr. H. S. Gradle, the committee has succeeded in having the American Medical Association produce the Industrial Visual Acuity test charts for distance and near. The distance charts conform to the Snellen formula, i. e., characters subtending a 5 degree angle, and the component parts subtending a 1 degree angle at the distance from 200 feet to 20 feet to determine a visual efficiency for distance, and the near charts for 14 inches. These, with a pad of the Industrial Visual Field Charts and the Industrial Motor Field Charts recommended by the committee, may be obtained from THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

The committee asks for its continuance as an active working body of the Section on Ophthalmology.

Respectfully submitted.

HARRY S. GRADLE.
ALBERT C. SNELL.
NELSON M. BLACK, C. ; ..

Council on Pharmacy and Chemistry

REPORTS OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS.

PAUL NICHOLAS LEECH, Secretary.

HOSAL AND BROMHOSAL NOT ACCEPTABLE FOR N. N. R.

Hosal and Bromhosal are products marketed by the Abbott Laboratories as "Two Substitutes for Table Salt where Sodium Chloride is contra-indicated." No adequate statement of composition is given in the advertising or on the package. The only analysis available appears to be that given for Hosal by von den Velden (The Low Salt Diet, *Clin. Med. & Surg.* 39:257 [April] 1932) as follows:

| | Per Cent |
|--|----------|
| Calcium | 11.7 |
| Sodium | 15.3 |
| Magnesium | traces |
| PO ₄ | |
| Poly-amino-acids | |
| Low fatty acids, amounts not specified | |

Concerning the composition of Bromhosal, von den Velden states: "Bromhosal is a 60 per cent bromine preparation on the basis of Hosal, composed of calcium-sodium double salts of poly-amino-acids on the one side and low fatty acids on the other." Thus, as far as the advertising and labels of the product marketed by the Abbott Laboratories are concerned, the preparations are at best semisecret.

HOSAL

The advertising emphasizes the idea that "It [Hosal] contains only a minute quantity of sodium, and is free from sodium-chloride." Ordinary table salt contains 39.6 per cent of sodium, and according to the von den Velden analysis, Hosal contains 15.3 per cent of sodium. The latter, therefore contains 39.2 per cent of the sodium contained in table salt; hardly to be spoken of as "a minute quantity." The misleading statement must be regarded as harmful in view of the well established fact that sodium, rather than chlorine, is important for the production of edema.

An associate of the Council's referee and two assistants performed some organoleptic tests to determine the flavor imparted to food by Hosal and the amount necessary to produce the desired degree of salinity in comparison with table salt. There was agreement that the flavor imparted to foods by Hosal was distinctly different from that of table salt and that the flavor was unpleasant, resembling somewhat the flavor of meat extracts. All of them found that the flavor was too unpleasant to push it to the degree of salinity to which they were individually accustomed. It was found that approximately 50 per cent more of Hosal than of table salt had to be used to produce any definite salinity. The referee's associate reported: "It may be pointed out that indiscriminate regulation of the salt intake loses sight of the fact that the electrolyte pattern constantly shifts in nephritis and that very frequently actual deficiencies of base make such restrictions inadvisable and even dangerous." The referee's associate added that a colleague has used potassium chloride in long standing cases of nephrotic edema and finds it extremely satisfactory, cheap, and without harmful effects over long periods. He quoted Peters' statement (Salt and Water Metabolism in Nephritis, *Medicine* 11:435 [Dec.] 1932): "... the regulation of the sodium chloride intake is not a matter for routine prescription but one that requires the most critical consideration in each individual case."

BROMHOSAL

The advertising circular states that "Bromhosal consists of 60 per cent bromine chemically combined with Hosal . . ." The misleading statements with regard to the absence of sodium chloride apply, therefore, to both products. The associate of the Council's referee reported that Bromhosal is definitely more palatable and saltier than Hosal. But he pointed out that the product is proposed not as a salt substitute, but as a medication. The advertising circular states: "Bromhosal is of value in all cases in which specific bromide therapy is indicated, particularly in epilepsy and epileptoid states, and in the

numerous diseases in which a depression of psychic excitation is desired. In certain vasomotor disturbances, and in insomnia and the psychic irritations during the menopause and menstrual periods, Bromhosal has proved of value." The product is therefore offered as a substitute for the official bromide preparations such as sodium or potassium bromide, which cost far less, without any evidence of advantage over these salts. It is the opinion of a neurologist who is an associate of the Council's referee that but little if any evidence of therapeutic superiority exists. It is pointed out that if sodium is not desired in bromide therapy, as in nephritics with edema, the official potassium bromide can be used. The referee's associate further pointed out that Bromhosal represents a mixed, and probably undesirable, type of therapy, since it combines the question of bromide therapy with that of the salting of food. It puts on the tables of patients a drug which is likely to escape the attention of the physician for long periods of time, whereas he is much more likely to check up on the medication if he has had to make out a prescription for the official preparation, which is entirely adequate for bromide therapy.

After careful consideration of the referee's and associate's comments, the Council declared Hosal unacceptable for New and Nonofficial Remedies because it is a preparation of semisecret composition marketed with misleading and unwarranted claims; it declared Bromhosal unacceptable because it is a preparation of semisecret composition marketed with misleading and unwarranted claims as a potentially dangerous substitute for bromide therapy with the entirely adequate official preparations.

LA MERCY MINERAL WATER NOT ACCEPTABLE FOR N. N. R.

La Mercy Mineral Water was presented by McKesson & Robbins, Inc., for consideration by the Council as a natural product from thermal springs at Los Banos, Calif., proposed for therapeutic use in the treatment of dysmenorrhea. The firm submitted a detailed analysis on the basis of which the following "Hypothetical Form of Combination" was declared:

| | Grains Per U. S. Gallon |
|--|----------------------------|
| Ammonium Chlorid (NH ₄ Cl) | 0.79 |
| Lithium Chlorid (LiCl) | Trace |
| Potassium Chlorid (KCl) | 0.50 |
| Potassium Bromide (KBr) | 0.09 |
| Potassium Iodine (KI) | 0.16 |
| Sodium Chlorid (NaCl) | 121.63 |
| Sodium Tetraborate (Na ₂ B ₄ O ₇) | 4.08 |
| Disodium Arsenate (Na ₂ HAsO ₄) | 0.04 |
| Calcium Phosphate (Ca ₃ (PO ₄) ₂) | 0.29 |
| Magnesium Carbonate (MgCO ₃) | 0.27 |
| Calcium Carbonate (CaCO ₃) | 0.41 |
| Calcium Sulphate (CaSO ₄) | 3.58 |
| Calcium Silicate (CaSiO ₃) | 2.60 |
| Silica (SiO ₂) | 0.01 |
| Iron Oxide (Fe ₂ O ₃) | 0.10 |
| Alumina (Al ₂ O ₃) | 136.75 |

Anticipating an objection to the name, the firm offered to market the product under any name that would meet the Council's requirement. The firm was informed that the name "La Mercy Mineral Water" is objectionable and that the Council would recognize either "Banos Mineral Water" or "McKesson Saline Mineral Water" as a suitable name.

In its presentation of the product, the firm admitted that scrutiny of the analysis would furnish no reason to believe that the product should have any specific influence on the pain or associated pains of dysmenorrhea, amenorrhea or the menopause, but it submitted 430 case reports as clinical evidence for the therapeutic value of the product in "Primary Dysmenorrhea, Complete Retroversion Infantile Uterus, Amenorrhea, Menorrhagia, Metrorrhagia, Endometritis, Neurasthenia, Fibroid Tumor, Cervical Erosion, Ovaritis, Salpingitis and Menopause."

The Council's referee examined the case reports and also submitted the material to a colleague who is an experienced gynecologist. Among the cases reported are forty-five cases treated by Dr. A. V. Pettit of San Francisco, the list of diagnoses of which includes, according to Dr. Pettit's statement, patients "who have many of the recognized causes of dysmenorrhea such as acute flexions of the uterus, the infantile or under-developed uterus, patients having small intramural benign tumors of the uterus and those having marked disturbances of the blood supply, mainly varicosities of the broad ligaments."

Dr. Pettit further states: "This about covers the field of dysmenorrhoea due to mechanical or physiological pathology." "Of these forty-five patients only two have reported no benefit." "This report must be considered simply a report of what patients say concerning the efficacy of the water." "From a purely scientific standpoint, the number of cases is far too few for the complete working out of the value of this water in the treatment of the various types of dysmenorrhoea. To do this thing properly it would require at least a year or more."

Records of smaller groups of cases by other physicians include cases of fibroids, menopausal symptoms and stenosis of the cervix. A consultant, among other observations, points out that postoperative stenosis of the cervix often is relieved spontaneously; that the complete and permanent relief of dysmenorrheic symptoms arising from infantile uterus is unusual, and that the statement that in one series relief followed in forty-three of forty-five cases, from whatever their cause, raises questions as to the accuracy of the observations attributed to the patients. The statement of the distributors that of 385 cases plus 45 control cases—making 430 cases in all that have been treated—only one has reported no benefit, seems to be a claim that more careful observations are unlikely to confirm. It is likely that moderate water drinking may benefit some patients with dysmenorrhea.

In the discussion of the referee's report, a member of the Council pointed out that there would seem to be no question that the therapeutic claims are unfounded, including as they do recommendations for use in developmental abnormalities, nutritional disturbances and inflammatory conditions of the uterus; it would seem that the La Mercy water would have the effect of a saline mineral water.

The Council declared the product submitted as La Mercy Mineral Water unacceptable for New and Nonofficial Remedies for lack of acceptable convincing evidence for its therapeutic value in the conditions for which its use is proposed.

REX-ORCIN NOT ACCEPTABLE FOR N. N. R.

Rex-Orcin is the proprietary name under which the Amp Research Laboratories, Corona, Long Island, N. Y., market a preparation for treatment of the scalp, stated to have the following composition:

| | |
|---|-------|
| "Tannic acid U. S. P..... | 0.5% |
| "Salicylic acid U. S. P..... | 1.0% |
| "Castor Oil, U. S. P..... | 24.5% |
| "Euresol (Mono acetate resorcinol)..... | 5.0% |
| "Ethyl alcohol | 69.0% |
| "Perfumed to render suitable for use." | |

The product appears to be only another one of the many hundreds of proprietary preparations on the market for treatment of the scalp. There is nothing new about the formula. It might be a little more complex than even many of the ambitious formulas on the market, but it can hardly be said that this adds anything to its value, for the opposite is probably the case. Certainly there is no new discovery in this preparation that justifies the proprietary name Rex-Orcin.

Resorcin has been used for years in the treatment of diseases of the scalp. The same is also true of resorcinol monoacetate (introduced as curesol) and of salicylic acid. Tannic acid, on the other hand, is not a common ingredient in this sort of preparation. Just what can be expected from this adjuvant is difficult to state. Of course, the castor oil in the preparation is an old remedy, generally added to alcohol preparations to overcome dryness of the scalp. The directions given on the label are likely to encourage ill advised use of Rex-Orcin by the general public. If it is desired to use such a preparation, it would be far better that the physician write an individual prescription.

Rex-Orcin is offered as "a stimulating and effective antiseptic." If it is rubbed in hard enough, it might cause a rubefacient action on the scalp. No evidence is offered to show that it is an "effective antiseptic for the treatment of hair and scalp." Just what is meant by this last statement only the manufacturers can say.

The Council declared Rex-Orcin unacceptable for New and Nonofficial Remedies because it is an unnecessarily complex and unscientific mixture marketed under an unacceptable proprietary name, with unwarranted therapeutic claims, and in such a manner as to lead to its ill advised use by the public.

Committee on Foods

GENERAL COMMITTEE DECISIONS

THE COMMITTEE ON FOODS AUTHORIZES THE PUBLICATION OF THE FOLLOWING GENERAL COMMITTEE DECISIONS ADOPTED FOR ITS OWN GUIDANCE AND FOR THAT OF FOOD MANUFACTURERS AND ADVERTISING AGENCIES ON FOOD COMPOSITION AND FOOD ADVERTISING.

RAYMOND HERTWIG, Secretary.

THE CLAIM "DIGESTS STARCH" FOR FOODS CONTAINING DIASTATICALLY ACTIVE MALT OR MALT EXTRACT

Such claims as "digests starch," "aids digestion," "digests other foods," "digests the starch of other foods," "contains natural digestive elements," and equivalent claims frequently accompany foods containing diastatically active malt or malt extract.

The normal person unaided is able to care for the digestion of foods. Any digestion of starch in ingested foods due to diastatically active malt or malt extract products included with a meal is of no practical significance. Aids of this character for starch digestion are not necessary. Any child or adult can digest starch. Saliva swallowed in eating is many times more potent for digesting starch than is any quantity of food containing malt or malt extract likely to be consumed.

It is not true that foods containing diastase "digest other foods." The diastase is incapable of digesting proteins or fats, important components of most foods.

Diastatically active malt or malt extract products have starch digestive properties, but they are of no significance for digesting starch or for aiding the normal processes of starch digestion. Starch digestive claims in advertising for this type of foods usually have therapeutic or medicinal implications which lead to self-medication and are unwarranted; they promote misleading advertising.

VAGUE "CLINICAL EXPERIENCE" CLAIMS

Vague claims such as "clinical experience with XYZ" has demonstrated its efficiency" and equivalent claims for foods are not informative to the public or physicians and because of misleading therapeutic implications are objectionable. Such claims should state what clinical experience with the foods has demonstrated; they should be supported by actual experience of physicians. Claims regarding clinical experience are justified only if specific and supported by sufficient evidence. Vague claims in general are not instructive and lead to deceptive advertising.

Claims of clinical experience cannot be based on replies to general questionnaires promiscuously distributed to physicians. Information and data so obtained cannot be rated as the results of clinical experience. In this connection see the General Committee Decision "Questionnaire Advertising."

ADDITION OF PHENOLPHTHALEIN, ACETYL- SALICYLIC ACID (ASPIRIN) AND OTHER DRUGS TO CHEWING GUM, CANDY AND FOOD ARTICLES

Medicating common food articles with drugs—such as the addition of phenolphthalein to chewing gum, acetylsalicylic acid (aspirin) to candy, and senna to bread—is becoming a growing menace and must be viewed with apprehension and concern as a danger to public health. The general appearance of these drugged foods does not distinguish them from the respective nondrugged forms; label declaration of the added drugs cannot be expected to prevent their fortuitous misuse or their consumption by the uninformed, the unobservant or those unable to recognize the significance of label statements. There is, therefore, the ever present likelihood that children and even adults may unsuspectingly or ignorantly consume such drugged foods with results that may be disastrous.

The addition of drugs to common foods tends to promote indiscriminate self-medication and is to be unqualifiedly condemned as a menace to public health. The preparation of medicines with confections, such as sugar or chocolate, as a

device for making unpalatable drugs more acceptable to the patient is quite a different matter from the addition of drugs to articles of food that are bought by the public without restriction. This ruling, therefore, has no reference to so-called candy medications prescribed by a physician and taken under his directions.

"TRICK" CLAIMS IN FOOD ADVERTISING

Claims in food advertising implying for the food advertised the merits of something more valuable (such as milk) with which it may be admixed for use are of the nature of "trick" advertising. These claims are so constructed grammatically as to connect the stated values with the advertised food, whereas such values in large part are provided by the other products of the mixture. This "trick" grammatical structure is illustrated by the statement: "XYZ made with hot milk is not only delicious but nourishing. It is rich in the proteins, fats, carbohydrates and minerals children should have." The antecedent of "it" is XYZ; the grammatical structure incorrectly makes XYZ the source of the fats, carbohydrates, minerals and proteins children should have. Claims of this character to all appearances are planned to "trick" the reader. Such a statement as "the mixture of XYZ and milk is rich in proteins, fats, carbohydrates and minerals (calcium and phosphorus)" is correctly informative and satisfactory but should be used in such a manner as to be free from false connotations.

Food advertising should be truthful in statement and by implication. "Trick" advertising and all other misleading forms are harmful to food advertising and merchandising generally.

REPORTS OF THE COMMITTEE

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION, AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

RAYMOND HERTWIG, Secretary.

CURTISS OSTRICH EGG CANDY

Manufacturer.—The Curtiss Candy Company, Chicago.

Description.—Sweet chocolate enrobed candy containing corn syrup, sucrose, gelatin, glycerin, tapioca starch, vanillin and coumarin.

Manufacture.—The ingredients in definite proportions are whipped to a viscous consistency and transferred by machine to "starch molds"; when firm, the molded pieces are mechanically removed, automatically enrobed with sweetened chocolate, cooled and wrapped.

| Analysis (submitted by manufacturer).— | | per cent |
|---|------|----------|
| Moisture | 7.0 | |
| Ash | 0.3 | |
| Fat (acid hydrolysis method) | 12.2 | |
| Protein (N × 6.25) | 2.1 | |
| Reducing sugars as dextrose | 15.3 | |
| Sucrose (copper reduction method) | 32.5 | |
| Crude fiber | 0.0 | |
| Carbohydrates (by difference) | 78.0 | |

Calories.—4.3 per gram; 122 per ounce.

TOPS-ALL FLOUR (BLEACHED)

Manufacturer.—Minneapolis Milling Co., Minneapolis, of the Commander Larabee Corporation.

Description.—A strong hard spring wheat "stuffed straight" flour; bleached.

Manufacture.—Selected hard spring wheat is cleaned, washed, tempered and milled by essentially the same procedures as described in THE JOURNAL, June 18, 1932, page 2210. Chosen flour streams are bleached and bleached with nitrogen trichloride (1.8 Gm. per 196 pounds) and with a mixture of benzoyl peroxide and calcium phosphate (½ ounce per 196 pounds).

Claims of Manufacturer.—For commercial bread bakeries.

LARSEN'S PRUNES (STRAINED-UNSEASONED) FLAVORED WITH LEMON JUICE

Manufacturer.—The Larsen Company, Green Bay, Wis.

Description.—Sieved prunes flavored with lemon juice, prepared by efficient methods for retention in high degree of the natural mineral and vitamin values of prunes. No added sugar or salt.

Manufacture.—Dried prunes are inspected for removal of any undesirable material, thoroughly washed and steamed until soft; the pits are removed; the prune pulp is sieved in steam atmosphere, is adjusted to a desired consistency with a small amount of water and lemon juice to produce a citric acid content of 0.5 per cent in the final product, is heated to 82 C. and automatically filled into washed cans, which are sealed and processed for thirty minutes at 100 C.

Analysis (submitted by manufacturer).—

| | per cent |
|---|----------|
| Moisture | 77.0 |
| Total solids | 23.0 |
| Ash | 0.7 |
| Salt (NaCl) | 0.1 |
| Fat (ether extract) | 0.1 |
| Protein (N × 6.25) | 0.9 |
| Crude fiber | 0.6 |
| Carbohydrate other than crude fiber (by difference) | 20.2 |
| Titratable acidity as citric acid | 0.5 |

Calories.—0.9 per gram; 26 per ounce.

Vitamins and Claims of Manufacturer.—See Larsen's Strained Tomatoes Unseasoned—Ready for Use (THE JOURNAL, July 1, 1933, p. 35).

HIGHLAND WHEAT BREAD (BLEND OF WHITE AND WHOLE WHEAT FLOURS)

Manufacturer.—Langendorf United Bakeries, Inc., San Francisco and Seattle.

Description.—White flour and whole wheat flour bread made by the sponge dough method (method described in THE JOURNAL, March 5, 1932, p. 817); prepared from white flour, water, whole wheat flour, sucrose, shortening, salt, powdered skim milk, yeast, molasses, a yeast food containing buttermilk, calcium phosphate and ammonium tartrate, malt extract syrup and a yeast food containing calcium sulphate, ammonium chloride, sodium chloride and potassium bromate.

Analysis (submitted by manufacturer).—

| | per cent |
|--|----------|
| Moisture (entire loaf) | 37.0 |
| Ash | 1.9 |
| Fat | 4.0 |
| Protein (N × 5.7) | 11.2 |
| Reducing sugars as invert | 4.5 |
| Sucrose (copper reduction method) | 0.1 |
| Crude fiber | 0.8 |
| Carbohydrates other than crude fiber (by difference) | 45.1 |

Calories.—2.6 per gram; 74 per ounce.

Claims of Manufacturer.—Prepared from a mixture of white and whole wheat flours.

GERBER'S STRAINED VEGETABLE SOUP

Manufacturer.—Gerber Products Company, Fremont, Mich.

Description.—Strained cooked peas, carrots, spinach, rice and barley flours, beef, tomatoes, and celery retaining in high degree the natural vitamin and mineral values; the coarser fibrous material is removed. No added seasoning or sugar. The vegetables are canned in season without salt or sugar, and at intervals are combined with the other ingredients and strained.

Manufacture.—The vegetables are grown from selected seed under the supervision of trained field men, harvested at the proper state of maturity, and immediately washed, drained and inspected. They are not blanched, thus avoiding loss of nutrients. The ingredients are heated under steam pressure until sufficiently softened in an atmosphere of steam and handled thereafter in a closed system and are not exposed to the air. The material is forced through a strainer of perforated monel metal, pumped through enameled metal tubing to glass lined vacuum tanks where in the practical absence of oxygen and at a low temperature the water content is adjusted to produce a uniform consistency in the finished product. The special equipment and procedure have been developed to protect vita-

min values which otherwise may be destroyed or seriously reduced. The product is automatically filled into hot water and steam washed cans which are immediately sealed (the air exposure is for less than one-third second) and processed.

Analysis (submitted by manufacturer).—

| | per cent |
|---|----------|
| Moisture | 89.9 |
| Total solids | 10.1 |
| Ash | 0.3 |
| Fat (ether extract) | 0.1 |
| Protein (N \times 6.25) | 1.9 |
| Reducing sugars before inversion (as invert) | 0.6 |
| Sucrose (copper reduction method) | 0.3 |
| Starch (acid hydrolysis method) | 4.7 |
| Crude fiber | 0.2 |
| Carbohydrates other than crude fiber (by difference) .. | 7.6 |

Calories.—0.4 per gram; 11 per ounce.

Vitamins.—The equipment is especially designed to exclude oxygen from the products during the cooking and straining operations, thereby efficiently protecting the vitamins.

Minerals.—All cooking water is retained, thus avoiding loss of minerals or water soluble nutrients.

Claims of Manufacturer.—Prepared for the diets of infants and invalids or for special smooth diets.

ROBIN'S BEST FLOUR (BLEACHED)

Manufacturer.—The Robinson Milling Company, Salina, Kan.
Description.—Hard winter wheat "patent" flour; bleached.

Manufacture.—Selected hard winter wheat is cleaned, scoured, tempered and milled by essentially the same procedure as described in THE JOURNAL, June 18, 1932, page 2210. Chosen flour streams are blended and bleached with nitrogen trichloride (one-seventh ounce per 196 pounds) and with a mixture of benzoyl peroxide and calcium phosphate (one-half ounce per 196 pounds).

Claims of Manufacturer.—For bread baking in the home and bakeshop.

NURMI'S EXTRA FINE BREAD

Manufacturer.—Nurmi's Bakery, Fresno, Calif.

Description.—A white bread made by the sponge dough method (method described in THE JOURNAL, March 5, 1932, p. 817); prepared from patent flour, water, unsweetened skimmed condensed milk, sucrose, lard, salt, yeast and a yeast food containing calcium sulphate, ammonium chloride, sodium chloride and potassium bromate.

WHITE HOUSE RICE

Manufacturer.—Standard Rice Company, Inc., Houston, Texas.

Description.—Scoured bran free rice.

Manufacture.—Brown rice as described under White House Natural Brown Rice (THE JOURNAL, May 27, 1933, p. 1689) is friction scoured to remove the bran coating, is passed between a rapidly revolving corrugated cylinder and a stationary corrugated case. The bran that is scoured off passes through the openings of the case and is removed by suction. The scoured rice is passed through a "brush" machine consisting of a revolving leather covered wooden drum enclosed in a vertical wire-covered case through which the polishings pass. The polished rice is passed through wire-covered reels to remove small rice and broken pieces. The prepared rice is heat or electrically treated to destroy insect life and is packed in wax paper cartons.

Analysis (submitted by manufacturer).—

| | per cent |
|---|----------|
| Moisture | 11.3 |
| Ash | 0.4 |
| Fat (ether extraction method) | 0.6 |
| Protein (N \times 5.95) | 6.1 |
| Crude fiber | 0.3 |
| Carbohydrates other than crude fiber (by difference) .. | 81.3 |

Calories.—3.6 per gram; 101 per ounce.

Vitamins.—Practically devoid of vitamins.

Claims of Manufacturer.—Not coated with talcum, "glucose" or other coating material.

CLAPP'S ORIGINAL PUREE OF APRICOTS

(CONTAINS SULPHUR DIOXIDE)

Manufacturer.—Harold H. Clapp, Inc., Rochester, N. Y.

Description.—Strained, cooked "sulphured" dried apricots. The method of preparation is efficient for retention in high degree of the natural vitamins and minerals.

Manufacture.—California dried apricots are given three separate washings to reduce the sulphur dioxide. (Tests show that the washing reduces the sulphur dioxide from 2,500 parts per million to less than 100 parts.) The apricots are slightly cooked, strained, filled into glass jars and processed as described for Clapp's Original Baby Soup (THE JOURNAL, June 24, 1933, p. 2011).

Analysis (submitted by manufacturer).—

| | per cent |
|---|----------------------------------|
| Moisture | 84.7 |
| Total solids | 15.3 |
| Ash | 1.1 |
| Fat (ether extract) | 0.5 |
| Protein (N \times 6.25) | 0.7 |
| Crude fiber | 2.4 |
| Carbohydrates other than crude fiber (by difference) .. | 10.6 |
| Sulphur dioxide | less than 100 parts per million. |

Calories.—0.5 per gram; 14 per ounce.

Vitamins and Claims of Manufacturer.—See Clapp's Original Baby Soup (THE JOURNAL, June 24, 1933, p. 2011).

LARSEN'S VEGETABLES WITH CEREAL AND BEEF BROTH. STRAINED-UNSEASONED

Manufacturer.—The Larsen Company, Green Bay, Wis.

Description.—Sieved vegetables (carrots, potatoes, tomatoes, peas, beans, spinach) with pearl barley and beef extract; prepared by efficient methods for retention in high degree of the natural mineral and vitamin values of the raw vegetables. Contains no added sugar or salt.

Manufacture.—With exception of the tomatoes, the vegetables are harvested, immediately delivered to the factory and processed as described for tomatoes (THE JOURNAL, July 1, 1933, p. 35); the tomatoes are regular canned products. The pearl barley is cooked for two hours to a gruel of desired consistency. The vegetables, barley and beef extract in formula proportions are thoroughly mixed, strained, canned and processed for sixty minutes at 116 C.

Analysis (submitted by manufacturer).—

| | per cent |
|---|----------|
| Moisture | 89.1 |
| Total solids | 10.9 |
| Ash | 0.6 |
| Salt (NaCl) | 0.2 |
| Fat (ether extract) | 0.2 |
| Protein (N \times 6.25) | 1.7 |
| Crude fiber | 0.3 |
| Carbohydrates other than crude fiber (by difference) .. | 8.1 |

Calories.—0.4 per gram; 12 per ounce.

Vitamins and Claims of Manufacturer.—See Larsen's Strained Tomatoes Unseasoned—Ready for Use (THE JOURNAL, July 1, 1933, p. 35).

TOP-N-OCH BREAD

Manufacturer.—Maddox & Jennings Bakery, Inc., Roanoke, Va.

Description.—White bread made by the sponge dough method (method described in THE JOURNAL, March 5, 1932, p. 817) prepared from flour, water, condensed whole milk, lard, sucrose, salt, yeast, a mixture of gelatinized white corn flour and soya bean flour, malt syrup, and yeast foods containing calcium sulphate, ammonium chloride, sodium chloride and potassium bromate, and calcium acid phosphate and calcium peroxide.

SWEET TOOTH SELF-RISING PANCAKE FLOUR

Manufacturer.—Black Brothers Flour Mills, Beatrice, Neb.

Description.—Self rising flour containing "first clear" wheat, white corn and rye flours, calcium acid phosphate, salt, sodium bicarbonate, corn sugar and dry skim milk.

Manufacture.—The ingredients in definite proportions are thoroughly mixed in a batch mixer and automatically packed in paper bags.

SATURDAY, JULY 22, 1933

PROBLEM OF MEDICAL PATENTS

Recently the question of the desirability of patents of products used in the field of medicine has been hotly debated. The Principles of Medical Ethics of the American Medical Association says specifically, "It is unprofessional to receive remuneration from patents for surgical instruments or medicines." It has been the pride of medicine down the centuries that it gave freely of its discoveries for the benefit of mankind. Jenner's contribution of vaccination against smallpox, Pasteur's method for the control of hydrophobia, Withering's contribution of digitalis, became the property of all who cared to use them for the prevention or treatment of disease.

As the science of medicine developed, however, new elements entered into its work and participated in its endeavors. Physicians began less and less to concoct their own remedies and to depend on the manufacturer of pharmaceuticals for the collection of materials and for their preparation and distribution. In an earlier day the physician who developed new devices or appliances manufactured a few with the aid of some neighboring blacksmith or carpenter. The modern physician is likely to delegate the manufacture to an industry capable of turning out thousands of units, in contrast to the ten or fifteen which might be used formerly. Greater dissemination of medical knowledge creates a greater demand for new drugs and new equipment. Moreover, the situation is complicated by the entrance into medical research of specialties associated with medicine yet not necessarily partaking of the ideals of the medical practitioner. Today the development of a new medicament may involve the participation of chemists, physicists, laboratory technicians, physiologists, biochemists and roentgenologic technicians who may not themselves be concerned at all with the traditions of medicine as a profession. Insulin, for example, was developed by biochemists, physiologists and a practicing physician. Whereas an ethical physician might not derive remuneration from a patent, biochemists or physiologists might do so. Certainly

the name of the physician Banting is as much associated with the discovery as those of his colleagues, Macleod, Collip and Best. Finally, if the discoverer fails to patent his discovery, any one else may do so and thus steal both the discovery and the profits. The tremendous advantages of being first in the field with a new medical preparation are well recognized in the pharmaceutical industry.

In a recent issue of *Science*, Dr. Allen Gregg¹ considered particularly the new questions raised by the patenting of products through universities. In order to avoid possible ignominy and recriminations against physicians who might patent medical discoveries, and especially when the work was done under the auspices of and with equipment provided by universities, it has become customary to have such patents taken out in the name of the university, college or research institution and to control and promote the preparations under boards appointed by these universities. Numerous universities now resort to such patenting to obtain money to support further research but also, possibly, with the idea of rewarding suitably the investigators of products used in medicine. Already medical patents are controlled by Harvard, Toronto, Columbia, Cincinnati, Wisconsin, Stanford, St. Louis, and Northwestern universities, by the Mayo Foundation, and by the Scarlet Fever Foundation of the McCormick Institute for Infectious Diseases.

As Dr. Gregg emphasizes, there may be excellent arguments in favor of such patents, yet their operation has already produced innumerable difficulties. Extraordinary jealousies develop between members of the same research staff because of special advantages accruing to those who derive income from patents. A tendency develops to promote new products rather than to examine them critically. The acquisitive desire, inherent in many persons, eventually leads to a psychology frame of mind described as "royalty crazy."

Vast sums must be accumulated for the protection of patents—to prosecute infringement. Extraordinary secrecy must be maintained, interfering with academic freedom in research. The existence of patents inhibits research on similar products or with the same materials by physicians in practice and by investigators in medical schools and universities. The university, once in the field of patents, as a routine attempts to protect every tiny innovation or result, eventually devoting more time and money to protect old discoveries than is spent on new research or on the studies necessary to determine the actual value of discoveries already made.

Sir Henry Dale,² director of the National Institute for Medical Research in London, accepts the medical tradition as embodying the true ideal, since the ultimate aim of medical research is to provide knowledge for the relief, cure or prevention of human suffering. In a

2. Dale, H. H.: Academic and Industrial Research in the Field of Therapeutics, address at the opening ceremony of the Research Laboratory of Merck & Company, Rahway, N. J., April 25, 1933.

recent address he contrasted the work done by physicians in practice and medical investigators in universities with the type of research carried on in the laboratories founded by industry. Sir Henry Dale expressed his conviction that a general use of patents in all parts of the field of therapeutic research would definitely hinder rather than promote progress. He felt that the greatest danger was in connection with a discovery of the biologic type. Particularly was he inclined to regard the medical patent as a peculiarly dangerous weapon when wielded by the good intentions of the academic amateur. The danger in patents in the chemical field did not seem to him so ominous, because only industrial research and vast organizations can make these preparations generally available at low prices. Nevertheless, only clinical trial in the hands of physicians under controlled conditions can ever determine with certainty the real value of any therapeutic product. Hence the development of such products must be a cooperative effort. This fact should not be forgotten by those who administer patents in the medical field.

Our new order of living in the machine age, the development of specialization in medical practice, the incorporation of great industries for the exploitation of laboratory discoveries, and similar factors seem to make necessary some change in the medical point of view concerning medical patents. The control of such patents by universities has to some extent assured standardization of products. Usually only reputable firms capable of developing and exploiting products honestly are granted licenses to participate in the manufacture and sale of products controlled by universities, although there are glaring exceptions. However, as has already been mentioned, there is extreme unevenness in the manner of administration of various patents by the groups involved. Conceivably the best interests would be served if some central body might be developed, wholly altruistic in character, capable of administering medical patents for the benefit of the public, and assuring a reasonable remuneration to the investigator, the devotion of much of the profit to research, and adequate returns to manufacturers willing to develop quantity production and distribution in an ethical manner. Such a central body might also set up requirements for adequate clinical research in connection with the development of new products, so that premature launching of unestablished products on the medical profession or on the public might be avoided.

In the opinion of the Council on Pharmacy and Chemistry of the American Medical Association, such premature exploitation is exactly what has occurred in relationship to the use of preparations of copper and iron. Leaving aside the question of priority in the discovery and the difficulties involved in preventing physicians from prescribing mixtures of copper and iron should they wish to do so; disregarding the fact that copper occurs as a natural contaminant in practically all

iron preparations, and that too in amounts apparently sufficient to bring about the desired therapeutic results, there still remains for debate the question as to whether or not the discovery is of practical value in the field of therapeutics.

The questions here raised must inevitably concern the scientific bodies of the American Medical Association as well as the Judicial Council, the House of Delegates and the Board of Trustees. Perhaps some suitable means will be evolved whereby the American Medical Association may lend its authority and influence to the establishment of a technic for the control of medical patents in the best interest of the public welfare and for the advancement of scientific medicine.

MANIFESTATIONS OF ANOXEMIA

The active cells of the body continually call for oxygen. This element is supplied by the arterial blood, which, in turn, depends on the respiratory processes to replenish its supply. The oxygen pressure in the blood must be sufficiently high to satisfy the bodily needs, if physiologic disaster is to be averted. The physician has long realized that anoxemia may attend hemorrhage and anemias of extreme type, because the oxygen carriers, the red blood cells, have become depleted in numbers or are deprived of their normal content of the respiratory pigment hemoglobin. Diseases of the circulation and of the lungs may bring about anoxemia in other ways. The severe symptoms and fatal effects of extreme deprivation of oxygen are quite familiar; the manifestations of mild oxygen hunger are not so well known, particularly because the body will often react so as to compensate for a diminution in the oxygen supply.

Life at high altitudes, unaided by special supplies of oxygen, involves the possibilities of malaise and disordered functions attributable to the lessened supply of oxygen incident to lowered barometric pressures. This has long been realized in mountain climbing and in balloon ascensions. The conquest of Mount Everest in the Himalayas, involving an ascent of less than 30,000 feet, has been prevented thus far not alone by the geographic and climatic difficulties but also by the problem of the oxygen supply. An altitude of 20,000 feet, without oxygen reinforcements is a possibility for only a few of the sturdiest acclimated persons. The advent of the airplane and the proposals to "fly high" above the clouds in every-day human transport brings the problem of the effects of even moderately lowered barometric pressure and oxygen tension of the air at such altitudes forcefully to the attention.

Several investigations¹ of moment in this connection have recently been conducted in the Department of

1. Van Liere, E. J., and Crisler, George: The Effect of Anoxemia on Hunger Contractions, *Am. J. Physiol.* 93: 267 (May) 1930. Crisler, George, and Van Liere, E. J.: The Effect of Anoxemia on the Digestive Movements of the Stomach, *ibid.* 102: 629 (Dec.) 1932. Van Lie e, E. J.; Crisler, George, and Robinson, Dennis: Effect of Anoxemia on the Emptying Time of the Stomach, *Arch. Int. Med.* 51: 796 (May) 1933.

Physiology at the West Virginia University in Morgantown. They extend the importance of studying anoxemia beyond the scope of the familiar diseases. First of all Crisler, Van Liere and their co-workers have demonstrated that even in moderate anoxemia the hunger contractions of the stomach are greatly decreased. The possible relation of this to the sensation of hunger is obvious. Furthermore, there is often a definite inhibition of gastric digestive motility as indicated by a decreased amplitude of stomach contractions and frequently by a fall in tone. Clinicians are, indeed, familiar with an apparent parallelism between gastrointestinal disturbances in the anoxemia of cardiac disease and the effects of anoxemia on gastric digestive motility. Finally, it has been found that, under carefully controlled observation, laboratory animals may show a prolongation of the emptying time of the stomach under anoxemic conditions. At a pressure of 560 mm. of mercury, which corresponds to an oxygen percentage of 15.35 and to an altitude of 8,000 feet, several animals showed a definite retention of food in the stomach. The higher the degree of anoxemia, the greater the prolongation of the emptying time of the stomach. At a barometric pressure which corresponds to an oxygen percentage of about 9.4 and to an altitude of 20,000 feet, food sometimes remained in the stomach as long as twenty-four hours. The altitudes represented by the figures quoted do not exceed the heights often reached in airplane travel. These modern studies of interrelations between mild anoxemia and gastrointestinal functions are therefore timely.

THE "TRACE" ELEMENTS IN NUTRITION

Fifteen years ago, Osborne and Mendel¹ called attention to the paucity of knowledge regarding the mineral nutrients. They asserted that there is no adequate experimental basis whatever to permit tenable statements regarding the indispensability or even the minimum requirement of any of the inorganic constituents of the dietary with the possible exception of calcium and phosphorus. A recent essay by Mary Swartz Rose² on the nutritional significance of some mineral elements occurring as traces in the animal body again points out that for many years interest in the study of the mineral elements in relation to nutrition was temporarily overshadowed by the evidence of organic factors potent in growth; namely, the vitamins. The significance of iodine in small amounts had, of course, been realized since the beginning of the century, following Baumann's discovery in 1895 that the element is a regular constituent of the thyroid gland. Investigation as to the occurrence and possible function of "trace" elements in both plant and animal life is now

exceedingly active. Boron, zinc and manganese have all been shown essential to the growth of maize; boron to a great variety of dicotyledonous plants; without zinc, wheat and barley die in the early stages of growth, and buckwheat, sunflowers, broad beans and red kidney-beans never come to full maturity or produce seed.

In a book published under the title "The Most Nearly Perfect Food" the authors,³ describing the importance of milk, point out that it is particularly useful in the diet because it contains all the minerals found in the body. It has calcium, phosphorus, potassium, sodium, magnesium, iron, chlorine, iodine, sulphur and other minerals, in addition to carbon, hydrogen, oxygen and nitrogen. Three of these minerals, calcium, phosphorus and iron, deserve special discussion because of their unusual importance.

The difficulties of investigation are not inconsiderable in any search of "trace" elements in biologic materials. It has been greatly aided in recent years by the use of the spectrograph, which has revealed the ubiquitousness of many elements in the tissues of living organisms. Three extensive reports⁴ are now available regarding the components of milk. In view of the fact that the samples examined have come from diverse sources in Europe, Great Britain and the United States, it is not surprising that there are some divergencies in the reported observations. Contaminations with extraneous materials are not easily avoided.

The results on the so-called biologically rare elements in milk examined in the School of Hygiene and Public Health at the Johns Hopkins University in Baltimore include the following elements found in small quantities (traces) in all milk samples: barium, boron, copper, iron, lithium, rubidium, strontium, titanium and zinc. Of these, barium is the only one that has not been reported previously. The presence of aluminum and manganese was not definitely demonstrated, although these elements were present in the feed mixture. The presence of antimony, arsenic, bismuth, cesium, cobalt, cadmium, fluorine, germanium, gold, indium, lanthanum, mercury, molybdenum, nickel, osmium, palladium, silver, zirconium, chromium, lead and tin could not be detected, although Zbinden concludes that the last three of these elements, chromium, lead and tin, are present in European milks.

The nutritional importance of iron among these "trace" elements is thoroughly established; there is little doubt of a possible beneficent rôle of traces of copper in hematopoiesis. Manganese is regarded as essential for a complete diet, while fluorine, aluminum and nickel have been found to be dispensable.⁵ The

necessity for the presence of zinc has been debated. It has been apparent for some time that the zinc content of the tissues is somewhat mobile and depends, to some extent, on the content in the diet. The latest research, by Newell and McCollum⁶ at the Johns Hopkins University involved the use of a diet which supported growth in animals although it had a zinc content of the order of 10^{-7} part, or less. Therefore, as the Baltimore investigators conclude, zinc is probably not an essential nutritional factor in the growth of animals.

Current Comment

CHLOROPHYLL AND THE DIET

The interest that has been awakened in recent years as to the possible nutritive significance of some of the plant pigments that are a part of common foods has repeatedly been directed to the widely occurring substance chlorophyll. There are several immediate reasons for this attitude. Chlorophyll is a compound of importance for the development of vegetable tissues. Green leaves constitute a wholesome food intake for many animal species. Consequently, as a recent writer has remarked, many practical observers have reached the superficial conclusion that chlorophyll in fresh green plant tissues helps to produce the good nutritive results noted in herbivora. Added to this conjecture is the more rigorously established fact that chlorophyll is related in chemical structure to the respiratory pigment hemoglobin, an essential in animal welfare. The hope that, owing to the existence of organic groups of a similar nature in both chlorophyll and hemoglobin, the plant pigment might prove to be effective in certain types of anemia in which regeneration of hemoglobin is called for has proved to be rather futile. It has been stated that chlorophyll, in addition to its hematopoietic properties, increases the feeling of vigor and well being.¹ These are, of course, features of health that cannot easily be evaluated in a scientific way. It might be expected, however, that the newer methods of nutrition research on laboratory animals would permit the demonstration of any specifically beneficial effects of a substance assumed to have the potentialities gratuitously ascribed to chlorophyll. Studies recently completed by Edwards and Holley² at the Georgia Experiment Station have furnished nothing better than disillusionment as to the hoped for nutrient potencies of chlorophyll. Apparently the greater part of the ingested pigment is eliminated as pheophytin in the feces. It should be recalled, however, that edible plant products rich in the green pigment are likely to contain the potent pigment carotene and vitamins present in less conspicuous forms. Such a parallelism does not warrant indirect and undue inferences as to any physiologic value of chlorophyll for the animal organism.

Association News

MEDICAL BROADCAST FOR THE WEEK

American Medical Association Health Talks

The American Medical Association broadcasts on Tuesday and Thursday from 9:15 to 9:20 a. m., Chicago daylight saving time, which is one hour faster than central standard time, over Station WBBM (770 kilocycles, or 389.4 meters).

The subjects for the week are as follows:

July 25. Babes in the Woods.

July 27. Ringworm.

There is also a fifteen minute talk sponsored by the Association on Saturday morning from 9:45 to 10 o'clock over Station WBBM.

The subject for the week is as follows:

July 29. Endocrine Glands in Children.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ARIZONA

State Board Elects.—Dr. Ira E. Huffman, Tucson, was elected president of the Board of Medical Examiners of the State of Arizona at its meeting, June 27. Others elected are Dr. Clarence W. Adams, Globe, and Charles C. Bradbury, D.O., Phoenix, vice presidents, and Dr. John H. Patterson, Phoenix, secretary.

CALIFORNIA

A New Roentgen Club.—The Pacific Roentgen Club has recently been organized by California roentgenologists, with Dr. Lowell S. Goin, Los Angeles, as chairman and Dr. Leo H. Garland, San Francisco, as secretary. The object of the club is to keep the practice of radiology in diagnosis and treatment of disease in the hands of licensed practitioners of medicine. The club registered objection to the exploitation of any physician for the gain of nonmedical concerns. It charged that, although California laws prohibit practice of medicine by corporations, many corporations are in fact practicing radiology. A program is now being mapped out to carry through the principles set forth: to prevent further inroads on the practice of the specialty, to improve standards and to obtain recognition for radiology as a branch of medicine.

History of Society.—The early history of the San Francisco County Medical Society was brought to light recently through the finding of a volume entitled *Pacific Medical and Surgical Journal and Medical Press*. These pages revealed that the society was formally organized in 1868 with Dr. J. P. Whitney as president. They contain the annual address of Dr. Henry Gibbons before the society in 1869, and those of "Edwin Bentley, Assistant Surgeon, U. S. A., J. P. Whitney, M.D., and C. B. Holbrook, M.D.," for the years 1870, 1872 and 1873, respectively. It appeared that there had been a society in existence before 1868, but that it was not active. Issues of the *San Francisco Medical Press* which were also found in the book were volume 1, numbers I and II, January and April, 1860, and volume 2, number VI, April, 1861.

CONNECTICUT

Dr. Osborne Receives Chompret Prize.—Dr. Oliver T. Osborne, emeritus clinical professor of therapeutics, Yale University School of Medicine, New Haven, was awarded the Chompret Prize, established by the International Academy of Stomatology and the American Stomatological Association, at the recent annual meeting of the latter. Dr. Osborne received this award for his "contributions to the science of stomatology and for his untiring labors to bring dentistry and medicine to a plane of better understanding and appreciation of their common problems for the good of mankind." The prize was established this year in honor of J. Chompret, professor of

stomatology, French School of Stomatology, Paris, to commemorate the first decade of continuous labor of American dentists in scientific stomatology.

ILLINOIS

Courses in Pediatrics.—A series of one day lecture courses in pediatrics, to be held in eleven districts of Illinois, under the auspices of the American Academy of Pediatrics and the education committee of the state medical society, was inaugurated in Bloomington, McLean County, July 13. The most recent information on problems concerning the care of children and the prevention of childhood diseases will be discussed in these courses, the second of which is opening today, July 22, in Warren County.

Chicago

University Health Service Revised.—The University of Chicago Health Service plan for the staff was separated from the University Health Service conducted for students, July 1, and reorganized as a special clinic in the University Clinics under the direction of Dr. George F. Dick, professor and chairman of the department of medicine. The new clinic will be on the third floor of the medical (west) wing of Billings Hospital. Members of the professional staff with the degree of doctor of medicine may now report directly to the special clinic in which they desire service, but other employees must report to the health service first. On request, at the discretion of the physician in charge, the latter may be referred to special clinics as necessary. Under the revised program, Dr. Luke W. Hunt has been appointed clinical assistant in the department of medicine in charge of the health service for the staff. The health service program for the staff and employees of the clinics group at the university was inaugurated, Dec. 1, 1931. Contributions of \$1 a month were deducted from their salaries and formed a fund which was used only for defraying the costs of medical and hospital service to the individual participants of the plan (THE JOURNAL, Dec. 5, 1931, p. 1715).

Provident Hospital Dedicated.—An informal program marked the dedication of the new \$3,000,000 Provident Hospital and training medical center for Negroes, June 1, although it had been open for business since May 15. Mr. A. L. Jackson, president of the board of trustees, presided, and speakers included Mr. Edwin R. Embree of the Julius Rosenwald Fund; Col. Albert A. Sprague; Dr. Henry S. Houghton, director of the University Clinics; Dr. Franklin C. McLean; Mrs. George Cleveland Hall, president of the woman's auxiliary board of the hospital, and Admiral Norman J. Blackwood, medical director. The institution is located in the remodeled building of the old Chicago Lying-In Hospital on Fifty-First Street. Previously it had been operating more than forty years at 16 West Thirty-Sixth Street. The training center is the outgrowth of an agreement entered into between the Provident Hospital and the University of Chicago in 1930, with the objective of improving the standard of medical practice and nursing among the colored race. Preference in appointments is to be given to colored physicians, although individual appointments are to be determined only on personal and professional qualifications regardless of race. About \$1,250,000 was used for the purchase and remodeling of buildings formerly occupied by the Chicago Lying-In Hospital. The gift of \$1,000,000 by the General Education Board of the Rockefeller Foundation will be administered by the University of Chicago for teaching purposes in the hospital, and the remainder of the fund will be used for endowment and equipment. Dr. Blackwood will continue as medical director, a position he has held since April, 1930.

IOWA

Physicians Honored in Anniversary Celebration.—The Henry County Medical Society celebrated its thirtieth anniversary in New London, June 13, and at the same time paid honor to Dr. Otto A. Geeseka, Mount Pleasant, upon his completion of fifty-five years in the practice of medicine. Dr. William S. Lessenger reviewed the thirty years of the society's history. He, Dr. Geeseka and Dr. Walter A. Sternberg, Mount Pleasant, and Dr. Garrett M. Van Ausdall, New London, are the only living members of the early organization. Dr. Geeseka was presented with a gift.

Society News.—At the summer meeting of the Austin Flint Cedar Valley Medical Society, in Cedar Falls, June 20, speakers included Drs. Sylvester W. Barnett on "Mononucleosis"; Thomas J. Irish, Forest City, "Prophylaxis and Treatment of Gas Bacillus Infection"; Merle J. McGrane, New Hampton, "Report of Series of Perforated Peptic Ulcers," and John C. Hancock, Dubuque, "The Autopsy." Clinics were conducted

by Drs. Virgil S. Counseller, Rochester, on "Carcinoma of Bladder"; Glenn E. Harrison, Mason City, on pediatrics; Claude F. Dixon, Rochester, Minn., surgery, and Cecil S. O'Brien, Iowa City, the eye. Prof. Roy L. Abbott of Iowa State Teachers College, Cedar Falls, made an after dinner speech on "The Doctor of 1999."

LOUISIANA

Society News.—The Orleans Parish Medical Society was addressed at New Orleans, June 26, among others, by Drs. Ralph L. Lawrence on "Lung Abscess," and Marion K. King, "Cardiovascular Syphilis."—Drs. Benjamin T. Ferguson, Waverly, and John L. Kelly, Oak Grove, addressed a meeting of the Tri-Parish Medical Society (East and West Carroll and Madison parishes), in June, on diseases of the prostate and otitis media, respectively.—Recent speakers before the Bi-Parish Medical Society were Drs. Cecil Lorio, Baton Rouge, and C. Jeff Miller, New Orleans, on "Problem of the Thymus, with X-Ray Plates" and "Chronic Cervicitis," respectively.—The Third District Medical Society was addressed in Franklin, June 8, by Drs. Leon J. Menville, on "Bone Infections"; Maurice J. Gelpi, "Correlation of Irradiation and Surgery in the Treatment of Malignancy," and Daniel N. Silverman, "Treatment of Certain Common Disorders of the Intestinal Tract." All were from New Orleans.—At a meeting of the Seventh District Medical Society in Elton, June 22, Dr. Stanford Chaille Jamison spoke on "Practical Points on Physical Diagnosis"; Hiram W. Kostmayer, "Use of the Hormones in Gynecologic Practice," and Charles J. Bloom, "Infant Feeding." The speakers were from New Orleans.

MARYLAND

Conference on Antisepsis.—Sixty-five chemists, bacteriologists, physicians and surgeons attended a conference in Baltimore, June 26, sponsored by Johns Hopkins University to discuss ways of combating disease by antisepsis. Speakers included Justina H. Hill and Edwin C. White, Ph.D., instructor in urology and associate in chemical urology, respectively, at Johns Hopkins, and Fitzgerald Dunning and Wilton C. Harden. Drs. Hugh H. Young and Joseph Colt Bloodgood were guests of honor at a dinner, which concluded the session.

MICHIGAN

Cancer Clinic at University Hospital.—The board of regents of the University of Michigan approved the establishment of a cancer clinic at the University Hospital, June 16. The clinic will be operated by a committee composed of members of the hospital staff, under the supervision of Dr. Harley A. Haynes, medical director of the institution.

Personal.—Dr. William J. Seymour was the recipient of an honorary degree of doctor of laws at the fiftieth annual commencement of the University of Detroit, June 9, in Detroit.—The College of the City of Detroit conferred the degree of master of science in gynecology on Dr. David M. Davidow at its annual commencement, June 6, and the honorary degree of doctor of letters on Dr. Stanley G. Miner.—Dr. Charles J. Scavarda has resigned as health officer of Flint to enter private practice.

Peninsula Meeting.—The Upper Peninsula Medical Society will hold its annual meeting in Escanaba, August 10-11. On the program will be Drs. Frank A. Kelly, Detroit, speaking on "Hernia with Spinal Anesthesia"; Moses Cooperstock, Marquette, "Management of Lobar Pneumonia in Childhood"; Damon A. Brown, Madison, "Chronic Infection of the Prostate and Urethra," and Charles L. Brown, Ann Arbor, "Consideration of Digitalis, Diuretics and Diet." Drs. James D. Bruce, Ann Arbor, and Frederick C. Warnshuis, Grand Rapids, will discuss, respectively, "An Essential in Medical Education and in Medical Practice" and "Medical Economics Applied to Practice." Speakers in the second day's session will be Dr. Norman F. Miller, Ann Arbor, on "Lower Urinary Tract Infections"; Dr. Brown, "Urogenic Heart Disease, Hyperthyroidism and Myxedema," and Dr. Warnshuis, "Head Injuries."

MISSISSIPPI

Reports Wanted for State Board File.—The Mississippi State Board of Health is interested in obtaining copies of the annual report for 1877 and the biennial report for 1886-1887, to complete the file since its organization in 1877. The board recently obtained the reports for the years 1890-1891 and 1894-1895, which had also been missing.

Society News.—Dr. Henry W. E. Walther, New Orleans, was guest speaker before the Pike County Medical Society in McComb, July 6, on "Transurethral Prostatic Resection."

At a meeting of the Issaquena-Sharkey-Warren Counties Medical Society in Vicksburg, June 13, the speakers were Drs. William P. Robert on "Preventing Diphtheria in Children"; Hiram C. Sheffield, Jackson, "Dementia Praecox," and Edley H. Jones, "Nasal Allergic Symptoms."

MISSOURI

Clinical Award.—The St. Louis Clinics is offering an annual award of \$100 and a certificate of award to the member of the St. Louis Medical Society who presents the best paper at meetings of the society during the year beginning January 1. The prize will be presented at the conference of the St. Louis Clinics in May, 1935.

Members Expelled.—Drs. Robert P. Miller and Eugene Carbaugh, Kansas City, were expelled from membership by the Jackson County Medical Society, June 27, for unprofessional conduct. According to the bulletin of the society, this action was taken on account of the physicians' alleged activities in connection with the Steuben Health Clinic and the Midwest Health Foundation, respectively.

Changes on Faculty at St. Louis University.—New appointments to the staff of St. Louis University School of Medicine, according to an announcement, June 21, include Drs. Julius H. Gross as assistant professor of ophthalmology; Jerome I. Simon, assistant professor of surgery, and Joseph L. Gross and Vincent J. LoPiccolo, assistant professors of medicine. Other changes on the faculty include promotion of the following physicians:

Eugene T. Senseney, professor of otolaryngology.
Samuel B. Westlake, associate professor of otolaryngology.
Alexander E. Horwitz, associate professor of orthopedic surgery.
Franklin H. Albrecht, associate professor of orthopedic surgery.
Fritz Neuhoff, associate professor of internal medicine.
Emmett P. North, assistant professor of ophthalmology.
Julius A. Rossen, assistant professor of pediatrics.
John W. Stewart, assistant professor of surgery.
Robert D. Alexander, assistant professor of surgery.
Eugene Lee Myers, assistant professor of otolaryngology.
Eugene Lee Shrader, assistant professor of internal medicine.

Dr. John Zahorsky was made director of the department of pediatrics; previously he had been chairman.

MONTANA

Spotted Fever.—Forty-five cases of Rocky Mountain spotted fever had been reported to the Montana state health department from various sections of the state, according to newspapers, June 17.

NEW YORK

Society News.—Dr. Nelson K. Fromm addressed the Medical Society of Albany County, June 28, on "Bilateral Cervical Rib," and Robert A. Robinson, D.D.S., showed a motion picture of operations for removal of impacted teeth and cyst of the superior maxilla. At the quarterly meeting of the Ontario County Medical Society, Geneva, July 11, Dr. George M. Gelsco, Rochester, discussed clinical aspects of trichomonas vaginalis and Dr. George W. O'Grady, Rochester, pathologic aspects.

Hospitals Adopt Uniform Dispensary Admission Plan.—Rochester hospitals and dispensaries have recently adopted a uniform plan for admission to the outpatient departments. All patients applying for treatment are first asked whether they have a family physician or have recently been under the care of a physician. If either question is answered affirmatively, the applicant is requested to return to the physician for a recommendation for admission. If the condition demands immediate attention, the admitting officer communicates with the physician by telephone. If the latter cannot be reached, the patient is admitted temporarily and a letter is sent to the physician asking his approval. An income table has been drawn up as a guide in determining eligibility for dispensary treatment. If an applicant is found ineligible and has no family physician to whom he may be referred, the hospital authorities recommend at least three members of the hospital staff. Patients who are able to afford services of a private practitioner and refuse to do so are to be denied admittance to the dispensaries. Every effort will be made to prevent "shopping," and patients will be transferred from one dispensary to another only on request of the referring dispensary. Other regulations concerned provision of drugs for both acute and chronic cases, surgical appliances and glasses, and cooperation with welfare agencies. A permanent joint committee representing the hospitals and the Medical Society of Monroe County was established, with Dr. Sol J. Appelbaum as chairman. To this committee will be referred all matters of common interest to hospitals, outpatient departments and dispensaries.

New York City

Changes at Columbia.—Dr. Bernard Sachs has been appointed professor of clinical neurology and Dr. Harry Aranow clinical professor of obstetrics at Columbia University College of Physicians and Surgeons. Dr. I. Ogden Woodruff has been promoted to professor of clinical medicine.

Changes at Rockefeller Institute.—Dr. Cornelius P. Rhoads has been promoted from associate to associate member of the Rockefeller Institute for Medical Research and Dr. Theodore J. Abernathy has been appointed resident physician at the institute's hospital. Lawrence R. Blinks, Ph.D., associate in the division of general physiology, has accepted an appointment as associate professor of plant physiology at Stanford University, Calif.

Dr. Albee Receives Bowdoin Prize.—Bowdoin College, Brunswick, Maine, has awarded to Dr. Fred H. Albee the first Bowdoin Prize for "the graduate of the college who has made the most distinctive contribution in any field of human endeavor." This prize was established as a memorial to William J. Curtis, a graduate of Bowdoin in 1875, to be awarded every five years. It is to be four fifths of the income from a fund of about \$20,000. Dr. Albee was graduated from Bowdoin in 1917.

Hospital News.—According to the annual report of the New York Post-Graduate Hospital for 1932, recently made public, the hospital has finished fifty years of service, during which time 263,951 patients were treated. In addition 1,599,022 persons were treated in the outpatient department and more than 29,000 physicians received graduate training in the half century. Dr. Roberto Alessandri, Rome, Italy, gave an address, June 19, at the New York Polyclinic Medical School and Hospital, on "Postoperative Peptic Ulcer."

NORTH CAROLINA

Society News.—Dr. Douglas Vanderhoof, Richmond, Va., was guest speaker at a meeting of the Sixth Council District of the Medical Society of North Carolina, June 15, in Wake Forest. Dr. Vanderhoof discussed "Chronic Duodenal Occlusion." Among other speakers were Drs. Harold L. Amoss, Durham, on "Serum Treatment of Hemolytic Streptococcal Pneumonia" and Adlai S. Oliver, Raleigh, "Obstetric Analgesia." Dr. Hubert B. Haywood, Raleigh, was elected president. The North Carolina Urological Association met in Greensboro recently with the following speakers: Drs. John H. Neff, University, Va., on "Renal Calculi"; Sidney S. Smith, Jr., Raleigh, "Renal Infections"; Robert W. McKay, Charlotte, "Aneurysm of Renal Artery"; Andrew J. Crowell, Charlotte, and Edwin P. Aylea, Durham, both on prostatic resection.

Pediatric Seminar.—The thirteenth Southern Pediatric Seminar will be held at Saluda, July 24-August 5. Clinical material is provided in two children's hospitals at Saluda. Dr. William A. Mulherin, Augusta, Ga., is dean of the course, Dr. Frank Howard Richardson, Black Mountain, vice dean, and Dr. D. Lesesne Smith, Saluda, registrar. Among the lecturers will be:

Dr. Lawrence T. Royster, University, Va.: Upper Respiratory Infections; Physical Examination; Celiac Disease.
Dr. William L. Funkhouser, Atlanta: Congenital Feeble-mindedness; Habit Formation; Vomiting as a Symptom.
Dr. Robert A. Strong, New Orleans: Convulsions.
Dr. William Weston, Columbia, S. C.: Fundamentals of Nutrition.
Dr. Willard C. Davison, Durham: Diarrhea; Kidney Diseases.
Dr. Horton R. Casparis, Nashville: Tuberculosis.
Dr. Philip F. Barbour, Louisville, Ky.: Heart Conditions in Children; Endocrines.
Dr. Kenneth M. Lynch, Charleston, S. C.: Pathologic Conferences.
Dr. Allen J. Jervy, Tryon: Surgical Conditions in Children.
Dr. Oliver W. Hill, Knoxville, Tenn.: Influenza: Its Complications and Sequelae; Intracranial Hemorrhage: Its Symptoms and Manifestations.

OHIO

Personal.—Dr. Robert N. Wright has been appointed physician to Wooster College at Wooster, succeeding Dr. Herbert A. Wildman, who will enter private practice in Michigan. Dr. George D. Lowry has resigned as physician to Ohio Wesleyan University, Delaware, to enter private practice. Dr. Carey P. McCord, Cincinnati, received the honorary degree of doctor of laws, May 30, from Howard College, Birmingham, Ala., in recognition of his services in reducing the occupational hazards in the life of industrial workers. Dr. Myron D. Miller, assistant superintendent of Franklin County Tuberculosis Sanatorium, Columbus, for four years, has been made superintendent to succeed the late Dr. Charles O. Probst. Dr. Emerson M. Blake, Columbus, received a provisional appointment as assistant superintendent, subject to approval by the state civil service commission. Dr. Claud C. Burton of the staff of the Veterans' Administration Hospital, Lexington, Ky., has been appointed director of surgery at the National Military Home near Dayton, succeeding the late Dr. Samuel

B. Woodward.—Dr. Donald E. Yochem, Columbus, has been appointed superintendent of the Licking County Tuberculosis Sanatorium, Newark, to succeed Dr. Homer M. Austin.—Dr. William H. Carey, Bellefontaine, recently resigned as health officer of Logan County, after thirteen years' service; he was succeeded by Dr. Lee E. Traul, Middleburg.

PENNSYLVANIA

Increase in Tuberculosis.—More cases of tuberculosis were reported in Pennsylvania for 1932 than for the two previous years. The number of cases was 7,805, but the death rate of 54.6 per hundred thousand of population, representing 5,364 deaths, was the lowest in the history of the state. About two thirds of those who died were under 45 years of age.

Personal.—The Parent-Teacher Association of Brentwood High School gave a banquet, May 19, in honor of Dr. William H. Goodpaster, who was for sixteen years president of the school board and who is still school physician.—Dr. Mary M. Wolfe, superintendent of Laurelton State Village, received an honorary degree at the annual commencement of Bucknell University, Lewisburg.—The Cambria County Medical Society gave a testimonial dinner in honor of Dr. Daniel S. Rice, Ebensburg, observing his completion of fifty years in practice, July 13, at the regular meeting at the Chetremont Country Club near Cherry Tree. Dr. Jesse Lynn Mahaffey, state health officer of New Jersey, Trenton, was the guest speaker.

Philadelphia

Hospital News.—The new tuberculosis unit of Philadelphia General Hospital, finished but unused for sixteen months, was opened for patients, June 12. Ninety men from the old male tuberculosis unit were moved in immediately and it was expected that 130 women patients would be moved by the end of June.

Personal.—Yale University conferred the degree of doctor of science on Alfred Newton Richards, Sc.D., professor of pharmacology, University of Pennsylvania School of Medicine, at its recent convocation.—Dr. Thomas A. O'Brien received the honorary degree of doctor of laws at the annual commencement of Villanova College, Villanova, June 8.—Dr. Mary M. Spears was recently elected the first woman member of the American Proctologic Society. She is clinical professor of gastro-enterology at the Woman's Medical College of Pennsylvania.

TENNESSEE

Health at Memphis.—Telegraphic reports to the U. S. Department of Commerce from eighty-five cities with a total population of 37 million, for the week ended July 8, indicate that the highest mortality rate (19) appears for Memphis and the rate for the group of cities as a whole, 9.6. The mortality rate for Memphis for the corresponding period last year was 20 and for the group of cities, 9.7. The annual rate for eighty-five cities for the twenty-seven weeks of 1933 was 11.5, as compared with a rate of 11.9 for the corresponding period of 1932. Caution should be used in the interpretation of weekly figures, as they fluctuate widely. The fact that some cities are hospital centers for large areas outside the city limits or that they have a large Negro population may tend to increase the death rate.

VIRGINIA

Society News.—Dr. James Edwin Wood, Jr., University, addressed the Rockingham County Medical Society, May 15, on digitalis.—Dr. Lawrence T. Royster, University, addressed the Norfolk County Medical Society, Norfolk, May 29, on "Rheumatism and the Rheumatic Heart in Children."—At the semiannual meeting of the Northern Neck Medical Association at Heathsville, May 25, speakers included four Richmond physicians: Drs. John Shelton Horsley, Jr., "Sieve Graft"; Frank S. Johns, "Extra-Uterine Pregnancy"; William Wallace Gill, "Ocular Headaches," and Thomas E. Hughes, "Bronchoscopy and Esophagoscopy."—Dr. Frank R. Hopkins, Lynchburg, addressed the Lynchburg Academy of Medicine, June 5, on "Diabetes in Childhood."—Among speakers at a meeting of the Roanoke Academy of Medicine, June 5, were Drs. Frank Helvestine, Jr., on "Consecutive Perforations of Stomach by Peptic Ulcer" and William B. Huff, "Schiller's Lugol Test as an Aid to the Early Diagnosis of Cervical Cancer."—Dr. Marvin Pierce Rucker, Richmond, addressed the Medical Association of the Valley of Virginia, May 25, on "Painless Childbirth."—Dr. John B. Fisher, Midlothian, was elected president of the Alumni Association of the Medical College of Virginia at the recent annual meeting.—At the quarterly meeting of the Southside Virginia Medical Association in LaCrosse, June 13, the following speakers presented a

symposium on diseases of the kidneys: Drs. Kinloch Nelson and Algernon S. Hurt, Jr., Richmond; Allen Barker and Herbert C. Jones, Petersburg, and William T. Gay, Suffolk.

WASHINGTON

Society News.—The King County Medical Society held a special meeting in Seattle, June 15, to hear an address by Dr. George H. Whipple, Rochester, N. Y., on "Anemia, Liver Function and Hemoglobin Production."—The Seattle Academy of Surgery held its annual meeting at Harborview Hospital, July 12-13, with Drs. William Boyd, professor of pathology, University of Manitoba Faculty of Medicine, Winnipeg, and Alfred T. Bazin, professor of surgery, McGill University Faculty of Medicine, Montreal, as guests. Dr. Boyd discussed interstitial tumors of bone and Dr. Bazin, embryologic development of the umbilicus and urachus.

WISCONSIN

Dr. Miloslavich Goes to Yugoslavia.—Dr. Edward L. Miloslavich, formerly professor of pathology and bacteriology, Marquette University School of Medicine, Milwaukee, has accepted an appointment as director of the Medical College Institute at the Royal University, Zagreb, Yugoslavia, and will soon leave for the new position. Dr. Miloslavich was professor of pathologic anatomy at the University of Vienna, Austria, before coming to the United States.

WYOMING

Spotted Fever.—Seventy-four cases of Rocky Mountain spotted fever had been reported to the state department of health of Wyoming for the season up to June 28. Ten deaths had occurred.

GENERAL

License Lost.—The California State Board of Medical Examiners announced, June 23, that the license of Dr. Shelby P. Phipps Strange, San Francisco, had been reported lost. The license was issued to Dr. Strange, a graduate of Cooper Medical College, Aug. 28, 1912.

Journal of Pharmacology Transferred to Society.—At the annual meeting of the American Society for Pharmacology and Experimental Therapeutics in Cincinnati in April, Dr. John J. Abel, Baltimore, founder and editor of the *Journal of Pharmacology and Experimental Therapeutics* for twenty-four years, transferred the journal to the society as its official organ. With Carl Voegtlin, Ph.D., Washington, D. C., and Dr. Reid Hunt, professor of pharmacology, Harvard University Medical School, Boston, Dr. Abel formed the original corporation which sponsored the journal. Dr. William deB. MacNider, professor of pharmacology, University of North Carolina Medical School, Chapel Hill, was elected president of the society; Arthur L. Tatum, Madison, Wis., vice president, and Dr. Velyien E. Henderson, Toronto, secretary.

Special Board Examinations in Dermatology.—The American Board of Dermatology and Syphilology will hold written examinations for physicians who have limited their practice to this branch of medicine for at least five years (group B), Saturday, October 28, in New York, St. Louis, Boston, Cleveland, San Francisco, Philadelphia and Chicago. Applicants are required to submit at this time typewritten reports of ten cases personally observed, preferably in private practice. Oral examinations for both group A (physicians who have limited their practice for at least ten years) and group B will be held in New York, December 15 and 16. All who expect to take the examinations in either group must send their applications and credentials to the office of the secretary before September 1. Application blanks and further information may be obtained from the secretary, Dr. C. Guy Lane, 416 Marlborough Street, Boston.

Resolutions of Catholic Hospital Association.—Warning that all plans for financial remuneration to hospitals or to the medical and nursing profession should be considered first for the effect they might have on the medical service rendered by the institutions was contained in a resolution adopted at the closing meeting of the Catholic Hospital Association of the United States and Canada in St. Louis, June 16. The resolution declared that although medical and hospital economics are urgent they cannot be considered dominant and the problems arising from them must be solved with relation to their significance to the central problem: the provision of effective medical care to the patient. Another resolution adopted at the same time declares the adherence of the association to the principle enunciated by the pope that "birth control is an offense against the law of God and of nature" and that therefore hos-

pitals of the association will tolerate no practices contrary to this principle. In a third resolution the association stated its belief that care of the indigent is not solely a governmental responsibility.

Warning Against Impostor.—A Wyoming physician has reported to THE JOURNAL that a man using the name "D. P. Gordon" is preying on physicians in Colorado and Wyoming, claiming to represent a "Ukiah Grape Products Company" of New York. He is said to be in Wyoming at present, having already "visited" many physicians and dentists in Colorado. He is reported to be about 58 years old, well dressed, of heavy build, and to have a pleasing personality. The supervisor of permits of the Bureau of Industrial Alcohol in Denver reports that the Colorado State Medical Society and officers of the law are looking for the man and that as far as is known there is no such firm as the Ukiah Grape Products Company. In THE JOURNAL, Sept. 3, 1932, warning was published of a man posing as a salesman in Michigan for this firm. The physician reporting at that time explained that the alleged salesman declined to have the usual official papers made out, saying that his firm saved the customer that trouble. When the victim did not receive his order, he wrote to the firm but his letter came back marked "Removed—left no address."

Radio Talks.—The American Public Health Association is sponsoring a series of weekly health broadcasts over the "national farm and home network" of the National Broadcasting Company. The series is under the direction of a committee of the association appointed at the last annual convention in Washington, D. C., consisting of Drs. John A. Ferrell, Haven Emerson and Kendall Emerson, New York; Fred O. Tonney, Chicago, and Louis I. Dublin, Ph.D., New York. All statements used in the talks, which will be given under the general title "A Nation's Investment in Health," will be censored by the committee. Future speakers and subjects are as follows:

July 26, Dr. Kendall Emerson, The Political Health Conscience.
August 2, Dr. Charles E. North, New York, Milk Supplies.
August 9, George T. Palmer, Dr.P.H., New York, Safeguarding Child Life.
August 23, Dr. George H. Ramsey, New York, Epidemiology.
August 30, Dr. Fred O. Tonney, Laboratories and Research.
September 6, Dr. Lawrason Brown, Saranac Lake, N. Y., Tuberculosis.
September 13, Louis I. Dublin, Ph.D., Health Statistics.
September 27, Dr. Alfred F. Hess, New York, Safeguarding Infant Life.
October 4, Charles-Edward A. Winslow, Dr.P.H., New Haven, Conn., Costs and Results.

Broadcasts have already been presented by Dr. Tonney, on "The Health Budget"; Dr. Herman N. Bundesen, Chicago, "Sane Curtailment of Health Budgets" and George W. Fuller, New York, "Water Supplies and Health." Suggestions for subjects of further broadcasts are solicited from physicians and the public. They should be addressed to the American Public Health Association, 450 Seventh Avenue, New York.

Contaminated Milk Responsible for Thirty Epidemics.—Contaminated milk caused thirty epidemics in 1932, according to the annual report of Dr. Samuel J. Crumline, New York, field secretary, presented before the annual meeting of the Conference of State and Provincial Health Authorities of North America in Washington, D. C., June 5-6. In addition, two epidemics were traced to ice cream and one to cheese. Raw milk was the source of the infection in twenty-eight outbreaks. In one traced to ice cream, the owner of the store where it was sold had had typhoid fever twenty-five years previously and had a history of gallbladder infection, while, in the cheese epidemic, the milk used for the cheese had not been pasteurized. Four fewer epidemics occurred in 1932 than in 1931 and 353 fewer cases of sickness. Thirty-nine deaths from the typhoid epidemic caused by contaminated cheese were responsible for an increased number of deaths. For the second time in recent years there was no milk-borne epidemic of diphtheria in 1932. Fourteen epidemics were traced to carriers, fourteen to a case of sickness on dairy premises, one to infection from bottles and equipments and one to infection from a dairy water supply. The source of three epidemics was reported unknown. Although most of the outbreaks happened in the summer months, eight occurred in September. No epidemic was reported for November, repeating the record of 1931. The distribution of epidemics by community population showed that 48.5 per cent occurred in towns or rural communities of less than 2,500 population, indicating that an increasing proportion of milk-borne epidemics are in the smaller cities and rural communities which lack effective milk supervision and control, and where pasteurized milk is not generally available. These figures were based on fifty-nine reports received from all the provinces of Canada, all but two states, the District of Columbia and all the territorial possessions but two.

Society News.—The American Association of School Physicians will meet in affiliation with the American Public Health Association in Indianapolis, October 9-12.—Dr. Frederick H. Lamb, Davenport, Iowa, was chosen president-elect of the American Society of Clinical Pathologists at the recent annual meeting in Milwaukee. Dr. Alvin G. Foord, Pasadena, Calif., was installed as president; Dr. John J. Seelman, Milwaukee, elected vice president, and Dr. Alfred S. Giordano, South Bend, Ind., reelected secretary. Cleveland was chosen for the place of the next annual meeting.—The western branch of the American Urological Association will hold its ninth annual meeting in Vancouver, B. C., August 3-5. Guest speakers will include Drs. Hermon C. Bumpus, Jr., Rochester, Minn., on "Preoperative Preparation and the Postoperative Care in Cases of Prostatic Resection"; Winfield Scott Pugh, New York, "Electrosurgery: Its Application to Urinary Pathology," and Guy L. Hunner, Baltimore, "Calculus of the Upper Urinary Tract."—The tenth annual meeting of the Association of New York Central Lines Surgeons was held in Chicago, June 19-20. Drs. Gilbert FitzPatrick, Karl A. Meyer and Max Cutler presented a symposium on cancer and other speakers included Drs. George W. Hall, Chicago, on "Diagnosis of Head Injuries Without Skull Fracture"; Dean Lewis, Baltimore, President, American Medical Association, "Injuries of the Soft Parts"; Philip H. Kreuscher, Chicago, "Injuries to the Knee Joint." Dr. Morris Fishbein, Chicago, editor of THE JOURNAL, gave an address following the annual dinner.—The annual meeting of the Acro Medical Association of the United States will be held in Chicago, September 2-4, at the Palmer House, under the presidency of Dr. Frederick C. Warnshuis, Grand Rapids, Mich. Dr. David S. Brachman, Detroit, is secretary.—The National Medical Association will hold its annual convention in Chicago, August 13-14. Among speakers will be Drs. William H. Walsh, Chicago, on "Group Purchase of Hospital Service" and Rosco G. Leland, Chicago, "The Insurance Principles in Medical and Hospital Practice."—Dr. William W. Bauer, director, Bureau of Health and Public Instruction, American Medical Association, addressed the National Education Association, Chicago, July 5, on "School and Home Cooperation for the Health and Protection of Children."—The American Congress of Radiology, including meetings of the Radiological Society of North America, the American Roentgen Ray Society, the American Radium Society and the American College of Radiology, will be held in Chicago at the Palmer House, September 25-30.

FOREIGN

Personal.—Sir Charles Arthur Kinahan Ball, Dublin, has been appointed regius professor of surgery at the University of Dublin in succession to the late Sir William Taylor.—Dr. Ivan de Burgh Daly, professor of physiology, University of Birmingham, will succeed Sir Edward Sharpey-Schäfer on his retirement from the chair of physiology at the University of Edinburgh in September.

German Physicians Asked to Resign.—It is reported that the following instructors have been asked to resign from the Medizinische Akademie in Düsseldorf: Professor Boden, ordinarius and director of the medical polyclinic; Professor Ellinger, director of the pharmacologic institute; Professor Meyer, extraordinarius, and Privat-dozent Dr. Neustadt. The University of Greifswald (Germany), one of the oldest in existence, has been rechristened the Ernst Moritz Arndt University.

International Goiter Conference.—The third International Conference on Goiter will be held in Bern, Switzerland, August 10-12. American physicians who will take part are Drs. Henry S. Plummer, Rochester, Minn., who will speak on "Pathogenesis of Basedow's Disease"; Richard B. Cattell, Boston, "Iodine Treatment of Basedow's Disease" and Albert G. Webster, Baltimore, who will discuss new studies on the etiology of endemic goiter. Drs. Edwin P. Sloan, Bloomington, Ill., and Charles H. Arnold, Lincoln, Neb., are official delegates of the American Medical Association to the conference.

Dixon Memorial Lecture.—Colleagues and friends of the late Prof. W. E. Dixon, leading British pharmacologist who died in 1931, have accumulated a fund of £695 which is to be used to found a lectureship in his memory, it was decided at a meeting at the Royal Society of Medicine, June 1. The lecture will be delivered biennially or triennially on some subject of pharmacologic or therapeutic interest under the trusteeship of the Royal Society of Medicine. Professor Dixon was for many years associated with Cambridge University, where he is said to have made the school of pharmacy famous both by his own research and that of his students. He was joint editor of the *Journal of Pharmacology and Experimental Therapeutics* and was the author of a textbook in pharmacology as well as of many articles.

Government Services

Memorial to Colonel Bruns

A portrait of the late Col. Earl H. Bruns, U. S. Army Medical Corps, will be placed in an army tuberculosis hospital as a memorial, according to a recent announcement. Colonel Bruns, who died early this year, was for many years one of the leaders in tuberculosis work in the army. It is expected that the portrait will hang in some room or building to be named in his honor. Subscriptions for the memorial should be mailed to the secretary of the Denver Sanatorium Association, Dr. Arnold Minning, Republic Building, Denver.

Funds of Public Health Service Reduced

Expenditures of the U. S. Public Health Service for the fiscal year which began July 1 will be reduced from \$10,380,328 originally appropriated by Congress to \$7,860,000 by order of the Bureau of the Budget. Essential activities of the service will be maintained, although some will be curtailed. Of 376 commissioned medical officers, twenty-one were placed on the retired list, three discharged and one resigned. Quarantine and immigration activities in foreign countries have been reduced with the discharge of ten American physicians stationed outside the United States. Those who remained suffered reductions in compensation, as did most of the 700 acting assistant surgeons on part time service within the country. The appropriation for twenty-six marine hospitals and about twenty field relief stations was reduced from \$5,600,000 to \$4,420,000, a reduction partly met by economies in operation. Financial aid to county health units in twenty-eight states will be discontinued. Some of the units will be maintained by the counties and states, but many will probably be abandoned. Funds of the division of scientific research were cut 50 per cent, a reduction that was taken up in operation economies. Payless furloughs of two days a month will meet a similar cut in the maritime quarantine division. The division of mental hygiene will delay for one month the opening of service in new institutions in Detroit, Springfield, Mo., and Oklahoma. Altogether thirteen employees were discontinued in the Washington office, 650 at field stations and 310 engaged in rural sanitation. Twenty-five were placed on indefinite furlough and 1,500 others will take five days off without pay each month.

U. S. Public Health Service

Acting Asst. Surg. John P. Mayer, relieved at Pittsburgh and assigned to duty at the Marine Hospital, Seattle.

Passed Asst. Surg. William H. Sebrell, Jr., directed to assume charge of the office of nutrition investigations under the direction of the chief of the division of scientific research.

Surg. Estella Ford Warner, directed to assume charge of the office of child hygiene investigations, under the direction of the chief of the division of scientific research.

Passed Asst. Surg. (R) Henry H. Duke, relieved at Norfolk, Va., and assigned to duty at the Marine Hospital, New York.

Asst. Surg. Charles W. Folsom, relieved at Washington, D. C., and assigned to duty at Atlanta, Ga.

Medical Intern Jay E. Houlihan, relieved at Stapleton, N. Y., and assigned to Marine Hospital, Buffalo.

Medical Intern Floyd A. Hawk, relieved at Chicago, and assigned to duty at the U. S. Penitentiary Annex, Fort Leavenworth, Kansas.

Medical Intern Charles S. Sample, relieved at New Orleans, and assigned at the U. S. Penitentiary Annex, Fort Leavenworth, Kansas.

Medical Intern Edgar W. Moreland, relieved at Chicago and assigned at the U. S. Industrial Reformatory, Chillicothe, Ohio.

Medical Director Gustave M. Corput, relieved at Montreal, Canada, and assigned at San Diego.

Sr. Surg. George Parcher, relieved at Stapleton and assigned to duty at Bangor, Maine.

Acting Asst. Surg. George Hess, relieved at Chillicothe, and assigned at the U. S. Penitentiary, Atlanta.

Medical Intern Robert E. Blount, relieved at New Orleans, and assigned at the Marine Hospital, Galveston, Texas.

Medical Director French Simpson, relieved at Naples, Italy, and assigned at Fort Monroe, Va., in charge of the quarantine station at that place.

Surg. Walter G. Nelson, relieved at New York, and assigned at Ellis Island, New York.

Surg. Carl Ramus, relieved at East Boston, Mass., and assigned at Marine Hospital, New York.

Dr. George L. Cristy, placed on inactive status as passed assistant surgeon in the reserve corps, effective August 31.

Passed Asst. Surg. Eddie M. Gordon, Jr., relieved at Winnipeg, Canada, and assigned at Quarantine Station, Angel Island, Calif.

Asst. Surg. Roscoe C. Kash, relieved at Angel Island and directed to proceed to Nashville, Tenn., to establish headquarters.

Medical Director Samuel B. Grubbs, relieved at Honolulu, T. H., and assigned at Ellis Island, N. Y.

Asst. Surg. Waldemar J. A. Wickman, relieved at Pittsburgh, and assigned at Marine Hospital, Boston.

Asst. Surg. W. W. W. relieved at Boston, and assigned at Marine Hospital, New York.

Ewing Taylor, placed on inactive status as surgeon in reserve corps.

Paul J. Leechy, placed on inactive status as assistant surgeon.

Foreign Letters

LONDON

(From Our Regular Correspondent)

July 1, 1933.

The British Pharmacopeia

At a meeting of the General Medical Council, Sir Henry Dale, chairman of the Pharmacopeia Committee, reported that the total number of copies of the new edition sold was just under 30,000. It was recommended that, to meet a difficulty among manufacturing chemists and pharmacists arising from the fact that the date of publication of the new issue was also the date on which alterations became operative, the Council should approach the government with view to the introduction of a bill into parliament to enable the council to fix a date subsequent to the date of publication when the Pharmacopeia should go into effect. The experience of the Pharmacopeia Committee during the past four years has shown the importance of continuous work between the issue of each pharmacopeia and its successor. It has therefore been decided that, when the new commission takes office, provision shall be made for collecting scientific and technical literature, preparing and publishing preliminary reports, the issue of addenda, and the investigation of pharmaceutical and medical problems. It is considered that in the preparation of the next pharmacopeia the most numerous and important changes in the group of substances requiring standardization by biologic methods will be concerned with the serums and bacteriologic remedies. Dr. Percival Hartley has been appointed on the commission because of his direct knowledge of these.

The British Medical Association and Compulsory Vaccination

The council of the British Medical Association has made a recommendation with regard to vaccination which is a new departure in the profession's attitude. Medical opinion has always been in favor of compulsory vaccination. In 1923 the representative meeting of the association restated the official policy and practically universal conviction of the medical profession that vaccination in early infancy, repeated after such intervals as may be deemed necessary, is the only preventive of smallpox. Owing to the enormous number of unvaccinated persons, it recognized the danger of a pandemic and urged the government to take the necessary measures to avert this peril. In 1905 the percentage of vaccinations to births was 75.8. The percentage has continually diminished, until it was only 42.6 in 1928. The English have always been great individualists and resented interference with the liberty of the individual, in his religion or mode of life, more than any other people in the world. This they have carried to such an extent as to exempt the children of "conscientious objectors" from vaccination, although the consensus of expert opinion was that this was dangerous to the community. In the last report of the council of the British Medical Association there is mentioned the opinion, expressed in some quarters, that the diminution of vaccination is partly due to the compulsory nature of the present system (a declaration of conscientious objection is necessary for exemption) and that this might be replaced by a more satisfactory condition if vaccination were only voluntary. It is also pointed out that the mild type of smallpox that has prevailed in recent years has lessened the inducement to obtain the protection of vaccination. It has also been shown that vaccination is not entirely free from the subsequent danger of encephalitis. Careful consideration of these facts and of the suggestion that voluntary vaccination, encouraged by the propaganda of the local authorities, might achieve a higher proportion of vaccination than compulsory vaccination now obtains, had led the council to submit the following resolution: "That the

British Medical Association, while reaffirming its belief in the efficacy of vaccination in conferring immunity against smallpox, is of opinion that the time has arrived when the question whether greater protection against smallpox would be afforded by voluntary rather than by compulsory vaccination should be considered." This change of attitude has attracted considerable notice in the press.

Sir Walter Fletcher: An Organizer of Medical Research

Sir Walter Fletcher, F.R.S., secretary of the Medical Research Council, has died at the age of 59, after an operation. Born at Liverpool, he was educated at Trinity College, Cambridge, and graduated in 1894 with honors in the natural science tripos, taking physiology as one of his subjects. He became a demonstrator in the physiologic laboratories of the university. He made important researches into the chemistry of muscular contraction—oxygen supply, osmotic properties of muscle, significance of the lactic acid, and the association of heat rigor with intramolecular oxygen. From 1904 to 1914 he was tutor at Trinity. In 1914 he was appointed secretary of the Medical Research Committee, a new body formed to promote medical research and financed by funds provided by the national insurance act. The outbreak of the Great War diverted its activities to medical problems, which then arose. After the war the committee was reconstituted as the Medical Research Council. The numerous and important researches directed by the council are known all over the world. Dietetics and the deficiency diseases are some of the subjects in which knowledge has been materially advanced. In the direction of these researches, Fletcher, as permanent secretary of a constantly changing Council, played the most important part. He became known wherever medical research is in progress as a great organizer. In 1928 he went to India as chairman of the Committee on the Organization of Medical Research under the Government of India.

A New Portable X-Ray Unit

A demonstration has been given of a new mobile x-ray unit that has been added to the equipment of the ambulance service of the British Red Cross Society. Radiologic examination of a patient too ill to be moved from his home has presented serious difficulties. In recent years "portable" apparatus has been available, but with definite limitations. It is claimed for the new unit, which is at the disposal of physicians for reasonable charges, that it is capable of producing as good a result as can be obtained in a fully equipped hospital department. The outfit is housed in a neat automobile. Generator, switch boards and controls are in front of the car, and the interior is fitted with specially constructed developing tanks. The equipment includes broad and fine focus tubes, Potter-Bucky diaphragm, a folding couch and a universal tube stand. A special feature is an ingenious system of electrical regulation, which overcomes the distortion unavoidable when using a small portable apparatus connected to the ordinary house current. It is possible to obtain fully exposed roentgenograms of the chest in one-fortieth second or of the stomach in one second. Arrangements have been made for the submission of the films taken by the service, with the physician's history of the case, to a member of the British Institute of Radiology or to a radiologist selected by the physician, whose considered opinion is sent with the roentgenogram to the physician.

The Hardships of Physicians in Distressed Areas

In some industrial areas in England, as much as 80 per cent of the population is out of work and is likely to continue so for some time. In some of these areas the majority of the workers have been in the habit of arranging for medical attendance for their wives and families under some contract system. Medical attendance for the workers themselves is provided by

the national health insurance system. A correspondent of the *British Medical Journal* points out that when in steady employment these workers are good payers and receive medical attention for a contract payment of about 12 cents per week, generally deducted from the weekly pay by arrangement with the employer. Generations of workers have never known the need to pay a physician's bill. Now that the men are unemployed, the physicians in the distressed areas find it almost impossible to collect their levies. If they refuse to continue attendance, there is the risk that relatives and friends of the patients who come under the insurance system will go to more "sympathetic" physicians. The position of the physicians is serious and may become more serious, for the unemployed may run out of insurance benefit in time and this mainstay also may give way.

A Criticism of the Health Insurance System

At the Sanitary Congress, Dr. G. H. Pearce, health officer of Batley, Yorkshire, delivered his presidential address, in which he criticized the national insurance system. He said: "A large proportion of the medicine dispensed today under this system is both useless and unnecessary and an entire waste of money. Unfortunately, the patient does not believe this and insists on having his bottle. The general practitioner who tells the majority of his patients that they do not need medicine will soon require much smaller consulting rooms." It will be noticed that this condemnation extends beyond the insurance system to medical practice in general. The English working class has, in the words of the late Sir Frederick Treves, "a craving for bottles of medicine which is second only to the craving for strong drink." However, in the case of insurance practice the evil is intensified, for the craving can be indulged in without any additional payment, while in private practice it costs something.

The French Assembly of General Medicine

The *Assemblée française de médecine générale* brings together the modest practitioners of the rural districts and the masters of science in the large cities. The recent sixth session of the assembly devoted itself to the prevention of tetanus. The question has a wide interest at present. A court had imposed a severe penalty on a physician, after the death of a patient from tetanus, because he had not given an injection of antitetanus serum immediately after the injury. The whole medical profession protested against the decision, for it appeared to indicate that every injury, no matter how trivial, should be followed by an injection of serum. The evidence collected by the practitioners in the provinces revealed that there are regions of France free from tetanus—the large cities, for example, and the mining regions. There are regions that have a bad reputation for tetanus, these being universally known to local physicians. Tetanus in general has been less frequent since the war, a fact probably due to the increasing substitution of motor vehicles for horses. In the industries it is rare. In the rubber industry, for example, in 33,612 injuries (340 more or less serious) in which 710 injections were given there was not a single case of tetanus. In the mines, in 75,000 injuries only one case of tetanus developed. The very minor injuries, many of them unobserved, which receive no treatment, appear to expose the subject much more to tetanus than do the more important injuries, which require extensive dressings. It appears certain that there are subjects who have a natural immunity. But such immunity is lost in course of time. A discussion arose concerning the value of preventive serotherapy. The efficacy of such treatment was unanimously accepted. The new antitetanus anatoxin of Ramon has a potency ten times that of the serum heretofore used. Three injections at intervals of three weeks appear to confer

an immunity, and research on guinea-pigs appears to indicate that it lasts four or five years. The assembly took up also serum accidents, which seem to have become more frequent than before the war, especially the cases of persistent paralysis. It appears that an increased sensitiveness to the serum is gradually developing among the people, as is the case with respect to diphtheria. M. Bourguignon, who has had a long experience in the Hôpital de la Salpêtrière, said that the localization of the paralysis in the various muscles is determined by their weakest chronaxia. He cited the case of a family all the members of which, after an injection of antitetanus or antidiphtheria serum, developed paralysis affecting the same groups of muscles in all cases. One of the members, a physician, had given himself an injection of serum for a suspected sore throat, which was found afterward to be nondiphtheritic. The paralysis was due therefore solely to the serum. Mr. Alajouanine presented a paper on postserum paralysis. Some facts remain obscure; for example, the predilection for the right side, whereas the chronaxia is weaker on the left side. The note taken with regard to injections of antitetanus serum after injuries led to the following conclusions, which the assembly unanimously adopted: No absolute rule can be formulated. The practitioner remains the sole arbiter of his conduct in each case, and no court may hold him responsible if a case of tetanus develops, provided the physician, utilizing his experience and his knowledge, acted according to his conscience. It is evident that serum should be injected, in all cases of suspected wounds, in a milieu known to be infected. But, in view of the fact that untoward manifestations caused by the serum may be serious, it would be unjust to make every person who has an insignificant injury, not contaminated by soil or dust, and in a milieu in which tetanus is unknown, incur the risks of an injection of serum. The injured person may, furthermore, refuse to accept an injection. In that case, it is best for the physician to ask the patient to give him a written refusal, in order to protect himself before the courts in case of untoward developments.

The Congress of Legal Medicine

The annual French Congress of Legal Medicine was held, at the Institut médico-legal de Paris, May 24, under the chairmanship of Professor Balthazard. Professor Chavigny of Strasbourg spoke on the use of microbic cultures by belligerents in time of war, a use that the League of Nations has formally disapproved, although admitting that there is no means of preventing such use. Mr. Mazel of Lyons, who discussed posttraumatic delirium tremens, brought out that an attack of delirium tremens, possibly fatal, was not necessarily, when it followed a traumatism, the result of the latter. The legal responsibility for a traumatism was often difficult to prove before a court, the traumatism having usually but little importance. Mr. Etienne Martin of Lyons, taking up the discussion, observed that often at necropsy, after such accidents, one discovers an unexpected pneumonia, which is the true cause of death and which is entirely independent of the traumatism. A discussion arose between Messieurs Balthazard, Charpentier and Genil-Perrin as to whether delirium tremens constitutes a morbid entity of toxic origin. Professor Claude discussed "Psychopaths at Liberty," a subject which includes the delicate question of the proper adjustment between the rights of the harmless psychopath and the need of protecting society against the possible harmful acts of psychopaths. Professor Claude's thesis may be epitomized thus: dissemination among the public of the idea that many psychopathies are curable by appropriate treatment; increase in the number of centers for the detection and prevention of mental diseases, open to all comers at the hospitals; reservation of the hospitals of internment for subjects who are dangerous or incurable; organization of domiciliary treatment for other psychopaths, by a special personnel furnished by the hospital; compulsory notification of all subjects who are dangerous, who should be required

to appear before an examining board comprising a magistrate and a psychiatrist. The board should reach an immediate decision in regard to their disposition. Mr. Toulouse proposed the creation of centers of prophylaxis in the large cities, patterned after that in the Hôpital Henri-Rousselle in Paris, of which he is the director. Mr. Wervaerck described the new Belgian organization, which provides for the treatment of harmless psychopaths at liberty. During the past three years, the medico-judicial commissions have authorized the dismissal from the asylums of 252 patients out of 600 and have observed only five recurrences necessitating reinternment.

The Sanatorium for Students

The sanatorium established by the Union nationale des étudiants has been opened. The institution was begun eight years ago but its completion was retarded by financial difficulties. With an appropriation granted by the minister of public health, the sanatorium was finally completed. It is located in the mountains at Saint-Hilaire-du-Touvet, in the Dauphiné, on the plateau des Petites-Roches. Two other private sanatoriums, that of the Union métallurgique et minière and that of the department of the Rhone, are located in the vicinity. The new sanatorium consists of two buildings, one for women students and one for men students. The total number of beds is 150. The organizers believe that the patients, although for the time being taken away from their studies, should remain in contact with the university and intellectual life.

June 12, 1933.

Eugenics in Germany

In the newly established Reichsministerium für Volksaufklärung und Propaganda, a discussion developed in regard to the essentials for the future journalistic treatment of medical problems. Ministerialrat Conti, M.D., of the medical department of the Prussian ministry of the interior, brought out that one of the first duties of practical eugenics is to support the family idea in every conceivable manner. All scornful remarks, and jokes about the men who are heads of large families of children, should be omitted. Every opportunity should be taken to call attention to the fact that nearly every man who has become prominent in public life sprang from a large family. He emphasized further that the fear of Germany becoming overpopulated is unfounded. Commercialized abortion must be sternly suppressed.

The constantly declining birth rate, the impairment of families with absolutely healthy antecedents, and the frequent mingling of races and degeneration of the German family demand the closest consideration of the federal government, that such development may be checked and the German population be thus preserved. To secure aid in the elaboration of these measures, the minister of the interior has abolished the "federal commission for the consideration of demographic problems" and has summoned an "expert council for social and eugenic problems."

The *Deutsche Korrespondenz für Gesundheitswesen und Sozialversicherung*, previously published by the medical syndicates, is to be discontinued. In its place, the newly established Aufklärungsamt für Bevölkerungspolitik und Rassenpflege is planning to publish *Korrespondenz für Volksaufklärung und Rassenpflege*, which will contain material on all questions pertaining to the theory of hereditary transmission and the promotion of racial welfare. Also *Das Hörrohr*, which was often found in the waiting rooms of physicians, is to be discontinued and will be replaced by "*Neues Volk*," organ of the bureau for the promotion of population and racial welfare.

At the request of the special commissar for the public health service in the Free State Saxony, a department of the science of heredity and promotion of population and racial welfare will be organized in the Akademie für ärztliche Fortbildung in

Dresden. Three or four day courses are being considered, which all physicians of Saxony will be required to attend.

In Dortmund, a bureau of racial hygiene for the benefit of the city administration has been organized under the direction of a physician. Its first task will be to complete, from the standpoint of race hygiene, the collection of statistical data on the 80,000 school children. In this connection, the representative of the Bavarian ministry of justice gave, at the Congress of the Criminobiologic Society in Hamburg, June 7-10, an outline of a program for the protection of the state against inferior types of humanity. He emphasized that every German should be examined as to his biologic worth and, on the basis of the results, should be assigned to a corresponding position. Those who, on the basis of their hereditary aptitudes, could claim no assignment should be eliminated. Also criminobiologic science should from now on place itself at the disposal of the people's cause, and its exponents should be collaborators in the great movement for the regeneration of the people. It is their sacred duty, in the future, to afford the state protection against being overwhelmed by inferior types.

It is also significant that one of the most important addresses at this year's session of the Kaiser-Wilhelm-Gesellschaft zur Förderung der Wissenschaften was devoted to prognosis as to hereditary characteristics. Professor Rüdin of the Deutsche Forschungsanstalt für Psychiatrie in Munich considered the question of hereditary prognosis, or the computation of the probabilities of the hereditary risk for children. Preservation of the healthy hereditary elements and eradication of the pathologic elements constitute the bases of all race hygiene. In contrast with the theory of hereditary transmission in plants and animals, human hereditary biology must renounce experimentation and is thus entirely dependent on pure experience. The probabilities of a hereditary risk in a given case are computed with the aid of a large mass of statistical material. Persons with hereditary disorders must be detected, and in their progeny the percentages of the same or similar disorders must be determined and compared with the percentages found, on the average, in the general population. In the case of manic-depressive insanity, approximately 33 per cent of the children inherit the disease; in schizophrenia and epilepsy, the percentage is only 10. The percentage is much higher than is found in children, on the average. The hereditary menace is, of course, greatly increased if both parents are affected. Attention must not be confined to the parents but must be extended to the relatives, or the family group; for, even though the parents are healthy, if the relatives are affected it is quite possible that the pathologic inheritance will crop forth in spite of the fact that the parents are healthy. And, in addition to those with frank symptoms of the disease, a large portion of the descendants present all sorts of mental defects, for which group the collective term "psychopaths" is employed. The ideal sought is the allocation of every person, whether presenting healthy or pathologic hereditary antecedents, to a characteristic hereditary type. Through detection of the empirical hereditary prognosis, precise hereditary figures should then be established for each person's progeny. In this manner it would not only be possible to eliminate the elements with undesirable hereditary traits but it would likewise be possible to make known the individuals with sound hereditary qualities, whose lives and progeny could be protected in an adequate way; for the positive, constructive features of race hygiene are just as important as the negative, eliminating features.

Reorganization of the Medical Profession

As a preliminary to the future reconstruction of the medical profession in Germany, Dr. G. Wagner of Munich, the commissar of the medical syndicates, has adopted measures looking toward the amalgamation of the *Deutscher Aerztevereinsbund* and the *Hartmannbund*. The future amalgamation will hold

its sessions in Berlin, instead of in Potsdam or Leipzig. In keeping with these measures, the *Deutsches Aerzteblatt*, organ of the *Deutscher Aerztevereinsbund*, and the *Aerztliche Mitteilungen*, organ of the *Hartmannbund*, will be merged, as of July 1, under the title *Deutsches Aerzteblatt*. In view of the historical development of the two societies, it is only natural for each to have its own independent organ; but a number of physicians of keen insight cherish the opinion that an amalgamation of the two journals is not only feasible but desirable.

No Restrictions on the Number of Medical Students

In a previous letter (*THE JOURNAL*, Dec. 31, 1932, p. 2276), it was stated that there was widespread sentiment in favor of restricting the number of students and that measures looking in that direction might be given a trial. Likewise spokesmen of the medical profession had demanded the introduction of certain restrictions (*THE JOURNAL*, Oct. 8, 1932, p. 1276). The Prussian minister of public instruction has replied to the *Aerztevereinsbund* that, for the present, no attempt will be made for the establishment of uniform principles controlling the number of students or looking toward a selection of candidates for the summer semester of 1933. Further observations must be made before any action can be taken. Moreover, the German *länder* recently reached a general agreement in regard to the restriction of the number of graduates of secondary schools to be recommended for admission to higher schools of learning, aside from the recent further restrictions for racial reasons.

Professor Langstein's Death

The sudden death of Prof. Leo Langstein of Berlin, on June 7, at the age of 57, is announced. Born in Vienna, he studied medicine in Austria and later in Germany, and was for years assistant of Heubner at the *Universitäts-Kinderklinik* in Berlin. Langstein was one of the leaders in modern pediatrics. When funds were secured for erecting a research institute for the study of the physiology and the pathology of the infant, he occupied a prominent position in that institution. He became director of the Empress Auguste Viktoria House for combating mortality in children, located in Berlin. Under his direction this institution became a model establishment. With his talent for organization, he succeeded, even in difficult times, in securing the funds that enabled him to carry on. Thousands of women have learned, in the courses that Langstein organized, to care for their children. At the same time, he developed marked activity as a scientific investigator and as a teacher. He was one of the editors of the *Ergebnisse der inneren Medizin und Kinderheilkunde*.

ITALY

(From Our Regular Correspondent)

May 15, 1933.

Congress of Ophthalmology

At the fourteenth International Congress of Ophthalmology, held in Madrid, the Italian delegation was headed by Professor Ovio, director of the *Clinica oculistica* of the University of Rome. Professor Ovio presented an official paper on "Non-operative Treatment of Detachment of the Retina." Professors Bietti, Caramazza, Speciale and other Italian ophthalmologists presented communications on the same subject or participated in the general discussion.

Professor Di Marzio of the University of Bologna read a paper on the differences between the results of the Gonin operation and the results of diathermocoagulation. Professor Strampelli described results that he secured with subretinal injections of blood plasma in detachment of the retina.

Professor Ruata reported his research on the etiology of trachoma and on the use of a vaccine, which he has used with success for more than one year.

A New Society

The faculty of medicine of the University of Catania established recently the Società Medico Chirurgica di Catania, and Professor Foderà, dean of the faculty of medicine, was chosen president. At the first session, Professor Di Guglielmo discussed the treatment of undulant fever; Professor Sorge discussed undulant fever due to *Brucella paramelitensis*.

Academy of Sciences of Apulia

At a recent meeting of the Accademia pugliese de scienze in Bari, Spadafina spoke on the evolution of fibroblasts. His research led him to conclude that the fibroblasts in tissue cultures may, under certain stimuli, be transformed into macrophages.

Trinchera exhibited a large cyst of the right femur, complicated by a complete fracture of the neck of the femur. Recovery was effected in about four months by the application of a simple traction apparatus to the limb in abduction and internal rotation.

Sannicandro's research on polypeptidemia in pregnancy indicates that there is a constant increase of polypeptides during the first months of pregnancy but more marked during the later months. The polypeptidemia is independent of azotemia and is probably due to an abnormal production of polypeptides in the region of the placenta.

Scholarships for Foreign Physicians

The committee in charge of scholarships for foreign physicians attending the Istituto Mussolini in Rome has examined the papers of competitors from forty-two countries, and has selected a physician for each of the following countries: Austria, Belgium, England, Finland, Germany and Rumania. Each scholarship amounts to 6,000 lire (\$375), which includes maintenance for six months. The funds are supplied by the general management of the public health service and by the Cassa nazionale per le assicurazioni sociali.

Center for Cancer Diagnosis

In the civilian hospitals of Genoa, a center for the diagnosis and treatment of cancer has been established at the request of the minister of the interior. The center has a consulting service, in which physicians examine difficult cases to decide the nature of the study to be made in each case and to provide, if necessary, for admission of the patients to various hospitals.

Case of Chronic Obstruction of the Ileum

Dr. Pignatti of Brescia reported before the medicosurgical society a case of obstruction of the cecum, with dilatation of the distal loop of the ileum. Ten years previously the patient had suffered from peritonitis. For two years she had attacks of intestinal disturbance, which became more intense just preceding the surgical operation. There was a tumefaction on the right side. Radiologic examination revealed innumerable discoid shadows, which corresponded to the site of the tumor. It was assumed that the manifestations were caused by fruit seeds collected in a dilated loop of intestine and at the operation the distal loop of the ileum was found filled with watermelon and grape seeds, pressed together to form a large mass. The patient recovered.

The Medical Curriculum

Professor Giordano of Venice, speaking on the medical curriculum before the senate, stressed the danger present in some universities that the subject of anatomy be reduced to a mere routine. In his opinion the interval between graduation and the taking of the government examination is too short. Giordano holds that at least six months or a year of medical practice should be completed by the graduate before he is admitted to the government examination. This might be accomplished

by reducing to five years the university instruction (which now extends over six years) and by omitting certain specialties, which could be taken up in postgraduate courses. General medical culture, he said, is today much neglected.

Distribution of Gas Masks

Regulations have been enacted controlling the distribution of gas masks. In certain places, which will be determined, all the civil and military personnel that, in case of war, must carry on will be provided with masks, which will vary in type, depending on whether they are to be used by personnel that must not cease working during the progress of an air attack or by persons who can stop their work (the passive civil population) and seek protection in shelters. The masks needed for the various departments of the government will be supplied by the respective ministries, under the supervision of the ministry of war. The masks needed for the corporations associated with the government, for the provinces, for the communes and for private parties, may be secured by purchase directly from the authorized firms. The production of these types of masks is under the control of the central government.

Laboratory for Study of Physiology of Mountain Regions

In the Alpine school of the Guardia di finanza, a laboratory has been established for the study of physiologic problems pertaining to athletics. This laboratory, at Predazzo, more than 1,000 meters above the sea level, is equipped with modern apparatus for an examination of the respiratory organs and the cardiocirculatory system. The data collected will lead ultimately to the establishment of criteria for the selection of the type of constitution best adapted for mountain service.

BUDAPEST

(From Our Regular Correspondent)

May 31, 1933.

The Medical Meeting at Balatonfüred

A medical congress was held, May 9-16, at the picturesque bathing resort Balatonfüred on Lake Balaton. The congress was attended by an unusually large number of physicians; in fact, it belied the misery in the profession which, unfortunately, is extant. On the other hand, the large attendance is proof that physicians can spare a week to go to the congress, as they lose little by being absent from their practice. Joseph Simeglio, councilor of health, read a paper on "The Practitioner and Balneology." Practitioners are recommending less and less the use of natural waters, in spite of the fact that in the treatment of chronic diseases they are indispensable. The ways by which baths affect disease vary and it is necessary that physicians know about them. Balneology is not a compulsory study at the universities, but it should be regarded as a part of pharmacology and at the examinations at least one question on balneology should be given to every candidate. He explained that the baths act on the sensory nerve endings, and the stimuli originating there are conducted elsewhere. The effect depends on the temperature and chemical composition of the baths, and other circumstances.

Dr. Elemér Scipiadès read a paper on gynecologic hemorrhages, in which he outlined the principles of treatment. If there is an anatomic cause present, this has to be treated, usually by surgical methods. If no such cause is present, a search should be made for inflammation, in which cases the treatment can be medical only. If this can be excluded, then general treatment should be resorted to. In the treatment of some kinds of gynecologic hemorrhages an important rôle should be accorded to dietetic and balneologic treatment.

Dr. Istók Bertalan spoke of physical methods in the treatment of heart disease. He said that although during the last ten years more attention had been paid to physical medicine,

comparatively little had been given to its application to heart disease. He is of the opinion that much more should be done by physical means for heart disease. Drugs have a limited value in these disorders. Rest, regulated exercise, changes of environment, and, as far as possible, freedom from anxiety and mental worry are important. With certain kinds of baths the main effect is capillary dilatation and an increased blood flow, with a desirable readjustment of blood pressure. The reflex result of this on the heart, as shown by F. G. Thomson, is to slow the beat and increase its propulsive force. Following a short bath at 39 or 40 C. there was an immediate rise in the systolic pressure, but, almost always, a drop in the diastolic pressure. Even in the normal person a hot bath produces profound changes in the heart action. Carbon dioxide baths definitely affect the basal metabolism, cause an increased flow of blood through the peripheral vessels and so relieve the heart.

The number of physical defects is alarming in Hungary. At the last meeting of the Statistical Society, Dr. Michael Horvath, lecturer on orthopedics at the University of Budapest, made public some figures. He knows that the statistics are incomplete. His investigations prove that more than half of the defectives, and particularly those of the well-to-do classes, deny their physical defects. The statistics do not include the war invalids and the industrial cases, yet the number of cripples amounts to more than 27,000. In proportion to the small population, nine and a half millions, this figure must be regarded as excessively high. Most of the conscripted cripples are under age, and in good part their deformations are due to deficient housing and nutrition, rickets, tuberculosis and caries. If to these figures are added the war invalids and the industrial cases, the sad conclusion must be made that in Hungary one person in sixty-eight is of unsound body.

The Death of Professor Ferenczi

The Hungarian scientific world sustained a great loss in the death of the psychoanalyst Alexander Ferenczi. Immediately after Professor Freud of Vienna proclaimed his doctrines on psychoanalysis, Ferenczi went to Vienna and became a zealous and ingenious pupil and follower of his master. Coming back to Budapest, Ferenczi tried to win Budapest physicians over to psychoanalysis. He succeeded in gaining many ardent adherents, so that shortly afterward he founded the Hungarian Psychoanalytic Society and became its president. This society had to fight against prejudice, not only at the outset but even after psychoanalysis became established. Years later Ferenczi was elected one of the chairmen of the Vienna Psychoanalytic Union, which post he filled with zeal. In spite of the distance from Budapest to Vienna, he scarcely missed a meeting. His untimely death in his fifty-ninth year is mourned by psychoanalysts throughout the world. At the cemetery, Prof. Paul Federn, vice president of the Vienna Psychoanalytic Union, and Anna Freud, daughter of Professor Freud, delivered eulogies. Both emphasized that Ferenczi was a man who not only dealt with the practical problems of healing but also had an absorbing scientific interest in his work.

Marriages

GLENN CLOVIS LORD, Indianapolis, to Miss Rose-Ann O'Brien of Terre Haute, Ind., June 12.

RUDOLPH F. NIELSEN to Miss Lillian Petersen, both of Cedar Falls, Iowa, June 21.

THOMAS M. BOULWARE to Miss Mary Irene Hall, both of Birmingham, Ala., May 30.

ARNOLD CASSELL, New York, to Miss Rose Rapport of Bayonne, N. J., June 28.

CHARLES ADAMS HOLDER, Paris, France, to Mrs. Dorothy Caruso Ingram, July 5.

Deaths

William Blair Stewart ☉ Atlantic City, N. J.; Medico-Chirurgical College of Philadelphia, 1890; fourth vice president of the American Medical Association in 1907-1908 and a member of the House of Delegates, 1927-1930; fellow and governor of the American College of Physicians; past president of the Atlantic County Medical Society; assistant professor of materia medica and physiologic action of drugs at his alma mater, 1893-1898; member of the Atlantic City advisory board number 1 during the World War; at one time member of the board of education; formerly chief of the medical staff of the Atlantic City Hospital; aged 66; died, July 11, of heart disease.

Theodore Eugene Oertel ☉ Augusta, Ga.; Columbian University Medical Department, Washington, D. C., 1892; professor of clinical otology and otolaryngology, University of Georgia Medical Department; member of the American Academy of Otolaryngology and the Laryngology and the American Laryngological and Otological Society; served during the World War; fellow of the American College of Surgeons; on the staffs of the University Hospital, Wilkesford Hospital for Women and Children and the U. S. Veterans' Hospital, number 62; author of "Medical Microscopy"; aged 69; died, June 27.

Ira Carleton Chase ☉ Fort Worth, Texas; University and Bellevue Hospital Medical College, New York, 1899; member of the House of Delegates of the American Medical Association, 1910, 1918 and 1919, and member of the Judicial Council, 1919-1925; past president and secretary of the State Medical Association of Texas; fellow of the American College of Surgeons; on the staffs of St. Joseph's Infirmary and the Methodist Hospital; for eight years editor of the *Texas State Journal of Medicine*; aged 64; died, June 20, of carcinoma.

James Julius Richardson ☉ Atlantic City, N. J.; University of Maryland School of Medicine, Baltimore, 1889; formerly clinical professor of otolaryngology, Howard University College of Medicine; fellow of the American College of Surgeons; at one time on the staffs of the Providence and Freedmen's hospitals, Washington, D. C.; aged 65; died, June 28, of heart disease.

Weller Van Hook, Coopersville, Mich.; College of Physicians and Surgeons of Chicago, 1885; member of the Illinois State Medical Society; professor of surgery, Northwestern University Medical School, Chicago, 1896-1908; at one time on the staff of the Wesley Memorial Hospital, Chicago; aged 71; died, July 1, of cerebral hemorrhage.

Edward H. Kessler ☉ St. Louis; St. Louis Medical College, 1887; member of the American Roentgen Ray Society and the Radiological Society of North America; senior instructor in radiology, St. Louis University School of Medicine; on the staff of the Mount St. Rose Sanatorium; aged 68; died, June 10, of heart disease.

Frederick Treon ☉ Aurora, Ind.; Medical College of Ohio, Cincinnati, 1879; member and past president of the South Dakota State Medical Association; fellow of the American College of Surgeons; formerly on the staff of the Chamberlain (S. D.) Hospital and Sanitarium; aged 77; died, June 20, of arteriosclerosis.

Raymond David Kahle, Lima, Ohio; University of the City of New York Medical Department, 1884; past president and at one time member of the state board of health; formerly on the staffs of the City Hospital and St. Rita's Hospital; aged 73; died, June 16, of coronary thrombosis and arteriosclerosis.

Alfred Trenchard-Wood, Central Islip, N. Y.; Columbia University College of Physicians and Surgeons, New York, 1899; member of the American Psychiatric Association; on the staff of the Central Islip State Hospital; aged 59; died suddenly, June 25, of cerebral hemorrhage.

Lipman Miller Kahn ☉ New York; Memphis (Tenn.) Hospital Medical College, 1900; fellow of the American College of Surgeons; served during the World War; on the staffs of the Beth David and Lebanon hospitals; aged 53; died, June 25, of bacterial endocarditis.

Aldrich Robert Burton ☉ Philadelphia; University of Pennsylvania School of Medicine, Philadelphia, 1917; served during the World War; on the staff of the Mercy Hospital; aged 40; died, June 27, in London, England, of septicemia, following peritonsillar abscess.

George Darwin Jennings, Covina, Calif.; Northwestern University Medical School, Chicago, 1899; member of the California Medical Association; veteran of the Spanish-American

War; aged 60; died, June 6, of hypertension, chronic myocarditis and arteriosclerosis.

Harry Bugge Moe @ Deerfield, Wis.; Rush Medical College, Chicago, 1915; member of the Illinois State Medical Society; past president of the La Fayette County Medical Society; aged 44; died, June 16, in a hospital at Madison, of heart disease.

George Henry Bentz, Kearney, Neb.; Kansas City (Mo.) Medical College, 1902; member of the Nebraska State Medical Association; served during the World War; aged 62; died, June 3, as the result of injuries received in an automobile accident.

Anna Mary Dice, Columbus, Ohio; Ohio State University College of Medicine, Columbus, 1925; member of the Ohio State Medical Association; aged 50; died, June 28, in the University Hospital, of fibroid tumor of the uterus and endometritis.

Henry L. Irish, Turner, Maine; College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1875; member of the Maine Medical Association; aged 80; died, April 29, of malignant tumor of the prostate and sacrum.

Oliver S. Kash, Carlisle, Ky.; Kentucky School of Medicine, Louisville, 1882; member of the Kentucky State Medical Association; formerly county health officer; aged 77; died, June 24, of carcinoma of the throat.

Robert G. Hulbert, San Diego, Calif.; College of Physicians and Surgeons, Keokuk, Iowa, 1880; member of the California Medical Association; aged 81; died, June 1, of hypostatic pneumonia and arteriosclerosis.

Peter John Dervin, Boston; Albany (N. Y.) Medical College, 1892; member of the Massachusetts Medical Society; aged 62; died, June 9, of myocarditis, arteriosclerosis and carcinoma of the rectum.

Francis Xavier Derooin, Chicopee, Mass.; Harvard University Medical School, Boston, 1883; formerly member of the board of health and school committee; aged 78; died, June 11, of cerebral thrombosis.

William Benjamin Pickrell, Los Angeles; Dunham Medical College, Chicago, 1898; University of Illinois College of Medicine, Chicago, 1906; aged 60; died suddenly, June 10, of coronary thrombosis.

Frank W. Dimmitt, Sherman, Texas; Rush Medical College, Chicago, 1881; member of the State Medical Association of Texas; aged 73; died, April 9, of chronic myocarditis and mitral regurgitation.

Vernon Roberts, Dayton, Ohio; State University of Iowa College of Medicine, Iowa City, 1907; on the staff of the Veterans' Administration Home; aged 48; was shot and killed, June 29.

William F. Justice, Lancaster, Mo.; College of Physicians and Surgeons, Keokuk, Iowa, 1874; aged 79; died, June 26, in the Graham Protestant Hospital, Keokuk, Iowa, of myocarditis.

Otis W. McQuown @ Marion, Ind.; University of Indianapolis Medical Department, 1900; county health officer; served during the World War; aged 56; died, June 23, of heart disease.

Jay Melancthon Kilborne, Sioux City, Iowa; State University of Iowa College of Homeopathic Medicine, Iowa City, 1894; served during the World War; aged 60; died, May 25.

George M. Spencer, Grattan, Mich. (licensed, Michigan, 1900); aged 88; died, June 12, at the home of his son in Belding, of cerebral hemorrhage and arteriosclerosis.

Francis C. Herr, Ottawa, Kan.; Jefferson Medical College of Philadelphia, 1879; member of the Kansas Medical Society; aged 80; died, June 8, of carcinoma of the rectum.

Andrew Daniel Nelson @ Richland Springs, Texas; University of Texas School of Medicine, Galveston, 1898; aged 68; died, May 16, in a hospital at Temple.

J. William Davis @ Livingston Manor, N. Y.; Columbia University College of Physicians and Surgeons, New York, 1902; aged 56; died, June 24, of heart disease.

Theodore Allen Prouse, Greenfield, Mo.; University of Kansas School of Medicine, Kansas City, Kan., 1906; aged 59; died, May 27, of acute dilatation of the heart.

Hermann P. A. Carstens @ Forest Park, Ill.; Bennett Medical College, Chicago, 1912; aged 61; died, June 11, of coronary thrombosis and chronic myocarditis.

George E. Eye, Long Beach, Calif.; Ensworth Medical College, St. Joseph, Mo., 1895; aged 66; died, May 26, of coronary thrombosis and arteriosclerosis.

Edward Dennis Cartwright, McPherson, Kan.; Washington University School of Medicine, St. Louis, 1931; aged 26; was accidentally drowned, June 4.

Horace M. Champney, Belle Fourche, S. D.; Long Island College Hospital, Brooklyn, 1885; formerly county coroner; aged 75; died, June 15, of senility.

Joseph Allison Jarrell, Jackson, Ga.; Bellevue Hospital Medical College, New York, 1885; aged 74; died, June 8, of carcinoma of the stomach.

Roscoe Chase Baker, Billerica, Mass.; Denver and Gross College of Medicine, 1907; aged 55; died, June 27, of gastric ulcers and peritonitis.

Hobart Jay Holcomb, Deland, Fla.; Bellevue Hospital Medical College, New York, 1882; aged 73; died, June 25, of cerebral hemorrhage.

Alexander Ben Fairfield, Beamsville, Ont., Canada; University of Toronto Faculty of Medicine, 1926; aged 32; died suddenly, May 12.

Thomas A. Bickerstaph, Lagrange, Ohio; Hahnemann Medical College and Hospital, Chicago, 1895; aged 74; died, May 1, in Elyria.

Joseph Brantley Harvey, Hampton, S. C.; Medical College of the State of South Carolina, Charleston, 1888; aged 66; died in May.

Clarence D. Romans, Columbus, Ohio; Medical College of Ohio, Cincinnati, 1884; aged 79; died, June 12, of carcinoma of the rectum.

Albert John Kreitzer, Longmont, Colo.; Rush Medical College, Chicago, 1896; aged 75; died, June 19, of uremia and pyelonephritis.

John Bennett, Ava, Ill.; Missouri Medical College, St. Louis, 1898; aged 63; died, June 19, of heart disease and diabetes mellitus.

George O. Dibblee, Moores Mills, N. B., Canada; McGill University Faculty of Medicine, Montreal, Que., 1880; aged 77; died recently.

Noah Monroe Dukes @ Strawberry Plains, Tenn.; University of Louisville (Ky.) School of Medicine, 1890; aged 71; died, June 6.

Calvin Griffith McCullough, Chicago; Starling Medical College, Columbus, Ohio, 1883; aged 71; died, July 4, of cerebral hemorrhage.

Abraham L. Johnson, Prophetstown, Ill.; Rush Medical College, Chicago, 1891; aged 68; died, June 16, of coronary thrombosis.

George Edwards Abbott, Lakeside, Calif.; Harvard University Medical School, Boston, 1872; aged 84; died, May 28, of senility.

George P. Oldham, Raywick, Ky.; University of Louisville School of Medicine, 1882; aged 75; died, June 3, in Louisville, of uremia.

Forrest Lee Cosby, Columbus, Ga.; Atlanta Medical College, 1894; aged 68; died, June 11, in the Columbus City Hospital.

James Battle Farrington, Los Angeles; University of Texas School of Medicine, Galveston, 1899; aged 65; died, May 24.

Iman Wisse, Grand Rapids, Mich.; College of Physicians and Surgeons of Chicago, 1886; also a minister; aged 79; died, May 24.

Frank Romayne Wright @ West Allis, Wis.; Rush Medical College, Chicago, 1885; aged 70; died, June 22, of heart disease.

Arthur B. Sturm, Oak Park, Ill.; Rush Medical College, Chicago, 1899; aged 58; died, June 16, of cerebral hemorrhage.

Silas Elbert Morse, Dixon, Calif.; University of Kansas City (Mo.) Medical Department, 1882; aged 79; died, May 12.

Haig A. Sims, Montreal, Que., Canada; McGill University Faculty of Medicine, Montreal, 1904; aged 50; died, May 13.

Fletcher D. Norton, Columbus, Ind.; Indiana Medical College, Indianapolis, 1877; aged 80; died, June 26, of paralysis.

Lucien Marsolais, Montreal, Que., Canada; University of Montreal Faculty of Medicine, 1921; aged 36; died, May 11.

Ernest Peltier, Montreal, Que., Canada; School of Medicine and Surgery of Montreal, 1896; aged 63; died, March 15.

John Gilbert McMillan, Decaturville, Tenn.; University of Nashville Medical Department, 1900; aged 72; died, May 8.

David S. Fisher, Reading, Kan.; College of Physicians and Surgeons, Baltimore, 1884; aged 75; died, May 15.

John C. Aikman, New York; Detroit College of Medicine, 1891; aged 64; died suddenly, June 16.

James W. Smith, Cutler, Ill.; Missouri Medical College, St. Louis, 1881; aged 79; died, June 4.

Bureau of Investigation

MISBRANDED "PATENT MEDICINES"

Abstracts of Notices of Judgment Issued by the Food and Drug Administration of the United States Department of Agriculture

[EDITORIAL NOTE: The abstracts that follow are given in the briefest possible form: (1) the name of the product; (2) the name of the manufacturer, shipper or consigner; (3) the composition; (4) the type of nostrum; (5) the reason for the charge of misbranding and (6) the date of issuance of the Notice of Judgment—which may be considerably later than the date of the seizure of the product.]

Herb-O-Life.—Western Wonder Remedy Co., Cincinnati. Composition: Epsom salt, citric acid, plant drug extract and water. Cure-all. Fraudulent therapeutic claims.—[N. J. 18529; March, 1932.]

Livingston's Dyspepsine.—Livingston Medicine Co., Griffin, Ga. Composition: Chalk, magnesium carbonate, baking soda, starch, extracts of plant drugs and a small quantity of a phosphate. For dyspepsia, etc. Fraudulent therapeutic claims.—[N. J. 18530; March, 1932.]

Vincol Herb Tablets.—Vincio Herb Co., Dayton, Ohio. Composition: Extracts of red pepper, golden seal and a laxative drug. For stomach, liver, etc. Fraudulent therapeutic claims.—[N. J. 18531; March, 1932.]

Neu-Carb.—Gilsen-Howell Co., Jersey City, N. J. Composition: Chalk (42 per cent), magnesium carbonate (15 per cent), starch, talc and a bland oil flavored with peppermint. For digestive troubles, etc. Fraudulent therapeutic claims.—[N. J. 18534; March, 1932.]

Dipsol.—Bessell Chemical Co., Hackensack, N. J. Composition: Potassium chlorate (2 per cent), citric acid (2.6 per cent) and water (95.4 per cent). For sore throat, coughs, tonsillitis, etc. Fraudulent therapeutic claims.—[N. J. 18540; March, 1932.]

Leo's Pills for Kidneys.—Brewer and Co., Inc., Worcester, Mass. Composition: Buchu, bearberry and pichi. Fraudulent therapeutic claims.—[N. J. 18541; March, 1932.]

Leo's Vegetable Female Cordial.—Brewer and Co., Inc., Worcester, Mass. Composition: Viburnum, sugar, alcohol (8.3 per cent by volume) and water. Alcohol content falsely declared. Fraudulent therapeutic claims.—[N. J. 18542; March, 1932.]

Leo's Wonderful Herb Tonic.—Brewer and Co., Inc., Worcester, Mass. Composition: Aloe, sarsaparilla, a small quantity of an iodine compound, methyl salicylate, sassafras oil, alcohol, sugar and water. For kidney and liver disorders, rheumatism, etc. Fraudulent therapeutic claims.—[N. J. 18543; March, 1932.]

Leo's Nervine Tonic.—Brewer and Co., Inc., Worcester, Mass. Composition: Extracts of celery, alcohol (18.5 per cent by volume), sugar and water. Alcohol content falsely declared. Fraudulent therapeutic claims.—[N. J. 18544; March, 1932.]

Leo's Prescription No. 3568.—Brewer and Co., Inc., Worcester, Mass. Composition: Bearberry, alcohol (18.3 per cent by volume) and water. For kidney and liver disorders, etc. Alcohol content falsely declared. Fraudulent therapeutic claims.—[N. J. 18545; March, 1932.]

Leo's Rheumatic Elixir.—Brewer and Co., Inc., Worcester, Mass. Composition: Sodium salicylate (7.8 per cent), alcohol, sugar, and water. Fraudulent therapeutic claims.—[N. J. 18546; March, 1932.]

Leo's Antiseptic Powder.—Brewer and Co., Inc., Worcester, Mass. Composition: Boric acid, aluminum sulphate, salicylic acid, and small quantities of menthol, thymol, eucalyptol and methyl salicylate. Not antiseptic. For vaginal and nasal douche, etc. Fraudulent therapeutic claims.—[N. J. 18547; March, 1932.]

Maxey's Vegetable Tonic.—Maxey Medicine Co., Winston-Salem, N. C. Composition: Small quantities of caffeine, chloroform and ammonium chloride with oils of mustard, sassafras and clove, and water. For indigestion, etc. Fraudulent therapeutic claims.—[N. J. 18651; May, 1932.]

Maxey's One Minute Liniment.—Maxey Medicine Co., Winston-Salem, N. C. Composition: Chloroform, oils of mustard and clove, and methyl salicylate, with water. Fraudulent therapeutic claims.—[N. J. 18651; May, 1932.]

Number Twenty Seven.—Washington Wholesale Drug Exchange, Washington, D. C. Composition: Epsom salt, quinine sulphate, an iron compound and water. For influenza, malaria, etc. Fraudulent therapeutic claims.—[N. J. 18652; May, 1932.]

Anti-Rheumin.—Volz Co., Erie, Pa. Composition: Capsules containing acetanilid, acetphenetidin, salicylic acid and rhubarb. For rheumatism, pain, etc. Failed to declare presence or amount of acetphenetidin. Fraudulent therapeutic claims.—[N. J. 18654; May, 1932.]

K-K-K Keyser's Pink Kold Capsules.—Keyser Chemical Co., Inc., Cranoke, Va. Composition: Salol, guanine sulphate, camphor, ginger, red pepper and aloin. Fraudulent therapeutic claims.—[N. J. 18656; May, 1932.]

Gold Bond Sterilizing Toilet Powder.—Gold Bond Sterilizing Powder Co., Fairhaven, Mass. Composition: Talc and boric acid with small quantities of eucalyptol and methyl salicylate. Not antiseptic. Fraudulent therapeutic claims.—[N. J. 18657; May, 1932.]

Woolley's Bronchial and Lung Ointment.—John T. Woolley Remedy Co., Wabash, Ind. Composition: Oils of turpentine, mustard, sassafras and garlic, incorporated in petrolatum. Fraudulent therapeutic claims.—[N. J. 18658; May, 1932.]

Ward's Liniment.—Ward's Medical Co., Winona, Minn. Composition: Extracts of red pepper and sassafras, small quantities of camphor oil, with soap, alcohol and water. Fraudulent therapeutic claims.—[N. J. 18660; May, 1932.]

Uncle Jerry's Salve.—Jerry Hubbard Co., Miami, Okla. Composition: Petrolatum, linseed oil, rosin, Peru balsam and oils of cinnamon and sassafras. Falsely claimed to be antiseptic. Fraudulent therapeutic claims.—[N. J. 18663; May, 1932.]

Ulcicur.—Ulcicur Co., Inc., Chicago. Composition: (Liquid) a bitter drug such as gentian, alcohol, glycerin, sugar and water; (powder) bismuth subnitrate. For stomach ulcers, etc. Fraudulent therapeutic claims.—[N. J. 18665; May, 1932.]

Admirine.—Eucaline Medicine Co., Dallas, Tex. Composition: Hydrochlorides of quinine and cinchonidine, iron (ferric) chloride, a laxative drug, and a trace of eucalyptus oil with alcohol, sugar and water. "Body builder" and "blood medicine." Fraudulent therapeutic claims.—[N. J. 18666; May, 1932.]

Ergotole.—Sharpe and Dohme, Inc., Baltimore. Adulterated because below standard of strength claimed. Fraudulent therapeutic claims.—[N. J. 18667; May, 1932.]

Johnson's American Anodyne Liniment.—Chemicals and Drugs, Inc., Baltimore. Composition: Alcohol (14.8 per cent), a fatty oil, oils of turpentine and camphor, ammonia, ether and water. Fraudulent therapeutic claims.—[N. J. 18676; May, 1932.]

Narco Compound Syrup of Hypophosphites.—Hance Bros. and White, Inc., Philadelphia. Composition: Potassium, manganese, strychnine, iron, calcium and quinine hypophosphites in water. For tuberculosis, etc. Fraudulent therapeutic claims.—[N. J. 18677; May, 1932.]

Vegetable and Hemlock Oil.—Vegetable and Hemlock Oil Medical Co., Detroit. Composition: Chiefly turpentine oil. For lung disorders, catarrh, rheumatism, etc. Fraudulent therapeutic claims.—[N. J. 18681; May, 1932.]

Mackie's Pine Oil.—Johnston-Mackie Co., Inc., New Orleans, La. Composition: Essentially a coniferous oil. For skin eruptions, asthma, rheumatism, etc. Falsely claimed to be germicidal. Fraudulent therapeutic claims.—[N. J. 18686; May, 1932.]

Tuttle's Family Elixir.—Tuttle's Elixir Co., Boston. Composition: Camphor oil and a coniferous oil, ammonia, ox gall, alcohol (about 30 per cent by volume) and water. For rheumatism, neuralgia, corns, sore throat, etc. Fraudulent therapeutic claims.—[N. J. 18688; May, 1932.]

Lignol Ointment.—Girard Pharmaceutical Co., Philadelphia. Composition: Petrolatum and a tarry oil. Falsely claimed to be antiseptic. For skin diseases, etc. Fraudulent therapeutic claims.—[N. J. 18695; May, 1932.]

Lignol Soap.—Girard Pharmaceutical Co., Philadelphia. Composition: Essentially soap containing a tarry oil. Falsely claimed to be germicidal. For skin diseases, etc. Fraudulent therapeutic claims.—[N. J. 18698; May, 1932.]

Wiley's Palatable Preparation (Extract of Cod-Liver Oil with Malt and Hypophosphites).—Hance Bros. and White, Inc., Philadelphia. Composition: Extracts of plant drugs, compounds of phosphorus, iron, manganese, calcium, potassium, quinine and strychnine, with alcohol (11.6 per cent by volume), glycerin, sugar and water. Did not contain the cod-liver oil vitamins. For tuberculosis, nervous prostration, etc. Fraudulent therapeutic claims.—[N. J. 18699; May, 1932.]

Girard Uterine Tonic.—Girard Pharmaceutical Co., Philadelphia. Composition: Ground plant drugs and extracts of plant drugs. For "female disorders." Fraudulent therapeutic claims.—[N. J. 18700; May, 1932.]

Spasmoline.—Spasmoline Co., McComb, Ohio. Composition: Essentially castor oil (28 per cent by volume), extract of ipecac, with alcohol, sugar and water. For whooping cough, croup, etc. Fraudulent therapeutic claims.—[N. J. 18727; May, 1932.]

Teethina.—C. J. Moffett Medicine Co., Columbus, Ga. Composition: Essentially bismuth subnitrate, chalk, sodium citrate, calomel, and sugar, flavored with cinnamon. For diarrhea, cholera morbus, worms, etc., in children. Fraudulent therapeutic claims.—[N. J. 18729; May, 1932.]

Breeden's Rheumatic Compound.—Breeden Drug Co., Inc., Memphis. Composition: Potassium iodide, extracts of plant drugs, sugar, alcohol and water. Fraudulent therapeutic claims.—[N. J. 18731; May, 1932.]

Thorson's Soap Lake Salts.—Thorson's Soap Lake Products Co., Soap Lake, Wash. Composition: Essentially washing soda (50 per cent), Glauber's salt (25 per cent), common salt (10 per cent) and small quantities of other salts, moisture (13 per cent). Cure-all. Fraudulent therapeutic claims.—[N. J. 18733; May, 1932.]

Germ-Elim.—Creotina Chemical Co., and Germ-Elim Co., Belleville, Ill. Composition: Guaiacol, sodium hypophosphite, sugar and water. For skin disorders, etc. Falsely claimed to be antiseptic. Fraudulent therapeutic claims.—[N. J. 18735; May, 1932.]

Plantlax.—Nature's Herb Co., San Francisco. Composition: Essentially powdered crude drugs, extracts of nux vomica and aloe and a trace of peppermint oil, with alcohol and water. For liver and kidney disorders, etc. Fraudulent therapeutic claims.—[N. J. 18738; May, 1932.]

Hazard's Preparation.—C. A. Hazard Chemical Co., Youngsville, Pa. Composition: Borax, boric acid, salicylic acid (12 per cent), glycerin and water. For all skin diseases, etc. Fraudulent therapeutic claims.—[N. J. 18741; May, 1932.]

Correspondence

"THE PATHOGENICITY OF THE FUSIFORM BACILLUS AND SPIRILLUM OF PLAUT VINCENT"

To the Editor:—In THE JOURNAL, March 11, is published an article by Lichtenberg and his associates on this subject. The fundamental problems of fusospirochetal disease seem to have completely escaped the authors. In view of the tragedies that will surely follow application of their implied therapeutic deductions, we feel obligated to protest. The title is misleading. From its wording one would expect a discussion of the spirochetes, but they are ignored except as vaguely confused with the terms fusospirochetes and fusiform bacilli and are proved nonpathogenic by that dangerous method of assumption. The title errs in stating "the fusiform bacillus." It would have been more correct to have stated "a fusiform bacillus" and that tentatively.

In fusospirochetal disease the spirochete for the following reasons is considered to be most important:

1. Fusospirochetal disease of the mouth is limited exclusively to the dentulous age; i. e., the spirochete age. Prior to the appearance and after the loss of the teeth, spirochetes cannot be found in the oral cavity. That is: no teeth, no gingivae, no anaerobic nidi, no spirochetes, no fusospirochetal disease.

2. The frequency of the spirochetes in the oral cavity parallels to a striking degree the absence or extent of pathologic changes in the gingival structures. Spirochetes are absent or rare in the normal mouth but are frequent in gingivitis and periodontoclasia.

3. Fusospirochetal disease not infrequently occurs in epidemics and as the victims develop this disease the one characteristic and striking change in the oral flora is the appearance of the spirochetes in increasing numbers.

4. Pathologic examination of the diseased structures shows the spirochetes leading the bacterial invasion into the normal tissues.

5. Specific treatment, particularly solution of potassium arsenite or the salts of bismuth topically, and the arsphenamines parenterally, alone or in combination, causes the rapid disappearance of the spirochetes from the lesions. Coincidentally with their destruction comes clinical improvement.

6. The fusospirochetal complex when injected into animals uniformly produces lesions of a constant character similar to those observed in man.

7. Lastly and of most importance, the acute penetrating and chronic progressive forms of this disease cannot be controlled except by the topical, parenteral or combined administration of the specifics.

The foregoing facts are known by students of spirochetoses.

The authors have ignored the spirochetal issue and have based their deductions on their studies of the "fusiform bacillus." We will discuss that "organism" and briefly point out the "fusiform problem." In that the authors have failed to take their readers into their confidence as to the bacteriologic status of their "organism" and have so prudently withheld associated information we have been unable to form a concept of it, cannot conjecture as to its taxonomic position and consequently are quite unable to discuss the "bacterium" per se. We have only the authors' implication that they were dealing with a "fusiform bacillus." This is hardly sufficient in view of the impossibility of finding any two authorities who will agree as to what a fusiform bacillus is.

Even if the morphologic, cultural, dissociative and ecologic characteristics had been determined, its taxonomic position would have to remain *sub judice* until some unanimity of opinion has been reached as to what the fusiform bacilli are. While some doubt the existence of the fusiform bacilli, the majority

of workers believe there are many kinds. In view of the controversy that exists in the literature, it would be interesting to have the authors' statement as to the motility, oxygen requirements, morphology, arsenic tolerance, method of reproduction and staining reactions of their organism. It would be of further interest to know whether or not they observed pleomorphic or dissociative forms in their cultures.

It seems hardly possible that the authors could have conceived of producing a fusospirochetal infection by the use of the fusiform bacilli alone or in association with the cocci, for so far as we have been able to determine these organisms have never been indicted as the etiologic agents that produce this disease. It appears that their observations are in agreement with those of the American Society of Bacteriologists as published in the Determinative Bacteriology compiled by Bergy in 1925, which states that the fusiform bacillus associated with *Borrelia* in Vincent's angina, ulcerative stomatitis, gangrene and wounds is not pathogenic. In the last analysis the onus probandi would seem to rest on those who maintain that these organisms are not pathogenic.

In that the authors base their therapeutic deductions from the study of nonpathogenic organisms and the observation of five, fortunately self limited cases of fusospirochetal disease, we feel that their efforts have been more literary than scientific; they should, however, be of definite negative value in promoting interest in the problem of the spirochetoses. The studies per se are not convincing. If the healing of the oral spirochetoses were as simple as the authors imply, it hardly seems possible that this disease would have by itself developed a more diversified therapeutic armamentarium than all the other infections of the buccopharyngeal cavity put together. The arsenicals were first introduced into the treatment of the spirochetoses by the Chinese, 2,000 years B. C. Since then many treatments have come and gone but the specifics are still with us and, when used, except in the case of noma, produce satisfactory results. Since 90 per cent of the acute cases heal spontaneously or subside into a chronic inactive state without treatment, it is at once apparent why so many "cures" have been periodically advanced by those who have had limited experience with this disease. Years of experience in the treatment of the spirochetoses convince us that most acute cases heal spontaneously in spite of the "usual treatment" but that the acute penetrating and chronic forms cannot be controlled except by the use of the specifics. It is impossible to prognosticate which individuals will develop a severe infection and until some one can more satisfactorily solve the problem of the "tenth case," it seems advisable to continue the routine use of the specifics.

L. J. BELDING, M.D.,

P. H. BELDING, D.D.S.,

Waucoma, Iowa.

[NOTE.—The letter was sent to Dr. H. H. Lichtenberg, who replies:]

To the Editor:—It appears that the Drs. Belding believe our report was not made in good faith.

The sixteen (not five) cases of acute ulcerative stomatitis we reported were only of the severe form. None of them went on to a chronic course. We allowed them to run their course untreated because previous reports of cases treated with various therapeutic agents were all lacking in a comparable group of simultaneously observed control cases. An evaluation of a therapeutic procedure in any self-limited disease cannot be made unless this condition is fulfilled. We were therefore interested in observing the natural course of this disease in children and comparing it with the claims made for the various drugs.

Since the writing of our communication, there have appeared two short articles by the Drs. Belding which explain more fully what they mean by chronic specific gingivitis (Specific Gingivitis, *J. A. Dent. A.* 19:1995-1997 [Nov.] 1932; The

Relationship of *Borrelia Vincenti* to Oral Disease, Dental Cosmos 74:1218-1219 [Dec.] 1932). These cases have an incipient onset and are not recognized until well advanced. They describe "a dissolution of the continuity of the gingival ligament, edema, retraction of the gums, absorption of the interdental papillae and bleeding," . . . "if unchecked, leads to the complete destruction of the bony socket and ultimate loss of the teeth." We have not encountered in children this condition ordinarily or formerly called pyorrhea alveolaris. It is probably an entirely different disease from acute ulcerative stomatitis, and we do not mean that any deductions as to the treatment of this condition should be drawn from our results with the acute ulcerative stomatitis in children. Since the Vincent organisms are found only in dentulous mouths, probably because they have here the partial anaerobic conditions necessary for their growth, since their numbers increase in man and guinea-pig both with clean surgical trauma and since the lesions heal up rapidly with great diminution in their numbers, we cannot agree with these authors that the "*Borrelia vincenti* is always pathogenic, its presence in the oral cavity is pathognomonic of an existing gingivitis either gross or microscopic."

HENRY H. LICHTENBERG, M.D., New York.

"THE DIATHERMY TREATMENT OF DEMENTIA PARALYTICA"

To the Editor:—In THE JOURNAL, June 3, appeared a paper on this subject by Freeman, Fong and Rosenberg.

I have always emphasized that in most instances deteriorated, demented patients will not go into a remission and will not improve. Early in my work the malarial type of fever curve was abandoned as a model. Long sustained temperatures with a high plateau ranging above 103.5 F. for eight hours and above 105.8 and not exceeding 107 for four hours, have been employed and recommended by us for at least two years. I will return to the rationale of this a little later.

The average number of treatments has not been confined to ten or twelve. On the contrary, I believe that the number of treatments necessary to obtain results in a case of dementia paralytica average about twenty. Most remissions take place after the fifteenth, twenty-fifth and thirty-fifth treatment. I never abandon a case until the patient has had at least fifty treatments. Lately, I have discovered that even higher temperatures than 105.8 are well borne, and I am treating a number of robust individuals now at temperatures ranging between 107.6 and 108. I have even sustained a fever of 108.5 for four hours in selected individuals. This may sound incredible to some, but I am sure that fever produced by physical agents differs widely from fever caused by toxins.

Bessemans of the University of Ghent, Belgium, and Warren of Rochester, N. Y., in experiments conducted with tissues infected with spirochetes, have shown that temperatures of 41 C. (105.8 F.) sustained for two hours or 42 C. (107.6 F.), sustained for one hour are definitely spirocheticidal both in vivo and in the human organism. Bessemans has even conducted his researches to the point of experimenting with two adjacent syphilitic lesions. One was heated with diathermy, while the other chancre, when he dealt with duplicate chancres, or the other secondary lesion, when secondaries were used, was allowed to go untreated. The subcutaneous temperatures were carefully measured by means of a thermocouple. Thus he found that the heated lesion not only showed no spirochetes, when examined by means of the ultramicroscope, but also that the rabbit's cornea could not be infected with the serum derived from such a treated lesion, which might possibly contain some virulent spirochetes. The untreated lesions grew rapidly and developed in the usual manner. All in all, 446 cases have been reported in the literature. Dr. Freeman has neglected the cases of

Epstein and Paul and the cases of Jacobson. Summarizing all these, 133 have been reported to be in an absolute state of remissions, while 153 have been discharged from the hospitals. In the latter group there was not a complete remission, since the patients are not now earning their living by constructive work.

Therefore I believe that Dr. Freeman and his associates have again proved just what I have always contended, that comparatively short nonsustained temperatures and comparatively few fever treatments are useless, and that the optimal range of fever of this type for therapeutic purposes lies above 103.5 F. Furthermore, this temperature should be maintained for at least eight hours, four of which should range above 105.8.

If this work of Freeman proves anything at all, it emphasizes the necessity of adapting medical procedures to the specific needs of the individual patient, and not being satisfied with a routine procedure in cases which are hopeless from the beginning.

CLARENCE A. NEYMANN, M.D., Chicago.

[NOTE.—The letter was referred to Dr. Freeman, who replies:]

To the Editor:—Dr. Neymann may be correct in his contentions (a) that the patients were of an unfavorable type and (b) that the treatment was inadequate according to present standards. My associates and I suggested the same possible objections. We know, however, that by malaria we can produce an arrest in most cases at any period of the disease, even the most demented.

Before we can accept Dr. Neymann's statements of the remarkable therapeutic effects of diathermy we must have (1) a prolonged period of observation and (2) histologic verification of arrest of the syphilitic process in the brain.

Eleven years' experience with malaria permits us to draw satisfactory conclusions, since these criteria have been met. Five years' experience with diathermy has given us no encouragement.

WALTER FREEMAN, M.D., Washington, D. C.

"POSTOPERATIVE CONTROL OF NAUSEA, DISTENTION AND VOMITING"

To the Editor:—I read with interest the article on "The Postoperative Control of Distention, Nausea and Vomiting" by Dr. Paine et al. in the June 17 issue of THE JOURNAL.

In April, 1923, I published an article (*Surgery, Gynecology and Obstetrics*, pp. 572-573) representing a similar experiment. I had tried the tube both nasally and by mouth. As I had some cases that should keep the tube in for several days, I found that it was better by mouth. Since the writing of this article, I have used the tube in many cases with excellent results.

I think that these writers should be complimented for their exacting work and their calling attention to the use of the nasal catheter suction siphonage.

CONSTANTINE ODÉN, M.D., Muskegon, Mich.

EPILEPSY ASSOCIATED WITH HYPERINSULINISM

To the Editor:—In THE JOURNAL, February 4, page 321, is an article entitled "Epilepsy and Narcolepsy Associated with Hyperinsulinism," by Dr. Searle Harris of Birmingham, Ala. These cases are interesting. Since 1924, when Dr. Harris reported the first case of hyperinsulinism associated with epilepsy, many more cases have been reported in THE JOURNAL. Since 1929 I have been studying such cases and have made the following observations: 1. These patients, regardless of the type of epilepsy, show a low blood sugar; especially is this true prior to the epileptic seizure. These blood sugars range from

35 to 65 mg. per hundred cubic centimeters of blood. 2. Low blood sugars mean an anoxemia, alkalosis and edema of the brain, which increases the possibility of convulsions. 3. High blood sugars mean acidosis and dehydration, which decrease the possibility of convulsions. 4. In trying to increase the blood sugar of epileptic patients, one combines the dehydration method of Temple Fay and the acidosis method of Cobb and Lennox.

More work should be centered about the blood sugar in epileptic patients.

MARVIN SANDORF, M.D., Johnson City, Tenn.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

ACTION OF PENTNUCLEOTIDES IN NEUTROPENIA

To the Editor:—1. What is the action of pentnucleotides on the hematopoietic system? Of course it increases the number of polymorphonuclears, but what is the biochemical explanation for the stimulative effect on white blood cell formation; also is there any other effect on the blood-forming system? 2. How are the pentnucleotides prepared that are supplied in ampules for the treatment of agranulocytosis, and is there any danger of deterioration? T. L. HOWDEN, M.D., St. Joseph, Mo.

ANSWER.—1. It has been rather conclusively demonstrated that nucleic acid and its derivatives have a specific maturative and chemotactic influence on the neutrophil leukocytes. This has been demonstrated in experimental work by the increase in this type of cell in the peripheral blood and an increasing hyperplasia of myeloid elements in the bone marrow in rabbits. (Doan, Zerfas, Warren and Ames: *J. Exper. Med.* 47:403 [March] 1928). Furthermore, under long-continued chronic stimulation with injections of sodium nucleinate, extramedullary myelopoiesis has been produced in both the kidney and the spleen. These extramedullary foci show only neutrophil myelocytes without the presence of eosinophils, basophils, megakaryocytes or erythrocytes, which occur ordinarily in conjunction with myelopoiesis in the bone marrow.

The theoretical explanation and basis for this action is as follows: Sabin and her associates (Sabin, Doan, Cunningham and Kindwall: *Bull. Johns Hopkins Hosp.* 37:14 [July] 1925) have shown that there is a periodic increase in "nonmotile" neutrophilic granulocytes in the peripheral blood from time to time during the day. The disintegration of these cells releases primarily nucleic acid and its degradation products. Altmann originally isolated nucleic acid for the first time in 1877 from Miescher's "nuclein," obtained from the original residue of nuclear debris constituting the "pus" so readily available from human patients in those days of septic surgery. In 1924, Henry Jackson demonstrated the presence of pentose nucleotides in human blood. Thus, it is at least possible that the disintegration and turnover of granulocytes in the body may under ordinary circumstances furnish the stimulus through the nucleic acid for the delivery of replacements from the bone marrow. Pentnucleotide is proposed for use in granulocytopenia (idiopathic malignant neutropenia; agranulocytosis, with or without angina). Its usefulness in other conditions such as sepsis accompanied by leukopenia has not been demonstrated.

2. The method of preparation is described in N. N. R. 1933. The nucleotide is prepared by alkaline hydrolysis of yeast nucleic acid (N. N. R.) at room temperature according to the technic of Perkins and Jones (*J. Biol. Chem.* 62:557 [Jan.] 1925). The solution, after hydrolysis is complete, is made acid with acetic acid and the crude nucleotide precipitated as the lead salt, which in turn is decomposed with hydrogen sulphide and the filtrate containing the purified nucleotide is evaporated under diminished pressure at a maximum temperature of 50 C. to a small volume and neutralized with sodium hydroxide. From the resulting concentrated solution, sodium nucleotide is removed by absolute alcohol and dissolved in distilled water, and sufficient tricesol is added to make a 0.3 per cent solution. The final solution contains about 8 per cent of the sodium salts of what appear to be four nucleotides. After it has stood in an icebox for two weeks the pH is adjusted to 7.2 and the solution is run through a Berkefeld filter directly into small sterile ampules. (Jackson, Parker, Rinehart and Taylor, *THE JOURNAL*, Nov. 14, 1931, p. 1436). So far as is known, this material does not deteriorate after preparation.

RENAL GLYCOSURIA

To the Editor:—I am puzzled as to how best to treat a niece of mine, aged 20, always a bright student, usually close to the head of her class, and now ready for the senior year in college. Three years ago, when she first entered boarding school, she became enthusiastic in reducing, in the craze then at its height, though she was never fat. As she was leaving for school last fall I found sugar in the urine, yellow after a light meal, red brick-like after a full meal, and then sent her to Duke Hospital, where all examinations were negative except the sugar tolerance test, which was as follows:

| | Mg. per Hundred Cubic Centimeters | Urine |
|---------------------|---|--------|
| Fasting blood | 73 | 0 |
| ½ hour | 123 | 3 plus |
| 1 hour | 135 | 3 plus |
| 2 hours | 103 | 3 plus |

A month ago I found sugar in the urine ranging from 1.3 to 2.25 per cent, so I sent her back to the same clinic, where she remained five days with everything essentially negative except

| | Blood Sugar, Mg. per Hundred Cubic Centimeters | Urine Sugar, Per Cent | Urine, Cc. |
|--------------------|---|--------------------------|------------|
| Dextrose Tolerance | | | |
| Fasting | 100 | 0.33 | 200 |
| ½ hour | 145 | unsatisfactory | 50 |
| 1 hour | 167 | 1.25 | 22 |
| 2 hours | 150 | 0.95 | 13 |
| 3 hours | 110 | 0.40 | 104 |
| 4 hours | 100 | 0.40 | 105 |

The urine showed a specific gravity of 1.035, was acid, sugar was 4 plus, albumin plus, there were from 20 to 30 leukocytes per high power field, benzidine was 3 plus, acetone a trace (four days after the menstrual period). Roentgen examination showed no abnormality of the sella turcica. The impression was one of renal glycosuria. The patient was discharged, March 8. Last fall when sugar was first detected, she fainted an hour before the noon meal and again two days ago. Won't you kindly advise me from this brief account your suggestions as to diet and care? Should she eat sweets promiscuously and in abundance? Her ideal weight is 128 pounds (58 Kg.), her present weight 114 pounds (51.7 Kg.) and it has been from 110 to 116 pounds (50 to 52.6 Kg.) for the past year, never in her life quite up to the standard weight. I shall appreciate your advice. Please omit name.

M.D., Virginia.

ANSWER.—A diagnosis of renal glycosuria is based on: (1) the appearance of glycosuria with a normal or low blood sugar, (2) the fact that there is no constant or definite relationship between carbohydrate intake and dextrose excretion, (3) persistence of the glycosuria, (4) freedom from the symptoms of diabetes, (5) the fact that under observation the patient does not develop diabetes mellitus, and (6) the fact that the blood sugar curve after the ingestion of dextrose is normal. The blood sugar curve does not resemble that usually found in diabetes mellitus. It would seem advisable to exclude any disease of the thyroid or other ductless glands. Assuming this already to have been done, the patient should be allowed to have a normal diet. However, an early mild diabetes mellitus cannot as yet be completely excluded, and she should not be permitted to eat sweets promiscuously and should be under rather constant supervision in order to detect any possible early symptoms or signs of diabetes mellitus.

OVULATION AND FERTILIZATION

To the Editor:—1. Are the spermatozoa capable of fertilizing the ovum forty-eight hours after entering the female genitalia? 2. Is it proved that the unmated ovum retains its germinating ability for less than thirty-six hours? 3. Has the time of ovulation been proved? Is the statement that "ovulation occurs twelve to sixteen days before menstruation" correct and proved? Please omit name.

M.D., Maine.

ANSWER.—1. In the rabbit, sperms live at least ten hours. Hammond and Asdell found the range of fertility of sperms to be between twenty-four and thirty hours (fertility tested after artificial insemination). Two days after coitus, various authors found mostly dead sperms in the rabbit. In the human being, motile sperms were found seven and one-half days after coitus. However, the motility of these sperms diminished rapidly after thirty-six hours. Most of the sperms were dead at this time. It should be recalled that motility in sperms does not mean that such sperms have fertilizing properties. Whereas there are possibly notable exceptions, such as in the bat, in which copulation and fertilization are separated by five or six months, students are agreed that, in the human species, sperms are dead twenty-four hours after coitus. If by the question is meant the power of surviving sperms to fertilize when the sperms have been kept in a suitable buffered solution in vitro (and under otherwise favorable conditions), it can be said that such sperms have retained their fertilizing power in some animals for eight or nine days.

2. The unfertilized ovum is short lived according to the best evidence (including the human ovum). Such unfertilized ova

hardly live more than forty-eight hours. This statement implies that an unfertilized ovum could be fertilized thirty-six hours after liberation by the ovary and could germinate subsequently.

3. In five human cases the estimated time of ovulation (the ova having been recovered) was between the twelfth and the fourteenth day from the onset of the previous menses. In another instance the time of ovulation was placed on the eighteenth day after the first signs of menstruation. In the monkey, ovulation usually occurs on the thirteenth or fourteenth day. Ovulation may not only vary beyond these limits but even not occur although the menstrual periods occur regularly. The statement that "ovulation occurs twelve to sixteen days before menstruation" is fairly correct.

"Sex and Internal Secretions" edited by Edgar Allen, Baltimore, Williams & Wilkins Company, 1932, gives further information and bibliographic references.

TUBERCULOSIS AND PREGNANCY

To the Editor:—As far as I can ascertain, there is a considerable difference in opinion as to the advisability of interrupting pregnancy in arrested tuberculous cases. An interesting note from Paris in *THE JOURNAL*, January 21, would seem to indicate that final results are much better with interruption when done between the third and fourth month of pregnancy. Can you give me the latest thought and advice on this? I am confronted with the case of a woman, aged 34, with two living children, one 12 years of age, one 9. While they are not robust, the children seem to get along fairly well. Some years ago the woman was diagnosed as tuberculous by a competent man. She at that time had pleurisy with effusion and on moving into this district from Massachusetts had an evening elevation of temperature, which continued for a year. During this year she was mainly in bed at her home, which is admirably suited for such treatment. During the past year she has been able to be up and about and, with reasonable care against overexertion, gets along fairly well. Physical signs are lacking and roentgen examination of the lungs gives negative results. There has been no rise in temperature for the past year. She weighed 125½ pounds (57 Kg.) in May, 1932. The last menses occurred, Oct. 25, 1932. Dec. 3, 1932, her weight was 124 pounds (56.2 Kg.). Jan. 5, 1933, it was 123 pounds (55.8 Kg.). Physical signs of pregnancy are positive. She had some nausea in the beginning but has not had any for the past month. She is very anxious to go through with the pregnancy. I am concerned with the loss of weight. If an abortion is to be done, now is a good time. Please advise.

M.D., New Jersey.

ANSWER.—In this particular patient it seems that, although the usual three years of arrested tuberculosis has not expired, the patient is in sufficiently good condition to justify her in her attempt to carry her child to term and this procedure can be recommended. However, the usual treatment for tuberculosis, including diet, graduated exercises, graduated exposure to sunlight, and rest, ought to be punctiliously carried out during pregnancy.

The loss of weight is not of great concern, as many healthy women lose weight in the early months of pregnancy and put it on later. The treatment mentioned would take care of this matter.

While therapeutic abortion would not be recommended in this patient, if it should be decided on everything should be done under local anesthesia aided by morphine—no inhalation anesthesia of any kind being used.

AZOOSPERMIA

To the Editor:—My brother is 28 years old and has been married seven years. During this time his wife has never been pregnant, although they have used no contraceptive measures for the past two years. I have examined several condom specimens within an hour or two after coitus and have never found any spermatozoa. My brother is a healthy, husky athletic man with no physical defects; he has never had any venereal disease, mumps or other serious illness. No other members of the family are sterile. His wife is also in excellent health. Can you offer any suggestions as to possible etiology, prognosis and treatment? Please omit name.

M.D., New York.

ANSWER.—In every case of azoospermia, the first thing to determine is whether the testicles themselves do not produce any spermatozoa, whether the various genital tubes are occluded, or whether the two conditions coexist. There are other conditions besides gonorrhea that may cause closure of the tubes. To make this differential diagnosis, a rather large aspirating needle should be inserted into the testicle and some of the testicular fluid withdrawn for examination. If spermatozoa (even if they are immotile) are found in this aspirated fluid, one can definitely diagnose that the tubes are occluded and treat accordingly, generally by an epididymovasostomy. If no spermatozoa are found, one may assume that the spermatogenic function of the testicles is at fault. In this case one may experimentally put the patient on tablets of the anterior lobe of the pituitary, starting with 5 grains (0.3 Gm.) four times a day

and gradually increasing until the patient takes 20 grains (1.3 Gm.) four times a day; that is, 80 grains (5.2 Gm.) a day. With this an outdoor life and a diet made up largely of milk and eggs is advisable. If the metabolism test is much below normal, thyroid extract may be given in conjunction with the pituitary tablets. Repeated condom examinations after a long period of continence should be made.

MERBAPHEN (NOVASUROL) AND MERSALYL (SALYRGAN) IN EDEMA

To the Editor:—Please discuss the clinical results of novasurol and salyrgan in cardiac dropsy. Which is the more efficacious and less toxic? Please omit name.

M.D., Texas.

ANSWER.—The organic mercury compounds merbaphen (novasurol) and mersalyl (salyrgan) are useful drugs in the treatment of cardiac dropsy. These drugs differ in their toxic reactions. Merbaphen can be given subcutaneously or intramuscularly with little or no local reaction, while mersalyl may cause marked local reactions, the effect of which may lead to actual sloughing. On the other hand, it is now generally agreed that general toxic reactions are more frequent and more marked following merbaphen than after mersalyl. When intravenous injection offers no difficulties, mersalyl therefore is the drug of choice. However, when the peripheral veins are difficult to inject, as when peripheral edema is marked, merbaphen injected intramuscularly may give satisfactory diuretic results. A safe general rule is to give an initial dose of 0.5 cc. of either drug. If there are no ill effects, this dose can be increased to 2 cc. and repeated every three or four days until the dropsy is controlled. If given more frequently, these drugs may have a toxic action on the kidneys. The simultaneous administration of the acid salts, calcium chloride, ammonium chloride and ammonium nitrate increases their diuretic action. The prompt and efficient action of these organic mercury compounds alone or in combination with other diuretic substances has shown that a burden can be removed from a weakened heart by the rapid resolution of dependent edema.

CHROMIDROSIS AND CYANEPHROSIS

To the Editor:—Last summer I was consulted by a woman patient who told me that, when she washed her hands and forearms, or when she took a bath, the water turned blue. Thinking that it was caused by the soap that she used, she took baths without soap, with the same result. This disorder is called "cyanephidrosis." I know nothing of this condition and ask that you enlighten me.

MORRIS HENRY, M.D., Helena, Ark.

ANSWER.—Every possible attempt should be made first to make certain that the blueness of the water is not due to some natural cause. Extremely hard water is likely to turn blue in the presence of various chemicals either in soap or on the surface of the body.

The first indication is to make sure that it is a real case of cyanephidrosis, blue sweat. A portion of the skin known to be involved should be cleansed carefully with soap and water by the physician or his assistant, then washed with ether, this allowed to evaporate, and collodion applied. If the blue color reappears under this, or when this is removed by the physician, the case may be accepted as genuine.

True chromidrosis is very rare and the black form is most common, the blue form coming next in frequency. In most cases the sweat is colorless when it first appears and then turns blue, leaving a deposit of dustlike particles about the sweat pores. These are soluble in oils or fat solvents more readily than in water, leading to the suspicion that the sebaceous glands may be involved; but the rapidity with which the color is produced, its deposit about the sweat pores rather than about the hair follicles, and its close connection with the activity of the sweat glands allays such a suspicion. The fact that the sweat glands themselves produce oil makes such an explanation unnecessary.

Various explanations of the nature of the blue deposits have been made. The common one, credited to Bizio and Hoffmann, is that it is indigo, derived from indican, formed in the intestine. A reaction for indigo is not always to be obtained, however. Collman and Scherer call it ferrous phosphate and Fordos states that it is procyaniue. Furthermore, blue sweat has been observed in copper workers, though the common color of their perspiration is green.

Except for the last mentioned class, all patients with cyanephidrosis have been neurotic individuals, mostly women. Pelvic and menstrual disorders have been associated in some cases. The intestinal conditions should be studied, including the flora of the tract. Constipation should be corrected and any underlying nervous condition treated.

HEADACHE AND MENSTRUATION

To the Editor:—A woman, aged 27, married, with one child aged 15 months, suffers from unilateral sick headache, initiated by a tired feeling and, at times, depression. The pain is felt through the right eye and the right side of the head to the occiput. There is no tenderness of the scalp or neck and no vertigo. The attacks usually end in sleep. They are most likely to occur after she has been very busy and are almost certain to occur after entertaining. The patient first menstruated at 13. She had sick headaches from 14 to 16, and they became severe after 16. The patient was unable to associate in her mind the attacks with her periods. The intervals between periods vary from twenty-one to twenty-eight days. The periods are of six days' duration and, prior to pregnancy, four days. There is a free flow for three days. They are without discomfort, though she had painful menstruation before pregnancy. Labor was normal. The headaches occur irregularly between one and three weeks apart and last from twenty-four to forty-eight hours. During the nine months of pregnancy and the first six months of the nursing period the patient had but three attacks, one early in pregnancy, one immediately after return home from the hospital, and one in April, 1932 (having nursed the baby from the previous October). During this time menstruation did not appear. From April to July (the end of the nursing period) and up to the present, the patient has menstruated every three to four weeks. She had headaches as of old (except less severe) from April on until July, much milder than in the past but since July again increasing in severity. Does the practical disappearance of this affliction during such a period of suspended menses suggest any direct manner of attack by endocrine therapy? The general health is good. Physical examination is negative. Please omit name and address.

M.D., California.

ANSWER.—In spite of the apparent relationship between the presence of menstruation and the headaches, it is highly doubtful whether endocrine therapy will be of any avail except psychically.

Just what glandular products to try is difficult to say. During the menstrual cycle, the important hormones present in the blood are the female sex hormone, or folliculin in the first half and progesterin in the second half of the cycle. It is hardly likely that these are responsible for the headaches, and, even if they were, no way of eliminating them is known except by pregnancy. On the other hand, during gestation, large amounts of the anterior pituitary hormones circulate in the blood. It may be that the presence of large quantities of these hormones prevents the appearance of the headaches; but this also is conjectural. One way to try to find out is to administer ampules of anterior pituitary hormones hypodermically every day for a number of weeks. However, the anterior pituitary hormones are most likely not the important factor in this case because the headaches subsided not only during pregnancy but also during the first six months of nursing.

The eyes, ears and sinuses should be carefully examined, but it may be that these headaches are similar to migraine and therefore difficult to overcome.

POSTPARTUM EXERCISES

To the Editor:—As there appears to be a marked difference of opinion with regard to the benefits of postpartum exercises, will you give me a routine for the normal puerperium? Kindly omit name.

M.D., Michigan.

ANSWER.—Beginning on the second day after delivery, patients should be placed in the Fowler position part of the day. In addition, they should lie on their abdomen for about fifteen to twenty minutes three or four times a day. These changes in posture help to maintain the downward drainage of the lochia and keep the vagina free of lochia, thereby diminishing the chances of infection that may result when the cervix lies buried in a pool of debris and bacteria. On the third or fourth day of the puerperium, patients may have a light general massage of the entire body except the abdomen and the breasts. This is passive exercise. Two days later, systematic exercises involving the arms, legs and abdomen are begun and carried out while the patient is in bed. These exercises improve the circulation, strengthen the tone of the abdominal muscles and hasten the patient's general recovery. The following exercises are recommended: The pillows are entirely removed or one pillow is placed under the patient's back. A series of deep breaths is taken. During inspiration the arms, which lie at the sides, are slowly raised either above the head or upward toward the ceiling. On expiration the arms are slowly returned to their original position. Then the head is raised and lowered a number of times, and following this the extended legs are elevated and lowered one at a time and later the two at the same time. This is followed by flexion of both the thigh and the knee of each leg and then of the two legs together. Next the flexed thighs are abducted a number of times. Then the patient assumes a sitting position with the arms extended along the sides of the body and, if the patient is able, she should repeat this exercise with the hands behind her head. This is followed by the knee-chest position, which should be

properly carried out and maintained for gradually increasing periods beginning with a five minute period. After the third week the patient may be instructed to perform the "monkey trot," that is, walk fast on both hands and feet a number of times a day, or she may be asked to practice the "mule kick." In all cases the exercises should consume only a few minutes at the start, and each day the time should be increased, depending on the patient's general feeling and her endurance. If the exercises increase or bring about a return of red lochia, they should be stopped for a few days.

TENOSYNOVITIS AND MYOSITIS

To the Editor:—A man, aged 27, has had a sensation of friction on flexing certain muscles for the past four years. It started in both knees and next involved the right elbow, then the left elbow and now is present in all those joints and also the left shoulder. On palpation, flexion and extension with the antagonistic muscles tensed gives a sensation of crepitus and the creaking can be heard. There has been no swelling or any other evidence of inflammation in either the muscles or the joints. He had gonorrheal urethritis six years ago, which was treated and apparently cured. He shows urticarial lesions irregularly placed on the arms and trunk. He works as a rancher. Any information on the cause and treatment of this condition would be appreciated. Please omit name.

M.D., South Dakota.

ANSWER.—This case may be classified as multiple tenosynovitis, possibly in a group called occupational synovitis. There may be an element of multiple myositis, which is analogous to such conditions as rider's knee, soldier's shoulder, fencer's bone and dancer's bone. Other conditions that come to mind are interstitial calcinosis, arthritis, myositis, synovitis, myositis ossificans, myositis ossificans para-arthritis and occupational tenosynovitis due to repeated injuries.

Many of these cases follow infectious disease and are not of traumatic origin. This patient may be developing a generalized calcinosis or generalized tenosynovitis. There may be an element of myofasciitis or fibrositis ossificans progressiva.

These various conditions are caused by infection and trauma. Trauma may be one severe blow or multiple minimal strains or sprains. The occupation of a rancher may account for these.

The tendon in a tendon sheath may be compared to an umbrella in an umbrella cover. If there is no free play of a tendon in its sheath, palpable and audible crepitus may be noted when the tendon is active. There may be a dry tenosynovitis.

In the treatment, the first consideration is rest. This may necessitate a change of occupation. The patient should note those activities which cause crepitus and discomfort and avoid them, just as one should avoid those foods which are known to cause gastric or intestinal disturbances. The application of a plaster-of-paris cast for a few days would make a good test of whether this form of treatment is applicable in this case. Later a removable splint should be tried. The splint should be removed twice daily for radiant heat and diathermy. Massage should be very cautiously tried. Its continued use depends on the response.

EFFECTS OF IODINE ON INSULIN IN HYPERTENSION AND DIABETES

To the Editor:—The wife of a local colleague had a cerebral hemorrhage seven weeks ago and now has hemiplegia on the right side. She is being given potassium iodide in fairly large doses at present. She has also diabetes mellitus and takes 40 units of insulin daily. Jensen, Schöck and Sollers (J. Biol. Chem. 98:93 [Oct.] 1932) have stated that a definite amount of iodine will permanently inactivate insulin. What influence should this report have on the treatment of such a case? I should be pleased to receive any information possible relative to the coincidence of hypertension and diabetes and also the treatment of hemiplegia due to cerebral hemorrhage either with or without complicating diabetic conditions.

M.D., Ohio.

ANSWER.—The experiments cited on the inactivation of insulin by iodine were conducted in a test tube, not in an animal, and were carried out with standard solutions of iodine rather than with a solution of potassium iodide. One milligram of amorphous insulin represents about 15 units and of crystalline insulin about 24 to 27 units and it was found that this quantity of insulin was rendered inactive by 0.3 cc. of hundredth normal iodine solution, or approximately 0.4 mg. of iodine. It is true that in 1 Gm. of potassium iodide there would be 0.765 Gm. of iodine, but the iodine in potassium iodide is not in a dissociable, reactive form and is not therefore likely to cause inactivation of insulin, which presumably the free iodine accomplishes possibly at the disulphide linkage, as suggested by Jensen and his co-workers. It is improbable that free iodine is set free in the body when potassium iodide is given, because some of the toxic effects of free iodine would be manifested.

There has apparently been no suggestion of inactivation of insulin with diabetic patients taking potassium iodide for bron-

chitis or syphilis, or with cases of hyperthyroidism when compound solution of iodine is employed.

Diabetic patients live so long and die so old that at present approximately half of the deaths of diabetic patients are due to arteriosclerotic complications, chiefly in the legs and heart, less commonly in the head and kidneys; and in many of these conditions high blood pressure is a factor.

For the treatment of hemiplegia due to cerebral hemorrhage the questioner is referred to the standard medical treatises. If the condition is associated with diabetes, insulin can be used with advantage under close supervision, but only with frequent tests of the urine and blood sugar, because hypoglycemia as well as rapid falls in the blood sugar must be avoided.

POISONING IN TINNING INDUSTRY

To the Editor:—A man, aged 34, with a severe irritated condition of the upper respiratory passages, especially the nasal mucous membrane, has no apparent constitutional symptoms. He is a tinner by trade, occupied in retinning cans. His procedure is to dip cans that have been "fluxed" with a mixture of hydrochloric acid and pure zinc into a vat of pure molten block tin. When this is done a heavy cloud of acid smelling fumes arise, which he is unable to avoid inhaling. He has tried some type of mask and finds that the fumes seem to condense under the mask, causing a dermatitis. The questions he would like to have settled are: 1. Is there any danger of absorption of any of the materials or combination of materials used in this process that might be the cause of some type of chemical poisoning? 2. Is there any particular type of mask he could wear to avoid the irritation of his skin and mucous membranes? I believe the condition solely one of surface irritation from the fumes of hydrochloric acid but would appreciate your opinion on the matter. Please omit name.

M.D., Maryland.

ANSWER:—Respiratory inflammation is a reasonable expectancy in this operation. Although the terms "pure zinc" and "pure molten block tin" appear in the query, such purity is not always represented by facts. Arsenic as an impurity in traces has rarely led to poisoning in which respiratory inflammation (especially of the nasal mucous membranes) is a feature. Zinc chloride may be used along with the acids in the preparatory processes. In the tin, lead has, in the past, been present at least as an impurity, in quantities sufficient to produce plumbism. Assuming that the metals as used are in fact pure, the respiratory disturbances may be accounted for as the result of acid vapors and zinc fumes. The tin is essentially harmless, although the fumes from any molten metal may not be wholly exculpated. The formation of some zinc chloride under the conditions stipulated in the query is probable. As for the direct questions:

1. Systemic poisoning may arise if other metals (arsenic, lead) are present in appreciable quantities as impurities. Acid vapors and zinc fumes are unlikely to cause direful systemic disease, although the zinc may lead to "zinc chills"—an acute affair; and the acids may lead to gastric hyperacidity and possibly to ulceration.

2. Best protection is likely to be obtained through the use of the hose type of mask rather than the filter type. The latter masks may in truth be shown to be efficient, but the amount of care required to keep them so is sometimes onerous. A discussion of the efficacy of respirators may be found in the February, 1933, issue of *National Safety News* (page 21) and U. S. Public Health Bulletin 177, 1928.

Local suction apparatus at the rim of the molten metal tank is practical. A discussion of this procedure for another industry may be found in *Public Health Reports* 43:2330 (Sept. 7) 1928.

SURPLUS TISSUE IN ABDOMINAL WALL AFTER PREGNANCY

To the Editor:—A woman, aged 30, who has had two children weighing 10 and 11 pounds (4.5 and 5 Kg.), respectively, at birth, shows a surplus of skin folds over her abdomen, plus the usual scarring caused by the previous gravid condition. She is slim and therefore feels that the surplus tissue is disfiguring. I would appreciate any suggestion that you may offer as to treatment or operative procedure, if any. Please omit name.

M.D., Chicago.

ANSWER:—The redundant skin may be held together with a girdle without operation. Operation for such an excess of skin carries a minimum of risk, the greatest being that of infection. The operation may be done by a transverse excision when the lower part of the abdomen is pendulous. In other cases a vertical excision may be performed. The only objection to the vertical incisions is that they may have to go above the umbilicus. If this is not desirable, two vertical excisions may be performed one on each side of the abdomen. The amount of skin to be removed varies, but the sutured edges should come together without tension or leaving wrinkles. Careful approximation must be obtained or there may

be an objectionable scar. The individual longitudinal scars resulting from pregnancy are usually too numerous to remove. This might be attempted in a few instances of very broad scars. As a rule, a good cosmetic result may be expected from a skilful operation.

SWELLING OF SCROTUM AFTER HERNIOTOMY

To the Editor:—Three months ago a modified Bassini type operation was done for right inguinal hernia in a youth, aged 20. At the time of operation, several veins belonging to the pampiniform plexus were incised and ligated. When the floor of the canal was reformed, special precautions were taken to strengthen it and the external ring, as the patient is asthmatic. Possibly the external ring was made too tight. Two days later, swelling of the right scrotum occurred. This receded under support and an ice bag but since then the scrotum has remained about three times the normal size and on several occasions considerably larger, and now the left scrotum also is slightly swollen, both receding slightly under support. What would be the logical cause? What is the prognosis? Is this swelling apt to persist through life? What besides scrotal support and ice bags can be done? Is another operation indicated to relieve a possible constriction of the new external ring? If the condition is circulatory rather than constriction of the vas, what can be done and why has it not cleared up rather than becoming worse, as lately? Please omit name.

M.D., California.

ANSWER:—The swelling of the scrotum following operation may have been due either to a hemorrhage or to venous obstruction. The persistent edema would indicate that there is obstruction to the veins of the cord.

The swelling may persist, become worse or gradually clear up; but, owing to the danger of atrophy of the testicle, reoperation is indicated at this time. The veins of the cord should be freed from pressure and any hematoma should be removed. Careful reconstruction of the inguinal canal with avoidance of any constriction of the cord will almost surely give relief.

The modified Bassini operation with the inclusion of the cord between the imbricated external oblique fascia is not so satisfactory as other methods of repair.

Any method of repair should avoid constriction of the cord even at the expense of a recurrence. However, it is not always possible to determine the constriction that may result from a sharp edge of fascia. After repair is complete it is always wise to examine for a possible constricting sharp edge and correct it by cutting or resuturing the fascia.

VERTIGO

To the Editor:—A man, aged 25, in good physical health, complains of vertigo and of impaired hearing in the left ear. The past history is negative for any severe illness and any definite eye ear, nose and throat infection of note. Vertigo and impaired hearing began about nine months ago and have gradually increased, with short remissions. The vertigo is aggravated by physical exercise and is temporarily relieved (incompletely) by lying down. A change in position from lying to sitting makes objects about the patient seem to whirl around. There is also difficulty in focusing the eyes, and this is more marked when the vertigo is more pronounced. Recently there has been marked difficulty in locating sounds. The patient has a speech difficulty (stammering) that has persisted since childhood. He was also left handed as a child. A diagnosis of labyrinthitis was made and a series of pilocarpine swabs were carried out with no definite change in the condition. From this information can you make any suggestion as to diagnosis or treatment? Please omit name.

M.D., Oklahoma.

ANSWER:—Changes in the blood or the blood pressure may be responsible for the condition noted. A careful blood examination and examination of the blood pressure should be carried out with the idea that possibly a hemorrhage or some other vascular disturbance may have occurred in the inner ear. Serologic tests should also be made to eliminate the possibility of syphilis. If there is much vertigo, complete rest should be enforced for a time, while the various diagnostic measures are being pursued. The use of sedatives such as bromides, and alteratives such as iodides, is sometimes of great benefit.

VARICOSE VEINS IN PREGNANCY

To the Editor:—What is the best treatment for varicose veins in a woman now four months pregnant? She has had three children. The veins are not very extensive but they are causing her enough pain to keep her awake at night. Is it better to have them treated surgically or elastic stockings advised? The veins are in the calves of the legs and also in the thighs. Please omit name.

M.D., Michigan.

ANSWER:—The injection treatment of varicose veins during pregnancy is successful in properly selected cases. The same tests for patency of deep circulation and for latent infection should be used that are employed in any other patient suffering from varicose veins. If the long saphenous vein is palpable and incompetent, it should be ligated close to the saphenofemoral junction, preliminary to injections. Activation of a

latent infection must be carefully avoided. Elastic stockings are useful as additional support but will not obviate the danger of postpartum thrombosis in the dilated veins. Injections are preferably avoided after the seventh month of pregnancy. The physician who undertakes the treatment of varicose veins during pregnancy should be aware of the limitations and dangers of this method and should have had experience in treating veins with injections.

POLLENS IN MICHIGAN

To the Editor:—Kindly inform me as to the pollen content (giant and dwarf ragweed) in Marquette, Mich. Which locality would be better for a tuberculous person affected with hay fever (ragweed) Mackinac Island or Marquette?

SAMUEL DESSEN, M.D., Chicago.

ANSWER.—No figures are available on the ragweed pollen content of the air at Marquette, Mich. Investigations at Sault Sainte Marie, Mackinac and Port Arthur, Canada, as well as at numerous other locations farther south, would lead to the belief that ragweed pollen is about as plentiful in Marquette as at Sault Sainte Marie or at Mackinac, where the ragweed pollen content of the air is about one tenth as much as in central Michigan, Wisconsin or Illinois.

There should be complete, or almost complete, freedom from ragweed at Marquette when the winds are off the lake, but the prevailing southwest winds are capable of carrying more than enough pollen to aggravate symptoms in most ragweed-sensitive persons. There would probably be no choice between the two places mentioned for a tuberculous patient with hay fever. Pollen statistics were given in THE JOURNAL, June 10, page 1848.

CHEILITIS AFTER PERSISTING HERPES OF LIP

To the Editor:—A man, aged 30, had a "cold sore" in January, 1930. It healed but always split. He allowed this to continue for four months and then had it canterized with the actual cautery two or three times. Then he had ultraviolet ray treatments to no avail. He had it canterized again and still got no results. A surrounding cheilitis developed and he finally went to the Mayo Clinic, where the infiltrated area was removed, but he still has a cheilitis. Boric acid ointment, Lassar's paste, ointment of rose water and tar ointments will not clear it up. What else do you suggest?

M.D., Illinois.

ANSWER.—It is possible that the continued inflammation is the result of repeated irritation by cautery and other treatment. In view of the fact that the lesion has already been removed and for that reason any beginning carcinoma has been removed, the lesion might be treated expectantly for a while, only a mild greasy coating, such as oil of theobroma, being used. These suggestions of necessity are of limited value, owing to the fact that it would be better to see such a lesion to express a comprehensive opinion about it.

ETIOLOGY OF REPEATED ABORTIONS

To the Editor:—I note with interest and disappointment your replies to M.D., North Dakota, and M.D., New York, on the etiology of repeated abortions (THE JOURNAL, June 17, p. 1937). Syphilis, so frequently given as a cause in the older textbooks, is rarely seen by the consultant in obstetrics. In order to check this statement I have just reviewed my cases, twenty-one in number, in which two or more spontaneous abortions occurred, and in not one was there a positive Wassermann or Kahn reaction in either husband or wife, nor was there any clinical evidence of syphilis or any microscopic evidence among those cases in which uterine products could be obtained. Certainly in this series syphilis played no part. These were private cases, however, and objection may be raised to my figures on that ground. While it is admittedly true that a similar study of clinic material would probably yield a higher incidence of syphilitic infection, I am convinced that syphilis is more of a coincidence than a true exciting cause. In my experience syphilis does play an important part in prematurity but a negligible one in repeated abortions.

Your reply to these queries did, of course, touch on other causes of repeated abortions, but my complaint is based on undue prominence given syphilis and the minor rôle attributed to other causes.

Chronic infection, especially oral, has been so frequently discussed in the literature of the past ten years in this connection as to be almost an overworked thesis; but apparently its importance remains in the knowledge of the special worker. Pioneer studies were made by Talbot of Massachusetts and Curtis of Chicago, who have reported their observations frequently and convincingly. I brought this to the attention of the dental society of South Carolina (J. South Carolina Dental A., 23: 45, 1930), but mine was a small contribution compared with that of the writers named.

Since reading these answers to your correspondents it has occurred to me that the publication of a study of a large number of repeated abortions might be of special interest and value. I believe syphilis is an incidental infection and, to quote from another answer on page 1937, "it is unfortunate that the presence of syphilis in a patient is often rendered responsible for all the pathologic conditions in that patient."

ROBERT E. SEIBELS, Columbia, S. C.

Council on Medical Education and Hospitals

COMING EXAMINATIONS

ALASKA: Juneau, Sept. 5. Sec., Dr. Harry C. DeVigline, Juneau.
AMERICAN BOARD FOR OPHTHALMIC EXAMINATIONS: Boston, Sept. 19. Application should be filed before August 1. Sec., Dr. William H. Wilder, 122 S. Michigan Ave., Chicago.
NATIONAL BOARD OF MEDICAL EXAMINERS: Parts I and II. The examinations will be held at centers where there are five or more candidates, Sept. 13-15. Ex. Sec., Mr. Everett S. Elwood, 225 S. 15th St., Philadelphia.
PUERTO RICO: San Juan, Sept. 5. Sec., Dr. O. Costa Mandry, Box 536, San Juan.

Hawaii April Report

Dr. James A. Morgan, secretary, Board of Medical Examiners, Territory of Hawaii, reports the oral and written examination held in Honolulu, April 10-13, 1933. The examination covered 10 subjects and included 55 questions. An average of 75 per cent was required to pass. Five candidates were examined, 3 of whom passed and 2 failed. One physician was licensed by endorsement. The following colleges were represented:

| College | PASSED | Year Grad. | Per Cent |
|---|--------|------------|----------|
| University of Colorado School of Medicine..... | (1932) | | 83.3 |
| Northwestern University Medical School..... | (1932) | | 82.7 |
| University of Nebraska College of Medicine..... | (1931) | | 85.1 |

| College | FAILED | Year Grad. | Per Cent |
|---|--------|------------|----------|
| University of Santo Tomas College of Medicine and Surgery | (1920) | 54.2 | 60.3 |

| College | LICENSED BY ENDORSEMENT | Year Grad. | Per Cent |
|---|-------------------------|--------------|----------|
| Northwestern University Medical School..... | (1931) | N. B. M. Ex. | |

*This applicant has received an M.B. degree and will receive an M.D. degree on completion of internship.

Maine March Report

Dr. Adam P. Leighton, Jr., secretary, Maine Board of Registration of Medicine, reports the written examination held in Portland, March 14-15, 1933. The examination covered 10 subjects and included 100 questions. An average of 75 per cent was required to pass. Five candidates were examined, all of whom passed. One physician was licensed by reciprocity and one by endorsement. The following colleges were represented:

| College | PASSED | Year Grad. | Per Cent |
|---|--------|------------|----------|
| College of Medical Evangelists..... | (1931) | | 81.9 |
| Harvard University Medical School..... | (1931) | | 88.1 |

Book Notices

Allergy and Immunity in Ophthalmology. By Alan C. Woods, M.D., Associate Professor of Ophthalmology, Johns Hopkins Medical School. The Wilmer Ophthalmological Institute, the Johns Hopkins Hospital and University, Monograph No. 1. Cloth. Price, \$2.25. Pp. 176. Baltimore: Johns Hopkins Press, 1933.

This is dedicated by the author to his father, the late Dr. Hiram Woods, who was one of the most universally beloved men in American ophthalmology. There is a foreword by Dr. W. H. Wilmer in which he aptly says, "We are just upon the threshold of our knowledge of immunological adaptation and this monograph pushes open the door a little wider." The author has divided his material into eight chapters, on general considerations on anaphylaxis, allergy and immunity; experimental studies on general ocular immunology; relationship of allergy to focal reactions in the eye; allergic conjunctivitis; antigenic properties and reactions of lens protein and uveal pigment; syphilis; tuberculosis, and therapeutic procedures. Each chapter is concluded by an adequate bibliography and at the close of the book is an author index and a subject index. It is not easy reading because of the nature of the subject, but the well chosen diction puts the matter clearly before the reader who is not immunologically trained. Particularly well done is the chapter on allergy and focal infection, wherein is a clear-headed analysis of the etiologic rôle of focal infection as pertains to ophthalmology. Conclusive proof is lacking that an allergic mechanism may be responsible for inflammatory lesions of the eye from chronic foci of infection, but much of the modern investigative work is pointing in that direction. Two of the best chapters are those dealing with the lens and with uveal pigment, for much of the modern knowledge of the immunologic reactions of those tissues has emanated from the laboratory of the author. The chapter on tuberculosis is sound, as is the treatment outlined for those conditions. The book is worth while for every ophthalmologist.

Vitamins and Other Dietary Essentials. By W. R. Aykroyd, M.D. Cloth. Price, 7/6. Pp. 218. London: William Heinemann, Ltd., 1933.

This book in everyday language gives a brief account of the more popular aspects of the science of dietetics for the general reader and the professional classes whose work lies in other fields. Chapters are devoted to the nutritional essentials, nutritional disorders, diet and teeth, minerals in nutrition, dietary values of foodstuffs, nutrition, physique and health, and the perfect diet. The extent of malnutrition is stressed. Public consciousness of this fact is a first step toward improved nutrition. The author is thoroughly conversant with his subject; his judgment on the practical significance of scientific nutrition is sound.

Industrial Microscopy: A Book Dealing with the Use of the Microscope and the Preparation of Specimens for All Who Use the Microscope in Industry. By Walter Garner, M.Sc., F.R.M.S. Cloth, Price, \$5. Pp. 389, with 208 illustrations. New York & London: Isaac Pitman & Sons, 1932.

The main object of this book, as stated in the preface, is to present in one volume an adequate number of methods of microscopic technic of general interest to the technical chemist. With this in mind, the author has attempted to make a judicious arrangement of the subject. Chapters I to VIII and XI contain sections on microscopic technic and accessories, measurement, counting and drawing, photomicrography, microchemical technic, inorganic and organic micro-analysis, and textile and paper-making fibers. The subject matter is pre-

sented in a clear and concise manner such as might be expected in a brief introductory book. It is disappointing, however, to note that only a page is devoted to metallography, which is included under accessories as surfacing metals for examination. The remaining chapters, occupying more than half of the volume, deal with botany, microbiology and insects, which will probably be found to be of more or less value for some industrial chemists. The advisability of combining two such dissimilar and highly specialized subjects as bacteriology and crystallography in a brief textbook is in itself problematic. It would seem impossible to do justice to either of them when treated together in a single volume. Obviously, the author's plan in presenting disconnected technics and descriptions of elementary structures without practical applications is apparent in these chapters. Microbiologic technic and entomology occupy some 100 pages. The chapter on bacteria follows closely the similar section appearing in Bergey's Manual of Determinative Bacteriology. The section on the examination of water consists of only a few pages, a treatment entirely inadequate for practical purposes. The chapters on botanic technic and structures are followed by several pages of practical applications on grains and starches, comprising, perhaps, the most useful part of the book. The analyst who has to consult a textbook for the identification of vegetable specimens, the microbiologic examination of water, beverages, foods, meat products, milk, soils, or tanning liquors will find it serviceable.

Cinquante techniques chirurgicales de Henry-Delagenière. Recueillies et rédigées par Yves Delagenière. Paper. Price, 50 francs. Pp. 315, with 63 illustrations. Paris: Masson & Cie, 1933.

This consists of a rather detailed description of the operative technic employed by Delagenière in what may be considered the fifty most common operations in general surgery operations on the stomach, intestine, genito-urinary system, head, neck and extremities. For almost every operation, one or more original procedures are described. The book can hardly be recommended as a textbook for students or as a source of information for surgeons, because the general field of surgery is not covered and because the subject matter is limited to a description of operations with little or no discussion of indications for operation or details of postoperative management. This is a worthy memorial volume to one of the leading exponents of modern surgical technic in France. Delagenière, educated in Paris, began his professional career in Mons, where he developed one of the leading surgical clinics in France. His major contribution to surgery was made during the World War, when he demonstrated the value of osteoperiosteal bone grafts.

The State and Higher Education: Phases of Their Relationship. By Fred J. Kelly, Chief, and John H. McNeely, Research Assistant, the Division of Colleges and Professional Schools, the U. S. Office of Education. With an introduction by Howard J. Savage, Secretary, the Carnegie Foundation for the Advancement of Teaching. The Carnegie Foundation for the Advancement of Teaching in Cooperation with the U. S. Office of Education, Department of the Interior. Paper. Pp. 282, with illustrations. New York: Carnegie Foundation for the Advancement of Teaching, 1933.

Among the problems that the current financial stringency has brought home to American higher education, none are more pressing than those underlying a clear understanding of the field of service that may appropriately be maintained by the individual college or university. In recent years the growth of student enrolments and the comparative ease with which funds could be secured have led institutions to increase their offerings without due regard to the possibility that at some time they might find themselves unable to maintain so expanded a service. The question whether expansion at one institution would result in unwarrantably duplicating the work of others appears to have been seldom if ever considered. The present economic situation has checked this movement sharply. Universities and colleges in increasing numbers are now asking just how they severally may best fit themselves into an adequate but economical system of higher education to serve a state, a region, and the nation.

Part I of this study describes the status of higher education in ten selected states as disclosed by the number, types and locations of institutions, methods of their control, and their curricular offerings. Selection of the particular states has been made with a view to exemplifying the variety of practices in vogue rather than on a basis of population, size or geographic

location. In describing the method of control, the authors treat public and private institutions separately. There is no attempt to appraise conditions found; the facts are allowed to speak for themselves.

The "Trend Toward Unified Control" is the title of the second study in this volume. In most of the states a multiplicity of institutions of higher learning have arisen, largely in response to local demands, and without any coordinating influence or central control. Since all of them, however, looked to their respective legislatures for support, the time was bound to come when their expanding and uncorrelated programs would be called in question. In recent years there has been a well marked trend toward the creation of a single body in each state to direct and control all of the tax supported colleges. A brief account is given of the process by which in thirteen states a central governing board has replaced the numerous independent bodies which formerly exercised the state's authority in the field of higher education.

While the several states naturally vary in their methods and policies, the general expectation is that educational opportunities for the youth of the United States should be essentially uniform. Some of the underlying factors affecting such opportunity are presented in part III. For each state are shown in tabular form the population, resources, student enrolment and revenues of public and private institutions. Also given are certain derived data, such as the estimated wealth per inhabitant from 18 to 21 years inclusive, and receipts for current expenses of public and private institutions calculated in terms of the population of 21 years and over.

From this wealth of statistical data, members of legislatures and other state officials may derive, not much comfort perhaps, but abundance of food for reflection.

La gastrophotographie. Par Pierre Bernay. Préface du Docteur Ch. Garin, professeur agrégé à la Faculté médecine de l'Hôtel-Dieu de Lyon. Paper. Price, 50 francs. Pp. 116, with 94 illustrations. Paris: Masson & Cie, 1931.

The first part of the volume deals with the development of the technic of gastrophotography by Porges and Heilpern, the special technic employed in the present investigation, precautions to be observed, and untoward reactions in the patients. Then follows a description of the appearance of the different regions of the normal stomach accessible to photography, amply illustrated. The remainder deals with the photographic appearance of the gastric mucosa in ulcerative gastritis, gastric cancer, gastritis, pernicious anemia, benign gastric tumors, gastric resections and gastro-enterostomy, all well illustrated with photographs arranged for stereoscopic vision. All photographs are attached to the pages so that they can easily be detached and placed in the stereoscope. The material is clearly presented. The monograph is modest in its claims for gastrophotography, both as to diagnosis and as to research.

Hydrotherapy in Hospitals for Mental Diseases. By Rebekah Wright, M.D., Hydrotherapeutist, Massachusetts Department of Mental Diseases. Cloth. Price, \$3. Pp. 396, with 92 illustrations. Boston: Tudor Press, Inc., 1932.

A book dealing exclusively with hydrotherapy has not been published for some years. In no other field of medicine is hydrotherapy so important as in mental diseases. Therefore there is an important place for such a book as this, and this book admirably fills this need. The book is divided into four parts. The first part considers in detail the technic of the hydropathic procedures that have proved practicable in hospitals for mental diseases. The directions are clear and concise and the illustrations are excellent. The second part is a short discussion of the training and duties of a hydrotherapist, the care of a hospital department, and the records and reports that a hydrotherapist should keep. The third part is for the physician who prescribes hydrotherapy for mental diseases. It considers the scientific basis of hydrotherapy, the effects of the various hydropathic applications, and the indications for hydrotherapy in mental diseases. The fourth part is for the superintendents of hospitals and sanatoriums for mental diseases and gives illustrations of equipment, floor plans and chapters on the construction and equipment of various hydrotherapy departments. It is a book that should be read by physicians interested in the treatment of mental diseases, studied by hydrotherapists in hospitals for mental diseases, and used for reference by superintendents of such hospitals.

Lehrbuch der Histologie und Histogenese. Von Dr. univ. med. Josef Schaffer, o. ö. Professor der Histologie an der Universität in Wien. Third edition. Cloth. Price, 20 marks. Pp. 576, with 640 illustrations. Leipzig: Wilhelm Engelmann, 1933.

A thorough presentation of subject is not often attempted in a textbook—in fact, few authors of such works know enough to do so. In this revision of his standard textbook Schaffer gives one of the few complete expositions of histogenesis and histology in the narrower sense. Unlike Maximow, he has restricted his field largely to structures that the medical student can be expected to see with the optical equipment at his disposal. There is, however, good evidence that cytologically distinct cells have different functions and that emphasis on the internal anatomy of cells is important for the development of histophysiology and pathology. The section on the organs of internal secretion, which has been largely rewritten for this edition, suffers especially from the failure to describe cell types. Aside from this, only minor criticisms can justly be made. The elimination of some sections of the second edition has made possible eighty new illustrations and numerous additions to the text, practically without increasing the size of the volume. Only a master could have written the concise and comprehensive historical introduction; its expansion is a welcome feature and should impress even a tyro. The space devoted to bone and teeth is still out of proportion to the rest, but this is perhaps justified by the author's extensive researches in the field. The clear general discussion of nervous tissues roused the hope that the new section on neuroglia might bring some order into the chaos; but this is expecting too much in the present state of our knowledge. The description of the vascular system does justice to a usually neglected field. Other valuable chapters are those on the skin, the digestive system, the placenta and the eye. The emphasis on the study of maceration preparations is also to be commended. The schemata and general theory of Schroeder have been introduced into the chapter on the female reproductive system, but various old inaccuracies still remain. The addition of a selected bibliography will be welcomed by teachers and is evidence of increasing interest in original sources among elementary students. The paper and illustrations are better than in the previous edition and the price is low for a work of such general excellence—a welcome feature in a German publication at the present time.

Gonorrhea in the Male and Female: A Book for Practitioners. By P. S. Pelouze, M.D., Associate in Urology and Assistant Genito-Urinary Surgeon of the University of Pennsylvania. Second edition. Cloth. Price, \$5.50. Pp. 440, with 92 illustrations. Philadelphia: W. B. Saunders Company, 1931.

The first edition of this work appeared under the title of "Gonococcal Urethritis in the Male" and confined its scope to this restricted phase of the subject. As many cases of gonorrheal infection in the male develop manifestations apart from the urethral inflammation, the omission of a discussion of the complications and remote manifestations of the disease was a serious drawback. However, the present volume covers in an able manner, in excellent arrangement, the subject of gonorrhea; and while one may not agree with certain of the deductions of the author noted throughout the volume, his insistence on the "utmost gentleness in the treatment of gonorrhea" is most heartily concurred in. The author gives the results of careful observation and extensive experience with a disease which up to the present time has generally been poorly treated. The recommendations for treatment in the various phases of the infection, both in the male and in the female, leave little to be desired, at the present state of knowledge.

Chemical Wave Transmission in Nerve. By A. V. Hill, F.R.S., Foulerton Research Professor of the Royal Society. Based on the Liversidge Lecture delivered at Cambridge on 13 May 1932. Cloth, \$1.25. Pp. 74, with 13 illustrations. New York: Macmillan Company; Cambridge, Eng.: University Press, 1932.

Dr. Hill provides a brief but clear, readable and authentic summary of what is now known concerning chemical and physical changes in nervous tissues induced by activity in the nerve cells and their processes. The monograph, being a lecture before British chemists, is primarily directed to laymen in biology, including chemists; but so many new and important facts in the field of nervous physiology have been established in the last few years that most physicians who graduated more than ten years ago can read it with profit.

Medicolegal

Malpractice: Failure to Use X-Rays.—The defendant treated the patient's arm, Dec. 3, 1930. He found a dislocated wrist and a lacerated wound on the back of the hand. The wound was treated, antitetanus serum administered, the dislocation reduced, and the arm put into an aluminum splint. The splint fitted the lower part of the hand and forearm only. On the following day a roentgenogram was made, but it was not made for the purpose of detecting a fracture and it did not disclose a then existing fracture of the radius. Two days after the accident, the defendant-physician assured his patient that no bones were broken, although, according to the patient's statement, the patient called his attention to a "scraping of the bones." The patient continued to have trouble with his arm, and on January 27 he returned to the defendant for further treatment. A roentgenogram then made showed a fracture of the radius, badly united. Two operations followed, but they left the radius so crooked as to make permanent the dislocation at the wrist and impairment of the arm. The patient brought suit, the trial judge directed a verdict for the defendant-physician, and the patient appealed to the Supreme Court of Wisconsin.

Expert testimony showed that the x-rays were customarily used by physicians in the vicinity where this case was treated, to diagnose fractures and to keep a check on the progress of the healing. The defendant-physician had x-ray apparatus and a fluoroscope in his office. The court concluded that under such circumstances the jury was entitled to believe that a proper discharge of the defendant's obligation required a more frequent and timely use of the x-rays than was made. Evidence was offered to show, too, that in treating a fracture of the radius it was customary to immobilize an arm both at the elbow and at the wrist and that the splint used by the defendant in this case was too short to effect such immobilization. There was therefore sufficient evidence, in the opinion of the court, to carry the case to the jury on the question of the defendant's negligent diagnosis and treatment. To prove that the defendant's failure properly to diagnose and treat the fracture had injured his patient, it was shown that the sooner a fracture is discovered and dealt with, the better the result usually obtained; that good results ordinarily follow proper treatment, and that the result in the present case was consistent with negligent diagnosis and treatment. The fact that open reductions of fractures are often necessary, and angulation and bowing of bones may result in the absence of negligence, as shown by the evidence in this case, did not leave the jury to speculate as to the causation of the patient's condition, since a finding can rest on a preponderance of probabilities. The judgment of the trial court was reversed and the cause remanded for a new trial.—*Schwartz v. Zellmer (Wis.)*, 245 N. W. 585.

Administration of Drugs by Iowa Osteopaths Unlawful.—A licensed osteopath prescribed for a patient a mixture of sodium bicarbonate, bismuth subcarbonate and magnesium oxide, to be taken internally. The state of Iowa, through its proper officers, contended that this was the practice of medicine and instituted proceedings to enjoin the osteopath from engaging in such practice without a license so to do. The court issued an injunction and the defendant osteopath appealed to the Supreme Court of Iowa.

The osteopathic practice act of Iowa (section 2554, Iowa Code, 1931) provides that a license to practice osteopathy or osteopathy and surgery shall not authorize the licensee to prescribe or give internal curative medicines. This, the defendant contended, authorizes a licensed osteopath to prescribe and give internal medicines that are not curative. The medicines prescribed in this case, she claimed, were prescribed, not to effect a cure, but to relieve distress. She argued that she had a right to prescribe them and should not be enjoined from doing so. The Iowa statutes do not define the words "internal curative medicine." The Supreme Court of Iowa, however, in *State v. Gibson*, 199 Iowa 177, 201 N. W. 590, declared that those words are not to be given a technical meaning but are to be construed in their usual and ordinary sense. Under that rule of construction it would seem that the legislature intended by this phrase to embrace more medicines than those technically known as specifics.

Moreover, when it is remembered that osteopaths do not deeply study pharmacology or materia medica, it seems hardly possible that the legislature intended to confer on them the right to prescribe or give all internal medicines except specifics. When the defendant used in the treatment of her patient the internal curative medicines that she prescribed, she practiced medicine. If an osteopath practices medicine without a license to do so he is subject to a penalty and in addition may be enjoined from practicing medicine without a license. A license to practice osteopathy is not a license to practice medicine. The license of an osteopath does not authorize him to go beyond the boundaries of his own calling and engage in another for which a different license is required. The injunction restraining the defendant from practicing medicine was affirmed.—*State v. Stoddard (Iowa)*, 245 N. W. 273.

Contracts: Limitation of Area of Practice; "Within Radius of Fifteen Miles" Construed.—The defendant, a licensed physician, practiced in the borough of Boswell, Pa. On March 2, 1928, he agreed to sell to the plaintiff, also a licensed physician, his house, office equipment, surgical instruments, and the good will of his practice, and to refrain from practicing "within the radius of fifteen miles from the borough of Boswell," for fifteen years after the date of the agreement. About Oct. 1, 1929, he opened an office in Johnstown, Pa. The distance between the plaintiff's office in Boswell, which he had purchased from the defendant, and the defendant's newly opened office in Johnstown, was 12.2 miles in an air-line. The plaintiff therefore entered suit to restrain the defendant from violating the terms of his contract. The trial court construed the words "within the radius of fifteen miles" to mean within fifteen miles computed, not by air-line, but by the nearest traveled way, and because the distance between the two offices computed in that way was 15.4 miles, the court dismissed the suit. The plaintiff appealed to the Supreme Court of Pennsylvania.

The meaning of the words used to define the area from which the defendant agreed to withdraw from practice, said the Supreme Court, is plain, unambiguous, and definitive. If the defendant intended when he sold his practice in Boswell to describe a district irregular in shape, its boundaries to be dependent on accessibility by public roads, he should have said so. The boundaries of such an area would necessarily have elements of uncertainty, for there might be dispute about which of several public roads was the nearest traveled public way. The court has no power to substitute for the words "a radius of fifteen miles," the words "fifteen miles by the nearest traveled public way or road," for the context of the agreement and the circumstances of the case exclude such substitution.

The case was remitted to the court below, with instructions to restrain the defendant from further violation of his contract.—*Johnson v. McIntyre (Pa.)*, 163 A. 290.

Bone Tumor Attributed to Trauma.—On or about Jan. 6, 1931, the plaintiff was loading a gas shovel on to a flat car. A plank that he was using to tighten a cable slipped, and the plank swung around and struck him. He was thrown from the car to the ground, striking his left hip and his abdomen. The defendant's physician, who treated him at the time, found a fracture of some ribs on the right side and injuries to a kidney and the stomach. After a time the plaintiff returned to work. In the latter part of April he had a severe pain in his back and in his left leg. He continued at work until August 27, when the trouble with his back and leg compelled him to desist. Roentgenograms showed a bone tumor, the exact location of which the published record does not disclose. In a suit arising under the workmen's compensation act of Nebraska, the physician who treated the plaintiff testified that the history of bone tumors shows in most cases that they arise from trauma and that it was generally agreed by all bone authorities that such a condition was usually the result of trauma. This opinion was concurred in by the physician by whom the roentgenograms were taken and by another. On behalf of the defendant, testimony was offered to show that trauma does not cause a tumor, although one physician testified that if there were signs of external violence and if the plaintiff had black and blue marks at the time of the injury, he would say that a trauma was the cause of his condition. From an examination of all the evidence, said the Supreme Court of

Nebraska, before which the case had come on appeal, we conclude that there is ample testimony showing that the tumor is a direct result of the injury suffered by the plaintiff.—*Stone v. Thomson Co. (Neb.)*, 245 N. W. 600.

"Good Health" Defined.—On March 12, 1928, the plaintiff went to St. Louis, Mich., where he took baths and consulted a physician. He was up and about, going to shows, circuses, etc. The physician who attended him testified that the ailment from which his patient was suffering was temporary, not serious, and that the patient left fully recovered. On March 16, 1928, the defendant delivered to the plaintiff a policy of insurance against sickness, which provided that the insurance was not to be in force unless the policy was delivered while the insured was in good health. On or about May 2, 1928, the plaintiff entered on a protracted period of sickness. This suit was to recover from the insurer the benefits to which the plaintiff claimed he was entitled under his policy by reason of that sickness. The defendant insurer denied liability, on the ground that the plaintiff was not in good health when the policy was delivered. The trial judge instructed the jury that "good health" means that a person "is free from disease that would seriously affect the general soundness of the system, and that he has not been attended by a physician for a serious ailment," and the jury rendered the verdict in favor of the plaintiff. The defendant insurer appealed to the Supreme Court of Michigan. The evidence of the plaintiff himself and of the physician who was attending him when the policy was delivered, that the plaintiff's ailment was temporary and not serious, gives support to the finding of the jury that the plaintiff, despite the ailment, was in good health at the time of delivery. The verdict therefore, said the Supreme Court, must be sustained. That it is against the great weight of the evidence was a question not presented on the appeal.—*Ligrow v. Abraham Lincoln Life Ins. Co. (Mich.)*, 245 N. W. 498.

City Liable for Typhoid Fever Contracted Through Public Water Supply.—The city of Helena, Montana, furnishes water to its inhabitants. The plaintiff contracted typhoid fever through water so supplied and sued the city to recover damages. The district court dismissed the action and the plaintiff appealed to the Supreme Court of Montana. The city contended that in furnishing water it acted in its governmental capacity and therefore was not liable and that in any event the laws that created a state board of health and county and city health departments deprived the city of its control of its water supply and relieved the city of responsibility. The city of Helena, in engaging in this type of activity, said the Supreme Court, stands on the same footing as a private individual or a business corporation similarly situated. The activities of the city in supplying water for domestic purposes, for pay, carry with them the duty to exercise care commensurate with the risk involved and to see that the water that it supplies is free from filth and germs that will affect the health of consumers. To allege that health officers have been negligent is no defense to a charge that the city knowingly delivered polluted water. The action of the district court dismissing the case was reversed and the cause remanded for further procedures.—*Campbell v. City of Helena (Mont.)*, 16 P. (2d) 1.

Evidence: Bias of Expert Witness May be Shown.—It does not constitute prejudicial error for counsel to bring out on cross-examination the fact that a physician testifying as an expert witness is a regular examiner for the insurance company in whose behalf he is testifying and that he is paid by the insurance company. Such evidence bears on the bias, credibility and interest of the witness. Cross-examination of this character, however, in the opinion of the Supreme Court of Idaho, should be carefully controlled by the trial court.—*Curtis v. Ficken (Idaho)*, 16 P. (2d) 977.

Workmen's Compensation Acts: Refusal to Undergo Fourth Major Operation.—Where an employee has undergone three major operations, his refusal to undergo another, the beneficial results of which are in doubt, does not constitute such unreasonableness as to preclude his right to compensation under the workmen's compensation act of Utah.—*Standard Coal Company v. Industrial Commission of Utah (Utah)*, 16 P. (2d) 926.

Society Proceedings

COMING MEETINGS

American Association of Railway Surgeons, Chicago, August 10-12. Dr. Louis J. Mitchell, 29 East Madison Street, Chicago, Secretary.
American Congress of Physical Therapy, Chicago, September 11-15. Dr. F. B. Balmer, 185 North Wabash Avenue, Chicago, Secretary.
Colorado State Medical Society, Colorado Springs, September 14-16. Mr. Harvey T. Sethman, 537 Republic Building, Denver, Executive Secretary.
Kentucky State Medical Association, Murray, September 11-14. Dr. A. T. McCormack, 532 West Main Street, Louisville, Secretary.
Michigan State Medical Society, Grand Rapids, September 12-14. Dr. F. C. Warnshuis, 148 Monroe Avenue, Grand Rapids, Secretary.
Ohio State Medical Association, Akron, September 7-8. Mr. Don K. Martin, 131 East State Street, Columbus, Executive Secretary.
Utah State Medical Association, Salt Lake City, September 14-16. Dr. L. R. Cowan, 305 Medical Arts Building, Salt Lake City, Secretary.
Washington State Medical Association, Seattle, August 28-30. Dr. Curtis H. Thomson, 1305 Fourth Avenue, Seattle, Secretary.
Western Branch Society, American Urological Association, Vancouver, B. C., August 3-5. Dr. George W. Hariman, 999 Sutter Street, San Francisco, Secretary.

SOCIETY FOR THE PREVENTION OF ASPHYXIAL DEATH

New York State Conference on Problems Relating to Death from Asphyxiation, held in New York, May 24, 1933

The President, PALUEL J. FLAGG, M.D., New York, in the Chair

Infant Deaths, with Special Reference to Asphyxia

DR. SHIRLEY W. WYNNE, New York: The infant mortality rate achieved in this city last year was almost down to 50 per thousand births, a rate that would have been thought impossible of attainment a generation ago. However, this low rate represented the death of 5,594 infants, and it is well to inquire whether many of these deaths could not have been prevented. During the past generation most of the reduction in the infant mortality rate has occurred in diseases of the digestive system; also some in the death rate charged to the pneumonias and to the infectious diseases. There has been little change in the rate charged to premature birth, injury at birth and other diseases peculiar to early infancy. Our great problem now in infant mortality is the reduction in neonatal deaths; i. e., the deaths which occur in the first few days of life. Of the infant deaths in New York City from 1929 to 1931, inclusive, nearly 24 per cent occurred in the first day of life; over 38 per cent occurred during the first week, and more than half of all infant deaths occurred in the first month.

It is clear that the activities carried on by the department of health can have little effect on about 40 per cent of the infant deaths, and I do not see how the pediatricians can contribute very much more. The great loss of infant lives occurs before the pediatrician has charge of the infants. The organized medical profession should face the facts brought out in this analysis and take steps to reduce what I consider to be still a considerable proportion of preventable deaths. Could not a considerable proportion of the deaths charged to atelectasis and asphyxia neonatorum be prevented by proper treatment? This, and other questions which a study of the causes of death during and immediately following childbirth would suggest, deserve careful attention. The problem of preventing deaths from atelectasis, asphyxia neonatorum and aspiration pneumonia might well be studied by this newly organized society. The department of health welcomes every effort which holds out the promise of reducing our mortality rates.

The Society for the Prevention of Asphyxial Death has suggested that the geographic location of areas in the city with excessive infant mortality rates would be of service, with a possible view of locating a future ambulance service. In Manhattan the "sore spots" for infant mortality are the central Harlem health center district, with a rate of 97 as against 72 for the borough as a whole, the Lower West Side, with a rate of 80, and East Harlem, with 77. However, in some of these districts there are so-called health areas in which the rates are considerably higher. Thus, in central Harlem there are two areas with rates of 121 and 119, respectively. An area on the Lower West Side has a rate of 107 and one in Kips Bay-Lenox Hill a rate of 104. Similar tabulations are available

for the entire city and will gladly be placed at the disposal of the society. It may be that the first efforts to reduce infant deaths caused by asphyxia should begin in these "sore spots."

DISCUSSION

DR. HAVEN EMERSON, New York: Every new movement dealing with the extent and quality of deaths reveals an inadequacy of fundamental information. The very development of this movement calls attention to the fact that two fundamentals are lacking on which social intelligence, en masse action or governmental action can be taken. One is the necessity for current reporting of all cases of sickness that come into the hands of institutions or medical agencies, or, it is to be hoped, ultimately into the hands of individual physicians. I should like to use the terms that are proposed by the biologists in discussing cellular survival. Death may be considered an irreversible process. But death by drowning at a certain point is a reversible process. So, in all these categories of deaths, those are being discussed which are reversible by means of technics now available, those which are really postponable, and those which are inevitable. The postponable deaths are those which occur in the course of poliomyelitis. It is not uncommon in an epidemic of poliomyelitis to find a person suffering from respiratory paralysis which is not necessarily of a permanent kind. If these patients are relieved for a period while the congested stages of the lesions in the spinal cord and bulb are recovered from, they may recover and carry on a reasonable normal life afterward. But if the damage is of a structural and permanent kind, affecting the anterior horn cell, a postponement of death may be effected by means of artificial respiration, but no recovery. So the approach to this problem demands that potential deaths be looked at from various points of view. I have fixed in my mind what is certainly a sharp impression in that of almost any young physician: the first instance in which a baby fails to start breathing because of conditions that have preceded in the length of the confinement, and finding oneself with all the usual physiologic resources uneffective simply for the lack of what is now available in artificial external negative pressure applied to the thorax. Dr. Wynne's analysis is clear in defining that fraction of all deaths under 1 year that may conceivably be preventable by appropriate technics at the time of birth or within the first few hours, or even within a day or two of birth. He estimated that there might be 400 lives saved a year in this city from deaths from asphyctic origin occurring in little children. This is twice as many as that now occurring annually from diphtheria, showing the expense quite properly incurred because of the knowledge in the matter of preventing those 200 deaths from diphtheria each year. A little intelligent organization, a knowledge of the resources, will achieve as much quantitatively in the saving of life from this group of deaths as it will in diphtheria. Physicians are sensitized, as it were, to the moral responsibility to remove diphtheria. We sort of feel that the death of an infant from asphyxia is an unavoidable accident, something unpreventable, unforeseeable. We have got to give up that attitude and determine the sources that are now available through the teaching of physiology, through the ingenuity of chemists, physicists, and mechanics, which can be brought to bear at the time and place where these deaths may be expected. There are only two problems of preventive medicine: One is a knowledge of the expected prevalence, the location, the distribution, the time and place and age occurrence of a disease that we think is preventable. The second one is the specific employment of preventive resources. We are further along in the analysis of the specific means of prevention than we are in a knowledge of the distribution or prevalence of these conditions. The state department of health can require that no laboratory offering diagnostic service should be without certain facilities for diagnostic aids in infectious diseases, that their technics must be of a certain quality, and that they must have personnel of a certain skill. An attempt to translate that theory into the operation of hospitals I believe would do damage at this stage, which is the experimental stage. Physicians do not know just what instruments or skills or materials are going to be always necessary. It is rather for us, through such a society as this, to make it common for institutions to have certain minimum essential conveniences with which to meet what are frequent emergencies. It can be

stated that for every 10,000 patients in a year there are going to be a certain number with an asphyctic emergency, and to meet those it would be suggested that this and that kind of equipment be provided. The final stage in any movement such as this is initiating will be expressed when the actuaries, the underwriters, the financially interested concerns attempt to express as a fixed human hazard these forms of accidental death as a basis of insurance. The insurance companies, quite aware of these deaths, have lost the significance of them because the international list of causes of death has been bent on etiologic factors and anatomic types of causes of death rather than having from all different categories a particular form of death assembled under one title. There is no such thing as the vital statistics of asphyxial deaths in the United States now.

Medical Examiners' Findings Relative to Asphyxial Death

DR. HARRISON S. MARTLAND, Newark, N. J.: [This paper consisted largely of references to colored lantern slides.]

DISCUSSION

DR. THOMAS A. GONZALES, New York: In regard to the strangulation cases presented by Dr. Martland, I have found that, in a series of about fifty cases of asphyxia due to ligature, suicidal deaths, in most instances there is little change in the internal tissues of the neck. That is ordinarily described in books as hemorrhage, tears and so forth of the inner number of thoracic arteries and various other ligaments. The striking feature of these cases is the strangulation mark on the skin of the neck. This is probably because in most suicides the body drops a short distance in contradistinction to legal executions, in which the body may drop 6 or 8 feet, with considerable trauma to the neck, even resulting sometimes in a fracture. In some strangulation cases, the marks on the neck are slight or absent, especially when soft material has been used in the strangulation. Among the fatalities in which there is difficulty in making a diagnosis are those due to general and local anesthesia and exposures to noxious gases in certain industries. With the possible exception of chloroform, which usually is easily extracted from the tissues, I have had difficulty in recovering the drug which is used in the anesthesia; in fact, repeated chemical analyses have been futile in this respect, and in all types of anesthesia, local and general. There has been no difficulty in recovering cocaine in suicidal deaths. In anesthesia there is a small quantity used, and in suicides generally large quantities are used. There is another factor perhaps in the cases in which the dosage is small: the drug splits up in the body rather quickly. Other conditions are often looked for to explain these deaths, such as status lymphaticus and, in older people, cardiac lesions and lesions in other organs. The clinical symptoms of these cases are often misleading. A man had an ulcerated bleeding carcinoma of the urinary bladder. Following spinal anesthesia, air was injected into the bladder for the period of the operation, and he died in a few minutes. The case was thought to be an anesthetic death because quite a number of spinal anesthetic deaths occur. The autopsy revealed air in the venous sinus. My opinion was that air entered in the dilated venous sinus in the ulcerated wound. There was frothy blood in the right heart. The blood vessels around the bladder were filled with air. In New York City in a year there are between 300 and 400 cases of accidents by carbon monoxide poisoning, without any relation to suicide. A great majority are from illuminating gas. A small percentage are from coal gas. Another small percentage are from the exhaust gases from combustion engines. In some carbon monoxide poisonings, the late effects are extremely interesting. Exposure to a massive dose or exposure to a repeated small dose may produce symptoms that are very important. These persons have headaches, a sense of constriction about the head, vertigo, dizziness, tremors and apathy, and they are stuporous at times. In the massive exposures there often occur cases ending in death; but when these patients come out of the carbon monoxide they have tremor and a mask-like face closely resembling the face of Parkinson's disease. Most of the accidental gas cases can be prevented. Most of them are due to carelessness. An educational program like the one the Society for the Prevention of Asphyxial Death is trying to put forward is of great importance. The

society should also back legislation to prevent the use of defective fixtures, which are the responsibility of the owner of the house and not of the gas company. I have seen many instances in which carbon monoxide poisoning could have been prevented if the fixtures had been taken care of.

The Economic Aspect of Asphyxial Death

ALBERT W. WHITNEY, New York: I understand death from asphyxiation to mean any death from any cause whatsoever in which life might possibly have been saved if artificial respiration could have been induced; in other words, cases in which the proximate cause of death is inability to breathe.

A distinction will have to be drawn between cases in which prevention of death is theoretically possible and cases in which it is practically possible. All deaths by drowning are evidently due to asphyxiation, the word being used in this sense, but there are only a part of such deaths in which aid can be got to the drowning person; in a large number of cases the body is not even recovered. Evidently the most valuable statistical study will be one that undertakes to present the number of cases of asphyxiation in which it would have been physically possible to furnish aid that might have saved the life. It is very difficult to get statistical data bearing on this subject. Dr. Murphy, chief statistician for vital statistics of the Bureau of the Census, has been kind enough to furnish me what statistics he has, but this material deals only with the first part of the subject and is even then inadequate. One readily realizes what a difficult thing it is. One encounters all kinds of points of view. One point of view of the value of the human life might be the wealth produced, divided by the lives, or something like that. But the point is that it is a decidedly moot question and can be looked at from many points of view. One extreme point of view would be what the insurance company has to pay in a damage suit. That, of course, is based on what a jury thinks a life is worth.

There is no way to deal with the second part of the problem except by the use of judgment. Dr. Flagg's estimates for the city of New York are as follows: general asphyxia, 934; stillbirth, 946; atelectasis, 336; pulmonary complication, 158; premature birth, 426; total, 2,800. Taking the population of New York City to be 7,000,000 and the population of the United States to be 126,000,000, that would mean that these figures would have to be multiplied by 18 to get the approximate figure; that is, 50,400 for the United States as a whole. These figures for stillbirths, atelectasis and premature birth seem to me high. I have no figures for pulmonary complication.

The economic value of a human life is a moot question. The book by Dublin and Lotka entitled "The Money Value of a Man" gives the present worth (at a discount rate of 4.5 per cent per annum) of net future earnings (that is, earnings less living expenses) for an income class of \$1,000 a year at \$750 for age 0 and \$9,400 for age 30. Dublin and Lotka actuarially compute the value of the future earnings of a new-born baby at \$1,000 a year. This of course includes the probability of death at these various ages. If one computes that on an actuarial basis and takes out of that each year the living expenses, one finds on that basis, at a discount rate of 4.5 per cent, assuming ordinary mortality, that the value of a baby's life is \$750. In other words, the probable value of the difference between the earnings and the living expense for a baby that was just born would be \$750. For a man aged 30, it would be \$9,400. I am not saying that this is the proper figure. Of course many of the people that are drowned are not wage earners. It is assumed that these figures are applicable to the present case, the economic value of these 50,400 lives will be \$207,824,400.

DISCUSSION

LEON SENIOR, New York: Since Mr. Whitney's speculations on the economic value of human life are nothing more than speculations, I shall not take issue with him. I will confine myself to a subject with which I am familiar, workmen's compensation insurance. Institutions that insure the obligations of the employer for loss due to work accidents are interested in methods of prevention and in the restoration of the worker to life and health. Education is the foremost method in accident prevention. Insurance carriers hold to the doctrine that all accidents are preventable through education and proper supervision. The state labor department is one of the agencies for

establishing rules as a basis for education. In dealing with the subject of accidents due to asphyxiation, the Industrial Code provides the following rule:

Rule 741. All dust, fumes, vapors, gases, fibers, fogs, mists, or other atmospheric impurities that are emitted or created in quantities tending to injure the health of employees in or in connection with any process of manufacture which involves the formation or use of substances . . . that can be detected by a recognized standard method of chemical analysis shall be removed by means of suction devices as far as practicable at their point of origin.

Carbon monoxide, chlorine and cyanogen compounds are among the harmful substances which produce injuries unless proper precautions are taken against asphyxiation. Rule 724 of the industrial code provides that

Every workroom in which carbon monoxide is emitted or created in or in connection with any process of manufacture shall be provided with such ventilation that the carbon monoxide shall not exceed two parts in ten thousand volumes of air in any occupied part of such workroom.

For the calendar year 1931 the New York Labor Department showed 122 cases of compensated accidents due to gases. These 122 cases resulted in 28 deaths and 94 temporary disabilities, costing the insurance carriers and consequently the employers \$184,000. Carbon monoxide and dioxide was the cause of 51 cases, of which 3 were deaths; illuminating gas caused 32 accidents; hydrocyanic acid resulted in 4 cases, of which 1 was fatal. Electrical shock, if classed as causing asphyxial death, shows 647 cases in one year, of which 60 were death and permanent disability, and 530 temporary disability, with a total cost of \$555,853. Gas explosions produced 131 cases, of which 5 were deaths and 108 temporary disability at a cost of \$56,255. In the mines, black damp is formed by the combustion of nitrogen and carbon dioxide. Fire damp is formed by an explosive gas called methane. Acetylene mixed with air becomes an asphyxial hazard dangerous to industry. Blast furnace gas contains from 24 to 30 per cent of carbon dioxide. The extraction of gold from ore requires the use of chemical salts which, when in contact with air, form the deadly asphyxiant hydrocyanic acid.

I have encountered numerous cases of preventable losses due to asphyxia. About four years ago two men were killed in a plant located at Corlears and Water streets, New York. All employees had been warned to vacate the plant on Saturday afternoon, at which time it was to be fumigated by the releasing of cyanogen gas on the premises. Two of the workmen either neglected to comply or forgot the warning and went to the basement to sleep. Both were found dead on the following Monday after the factory had been cleared of gas. A thorough inspection of the premises might have saved the lives of these two men. In another plant in New York, an employee last winter, while admitting chlorine gas into a tumbler of starch in order to bleach it, loosened the coupling that closed the chlorine gas container. He was overcome, was rushed to a hospital, and died of asphyxiation. The accident might have been prevented if the employee had been thoroughly educated in the danger of his occupation. The newspapers, May 22, carried the news of a catastrophe in Newark, N. J., in which five men lost their lives in a gas pit of the tannery. A review of the case leaves one astonished at the contempt for the danger shown by the workmen and the firemen who attempted rescue efforts.

Prevention measures lie partly in the field of safety engineering and partly in the field of medicine. Industrial safety engineers have given much time to the study of accident prevention and to educational work. The time has come for the medical profession to undertake the second part of the problem; namely, the study of methods for restoring the injured after the occurrence of the accident. There is an economic aspect of huge importance to saving lives of men in industry, most of whom have dependents who have no other resources than the wage earned by the workman. Workmen's compensation is but a poor substitute for that wage, and yet workmen's compensation in this country represents a cost of at least \$150,000,000 per annum. This cost paid for insuring compensation benefits under the laws of our several states is the economic contribution, the economic loss, if you please, paid by society for work accidents, many of which are preventable. This economic loss takes no account of the physical and mental suffering, of broken homes, of injured workmen, of widowed mothers and orphaned children. Society has become, so to speak, acclimated to these results of industry using deadly

implements to accomplish its purpose to the point at which most persons accept the situation as beyond repair. It is the duty of technicians in public economy and in safety engineering and of physicians to arouse the public conscience, to dramatize the facts, and to encourage the men and the organizations that seek by research and study to reduce the social and economic loss resulting from the use of dangerous implements or substances in industry.

Modern Methods of Resuscitation in New York City

DR. DANIEL J. DONOVAN, New York: The police department of New York City, in discharging its primary function of safeguarding life, is constantly confronted by the three great emergencies of death by drowning, by gas poisoning and by electrical shock. The city of New York, with its heterogeneous mass, comprising twenty or thirty nationalities, is recognized as the largest asphyxiation ground in the world. Here it is that derelicts on the sea of life come from the four corners of the earth in a last desperate attempt to repair the ravages of fate and, failing, seek a painless path to eternity by means of gas poisoning or drowning. Here it is that from among the thousands who go in bathing during the torrid months of the year, many are rescued from the water only to die on beaches, docks and waterfronts because of the widespread lack of knowledge of how to apply artificial respiration. Deaths occasioned by drowning, gas poisoning and electrical shock approximate 12,000 in the United States annually. It is estimated that between 40,000 and 50,000 cases are successfully treated by the application of artificial respiration measures. When an unfortunate is rescued from the river or surf or is found inert in a gas-filled room or has been apparently shocked to death by contact with a live wire, the fact that he has ceased to breathe is not in itself an indication that death has taken place. There are records of submersion from eighteen to twenty minutes, after which the victims went on to complete recovery. However, it is probable that after from twelve to fifteen minutes' submersion recovery will be very unlikely. We all know we can hold our breath and the heart continues to beat. A very determined individual could probably hold his breath until he lost consciousness, but then he would breathe again and would soon be as well as ever.

If a person is submerged in water or if anything stops breathing, how long will the heart continue to beat? That is the time in which to start artificial respiration if recovery is to be effected. The nearer to the moment that breathing has ceased artificial breathing is instituted, the greater are the chances of success. If one is to treat successfully a person critically overcome by submersion, by gas poisoning or by electrical shock, one does so by substituting an artificial method of breathing for the natural one.

About fourteen years ago I became interested in the subject of artificial respiration. The problem, as I saw it, was how to equip as great a portion of the general public as possible with the knowledge necessary to act effectively when confronted with the emergencies of drowning, gas poisoning and electrical shock. It appeared to me that the teaching of artificial respiration should be made an integral part of the training of future police officers in the recruits' training school, as, aside from the direct effect of making these officers potential salvagers of human life, their demonstrations of the efficacy of artificial respiration when confronted with impending tragedy in the field of their daily duties would serve as a means of arousing the citywide interest of the public. About ten years ago I caused to be inserted in the curriculum a course of training in the Schäfer prone pressure method of artificial respiration. During their three months at the recruits' training school, every future police officer of New York City is thoroughly taught to apply this treatment.

In cases of gas poisoning, artificial respiration is supplemented by the use of a special apparatus known as the inhalator. The use of this apparatus does not supplant the application of artificial respiration but is used in conjunction with it. Carbon monoxide kills by altering the blood so that oxygen cannot be gathered by the blood in the lungs and carried throughout the body. When the blood has gathered carbon monoxide, it will lose it if the patient is placed in fresh air and breathes fairly well. It has been found that carbon monoxide will leave the body more rapidly if pure oxygen is

breathed instead of air, which is only one-fifth oxygen. Accordingly, gas victims are given oxygen by means of the special apparatus known as the inhalator, which consists of tanks containing 93 per cent oxygen and 7 per cent carbon dioxide. The latter stimulates breathing considerably and causes a patient to take larger breaths and more of them. The increased vigor of breathing brings in more oxygen and replaces the carbon monoxide with greater rapidity.

In 1925 the police department inaugurated its present emergency truck system, enabling me to put the inhalator to practical use. Police emergency trucks are high powered motor cars, built on the order of fire patrol trucks. A crew of twenty-one men is assigned to each, divided into three squads, and are on duty twenty-four hours daily in eight hour shifts. They are used only in emergencies, such as explosions, railroad disasters, fires and occurrences of lesser magnitude, such as a gas poisoning case in which emergency treatment is essential. At present there are twenty police emergency trucks on constant duty. Each truck is equipped with an inhalator and every member of the crews is adept in the use of the inhalator and the application of the Schäfer prone pressure method of artificial respiration. The records on file in the chief surgeon's office at police headquarters bear eloquent testimony to the efficacy of artificial respiration in cases of drowning, gas poisoning and electrical shock, and the supplementary use of the inhalator in gas poisoning emergencies.

Fundamentals of Peroral Endoscopy (Laryngoscopy)

DR. CHEVALIER JACKSON, Philadelphia: The easiest way to present the fundamentals will be by means of lantern slides. Twenty years ago, Yandell Henderson had not said in making his discoveries that carbon dioxide must be given in conjunction with oxygen. It was thought that the carbon dioxide was acting somewhat in the manner in which carbon monoxide is now known to act. Carbon dioxide was thought to be toxic. Twenty years ago the oxygen tank was without any carbon dioxide because nothing was known about that. An oxygen tank is connected up by means of a pipe, the bronchoscope insufflating oxygen directly into the lung. Before insufflation, the secretion is taken out by negative pressure, by aspiration. Bronchoscopy for asphyxia is not done outside the bronchoscopic clinic. My associates and I never do a bronchoscopy without having the oxygen tank beside the table, because asphyxia is one of the emergencies we must always be prepared to encounter. We encounter asphyxia 500 times to the once that we have any trouble with the artery circulation. When we have a patient with normal asphyxia, in order to get a straightened rigid tube around all the corners, running around the corners back of the tongue and then into the larynx, we have four different angles to turn. In order that the straightened rigid tube, the bronchoscope, may be introduced, the patient must be in a certain position. His head must be elevated so as to bring the trachea in line with the operator's eye, provided the patient is not asphyxiated. When a patient is asphyxiated, he is as limp as a rag. With an instrument one can look directly down into the trachea without any resistance on the part of the patient, because he is completely relaxed. One thing about asphyxia is complete and absolute relaxation after respiration has stopped. We are careful to lift the patient's upper lip to put it out of the way. The directoscope is put in, and by a lifting motion the curves are obliterated. The cross-section of the head of a man who was asphyxiated with suicidal intent shows the crowding back of the tissues. In a patient asphyxiated from suicidal intent, everything is crowded back against the back wall and the larynx is completely obliterated.

Supposing that man is cut down before his heart has stopped. We put in a laryngoscope, lift up on it, pull away, pull all of these tissues that have been crowded back by the rope; we lift those away to clear that area. In nearly all anesthetics there is a dropping back of the tongue and all the tissues. It is to clear this airway that Dr. Flagg devised a laryngoscope available for general use for the prevention of asphyxia. It has prevented thousands from passing away under anesthesia by clearing the airway. This instrument is not used to pry on the upper teeth. It is a lifting motion. The whole head is lifted off the table in order to clear this area. The operator can look straight into the windpipe, put in an aspirating tube

and clear out the obstructing mucus. He is then ready for the insufflation of the oxygen with its 5 to 10 per cent of carbon dioxide.

There is no use trying to force in oxygen and carbon dioxide when the larynx is plugged up. This drives the plug in tighter. The only way one can determine whether or not there is any obstruction is to look and see. One looks in the mouth but can't see down to the larynx unless the tongue is displaced with the direct laryngoscope.

A bronchoscopic operating room is prepared to deal with obstructions in the air and food passages and to deal with every emergency and every problem that can arise. It is adapted for the relief of asphyxia in patients who can be brought in. Practically none of the patients whose deaths Dr. Donovan cited could be taken to a bronchoscopic clinic in time to save their lives. To save those lives, something a great deal better mobilized than a bronchoscopic clinic must be available. There must be some sort of ambulance service that can get promptly to the patient and that can be equipped not only with the small instrumentarium required, but with men trained in its use. That is an absolute necessity.

A patient who is asphyxiating from any obstruction above the level of the clavicles gives unmistakable signs of what is the matter with him. At every inspiration his chest sinks in. There is a sinking in at the suprasternal notch. On expiration those depressions fill out. The patient takes another inspiration and again this sinking in occurs. The patient is becoming asphyxiated from an obstructive larynx dyspnea. It does not occur in asthma, in cardiac dyspnea, in any form of dyspnea but the obstructive larynx dyspnea, which is the most common of all forms of surgical dyspnea. I am not speaking now of gas accidents in asphyxia or of the industrial accidents.

Here is the other symptom: He is restless. He is working so hard to pump in air that he doesn't want to be bothered. He doesn't want to take food. He just wants to be let alone. He is putting in all his time to pull in air, because there is a sinking of the suprasternal notch. That is a typical picture of asphyxia from an obstructive larynx dyspnea. After the breathing is stopped, one will have to get it started again.

DISCUSSION

DR. CHARLES J. IMPERATORI, New York: I agree with the method that Professor Jackson has presented. This method of Dr. Flagg's represents an emergency station in contradistinction to bronchoscopic clinics that are the repair shops. With regard to trauma and other objections that have been raised to this method, I can positively say that there are no traumas that will ensue provided the individual doing the laryngoscopy and the intubation has been given sufficient instruction and has sufficient intelligence. Any method, no matter how simple, can be made, one might say, a destructive method if the individual using it does not use his intelligence. The objections that have been raised at times that the intubation of the larynx will produce a paralysis of the cords and a stretching of the cords so that it will interfere with the voice eventually, and so on, are not to be considered, since this is a life-saving procedure. What is done by this method of Dr. Flagg's is, as it were, to extend the trachea and bronchi out beyond the mouth and beyond this danger zone, which has been described by Professor Jackson. And then, by the insufflation or the introduction of oxygen, the needed air or needed oxygen is supplied to the individual, plus this method of gas therapy. Gas therapy is not a new thing. It has been used for a long time. But with this method of Dr. Flagg's he has made it easy for those who are not continuously doing these bronchoscopic procedures. Formerly oxygen was used simply in the way of a mask or a tube and the patient's mouth and face were sprayed with the oxygen. But if the tongue had dropped back into the mouth and there was a great deal of secretion, even though the tongue was not pulled forward, frequently there would not be enough pressure to get the oxygen down into the trachea. These instruments that have been devised by Dr. Flagg are of great importance. There are certain things that must not be forgotten. There is still the operation of tracheotomy, which may be necessary following this procedure. I know it is not Dr. Flagg's idea that this is to supplant tracheotomies when they are necessary. This is entirely an emergency measure.

Fundamentals of Asphyxia

YANDELL HENDERSON, PH.D., New Haven, Conn.: This article appears in full in this issue of THE JOURNAL, page 261.

DISCUSSION

DAYTON J. EDWARDS, PH.D., New York: The primary disturbance in asphyxia is a reduction in the quantity of oxygen supplied to the tissue cells. Although oxygen is indispensable to the life of the cells, an excess of this substance has a toxic action. This presents, therefore, one of the most important problems in physiology, namely, the nature of the mechanism of the control of respiration, and the best means of supporting the respiratory process when a condition of failure seems imminent. It is recognized that carbon dioxide plays an indispensable part in the control of respiration. Much credit is due Dr. Henderson for focusing attention on this discovery and for reiterating with emphasis its practical significance. Experimental workers, while fully aware of the fact of diminished carbon dioxide during the early stages of anesthesia, have been slow to adopt corrective measures. At present the disastrous results of a moderate degree of asphyxia, plus the excessive decrease in the carbon dioxide of the blood, is a familiar sight in student laboratory work. The combination of partial anesthesia, a beginning asphyxia, and a reduction in blood carbon dioxide by hyperventilation is peculiarly lethal in effect. It is not surprising that difficulties have been encountered in establishing in clinical practice the principles of the use of carbon dioxide. The encouraging results reported are a tribute to those whose teachings have been carried on for years in the face of difficulties.

That the administration of carbon dioxide serves in some way to excite the respiratory center and thereby greatly increase the volume of air exchange in the lungs per minute is an easily demonstrated fact. But unless it can be definitely shown that continued carbon dioxide stimulation tends to establish favorable physiologic conditions in the organism, this procedure would seem to be of limited service. Dr. Henderson does not specifically state that an increased oxygen utilization occurs under carbon dioxide stimulation, but one is led to infer that this must result from the favorable oxygen-carbon dioxide relationship which he postulates.

In the use of carbon dioxide in asphyxia the conclusions to be drawn are (1) that it excites the respiratory center at a time when such a measure is desirable and (2) that it acts as a therapeutic agent to establish favorable physiologic relations. The grounds for the first claim seem quite easy to understand, particularly as applied to carbon monoxide poisoning and the postanesthetic period, since it is known that the ventilation of the lungs becomes increased through its action, and this brings into play essential factors to displace the monoxide combination of hemoglobin with the useful oxyhemoglobin. The other question, namely, the therapeutic effects of increased carbon dioxide, is more difficult to rationalize. Dr. Henderson stresses the rôle of carbon dioxide in restoring a favorable bicarbonate relation in the blood with an accompanying recovery of the normal irritability of the respiratory center. It is not easy to follow all the reasons for the bicarbonate shift, and questions will doubtless arise concerning this. Moreover, if the administration of carbon dioxide is not indicated in all cases of asphyxia, is it possible to set down quite precisely its indications? A question arises also whether there may not be overdosage effects. One group of observers state that breathing a 7.5 per cent mixture of carbon dioxide for twenty minutes produces a shock from which the system does not wholly escape for some hours. May not cardiac and vascular factors play essential rôles? Indeed, there is evidence that carbon dioxide exerts a definite effect on cardiodynamics, and recent experiments indicate that it produces changes in the caliber of the cerebral vessels which may have a bearing on other observations that the volume flow of blood through the respiratory center plays an important part in its regulation.

One need not be greatly concerned with one theory or another as to how carbon dioxide acts, since any theory one wishes to adopt will not alter the facts. The real answer is given by the results obtained in the use of carbon dioxide under carefully controlled conditions. The evidence is favorable.

(To be continued)

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Folliculin in Involutional States.—Sevringhaus presents the results he obtained in a series of thirty-two women, who presented psychic and nervous phenomena that are commonly associated with the involutional state, and whom he treated with folliculin. Hot flashes occurred in all the patients of the series, paresthesias in sixteen, insomnia in nineteen and psychotic pictures in seventeen. Obesity was observed in only thirteen, and hypertension in ten. Of this series six had artificial climacteric produced by irradiation or surgery, and there were three patients with a spontaneous premature menopausal picture, possibly to be considered as ovarian insufficiency. The author found the use of simple psychotherapeutic procedures and small doses of folliculin daily or oftener helpful in the psychotic cases as well as in the simpler vasomotor types and the pseudothyrotoxic types previously reported. The refractory nature of the artificial menopause leads to a discussion of the possible relationships of the pituitary and the ovaries at the age of the climacteric. Overdosage has caused the reappearance of menses in one truly menopausal woman, has provoked menorrhagia and increased dysmenorrhea in an early menopausal patient, and a single dose of 50 units has produced in still another woman a violent and persistent hot flash with great discomfort; therefore the author's dose in the present series was from 10 to 25 units at one time, given once or twice daily.

Gonorrhea in Immature Women.—Schaeffer and Kuhn state that douches, instillations and injections have been used empirically and ineffectually for too many years in the treatment of vaginal gonorrhea in the immature. They believe that the most effective approach is through the use of a relatively firm ointment base, injected by a technic that insures the pro-

duction of sufficient intravaginal pressure to cause invasion of the ointment into every crypt and corner. They recommend the use of plain anhydrous wool fat, incorporating an appropriate concentration of any worthwhile antiseptic. They use 1 per cent silver nitrate. The ointment should not be warm, as its quality of firmness facilitates distention of the vagina with the use of mild intravaginal pressure. Also, it is more easily and completely retained if cold and has the highest possible fluid affinity, which makes it a highly effective vehicle for carrying the antiseptic into the moist vaginal wall—in contrast to the usual petrolatum base, which is repulsed by moisture. Their clinical studies have been supplemented by the injection of postmortem specimens by this technic. By this method they have obtained a consistent, complete and satisfactory application of the medicament, which remains in the vagina over periods varying up to forty-eight hours. The use of this method in more than 2,000 treatments has in no instance resulted in any untoward incident.

Study of Abdominal Hysterectomies.—Samuels and Edlavitch report a series of 303 consecutive abdominal hysterectomies performed for a variety of pathologic conditions in which there was a mortality of 2.6 per cent. Approximately 85 per cent of the uteri were removed for myomas, chronic pelvic inflammation and malignant conditions, and the important symptoms necessitating surgical aid were pain, bleeding and tumor. There were eight instances of cancer of the fundus of the uterus and cancer of the cervix, four of each. Statistical reviews of major surgical operations at periodic intervals will reveal many interesting facts and tend to increase the efficiency of the surgical departments of hospitals.

Mitochondria and Dextrose-Glycogen Equilibrium in the Liver.—Hall and MacKay produced disturbances of the dextrose-glycogen equilibrium in the livers of rabbits by feeding them large quantities of dried and fresh carrots followed by periods of fasting, by feeding dextrose to the fasting animals and by injections of epinephrine in the fasting animals. Excessive amounts of glycogen, as high as 13.1 per cent, were obtained in the animals fed on dried carrots. Amounts ranging from 3.5 to 5.7 per cent were obtained in the animals fed fresh carrots and in those given dextrose. Injections of epinephrine produced mainly glycogenolysis. Marked changes in the mitochondria were observed in the animals fed on dried carrots. In place of the usual short bacilliform rods, long filaments, coarse spherules and plump rods were found condensed about the nucleus and to a lesser degree about the cell membrane. Twelve hours after fasting, this group produced coarse spherules without definite arrangement in the cytoplasm. Many of these

appeared to be semifluid. The administration of dextrose caused hypertrophy and enspherulation of mitochondria, with some tendency to paranuclear arrangement. The authors conclude that some relation exists between the mitochondria of the hepatic cell and the dextrose-glycogen equilibrium. They are unable to say whether or not the chondriosomes act as catalysts, as they appear to do in the synthesis of fat within the hepatic cell.

Effect of Roentgen and Gamma Rays on Human Skin.

—Duffy and his associates chose patients at random and administered the predetermined dose in order to determine the production of erythema in the human skin. Each patient was seen at weekly intervals for at least four weeks, and the presence or absence of reaction was noted. In their series of tests, the extensor surface of the forearm was used for all irradiations. This field was chosen because the 700 kilovolt machine activates a horizontal tube. Three types of radiations were used in these experiments: radiations produced by 200 and 700 kilovolts, and gamma rays from the radium element pack. Roentgen rays produced at 200 kilovolts were taken as the norm with which the other types of rays were compared. The roentgen output was measured physically before each set of skin tests, so that the error from daily fluctuation was avoided. Roentgen rays at 200 kilovolts produce a threshold erythema on the extensor surface of the forearm with 540 roentgens, measured in air. The rate of output of the 700 kilovolt machine as measured by this biologic effect is 8.6 roentgens per minute at a distance of 50 cm. The 4 Gm. radium pack at 6 cm. has an output of 2.8 roentgens per

minute according to the erythema reaction test. The calculated equivalent outputs of the pack for 10 and 15 cm. distances are 1.2 and 0.57 roentgens per minute, respectively.

Clinical Observation of Roentgen and Gamma Rays.—McNattin summarizes his clinical observations as follows: 1. Therapeutic doses of comparable effectiveness may be administered to tumors of the upper respiratory tract by the divided dose method, using 200 or 700 kilovolt roentgen rays, or gamma rays of radium. 2. A survey of such cases treated at the Memorial Hospital with each of the three qualities of radiation indicates that the tumor doses which, as a first approximation, may be considered to be therapeutically equivalent, are: for 200 kilovolt roentgen rays, 6 threshold erythema doses; for 700 kilovolt roentgen rays, 4.7 and, for gamma rays, from 1.6 to 2.2 threshold erythema doses, each administered fractionally over a period of three weeks (or longer in the case of gamma rays). The threshold erythema unit used by the author is equivalent to 600 roentgens of 200 kilovolt roentgen rays filtered by 0.5 mm. of copper and 3 mm. of aluminum, including back scattering, and administered at one time. When these tumor doses are administered, the skin reaction is marked in the case of the 200 kilovolt roentgen rays, also with the gamma rays, and, thus far, the least severe reaction has been in the cases treated with 700 kilovolt roentgen rays. On the other hand, after the skin has healed, the mildest subsequent changes are found in the cases treated with gamma rays. The constitutional effects have been relatively mild in patients treated with 700 kilovolt roentgen rays, and about equally severe in all cases treated with 200 kilovolt roentgen rays and those treated with the radium pack.

Diagnosis of Endemic Typhus and Rocky Mountain Spotted Fever.—Badger states that two members of the worldwide typhus-like group of fevers occur endemically in the United States: endemic typhus and Rocky Mountain spotted fever, which is now known to occur in widely separated sections of the country. The identification in the laboratory of an unknown strain of virus as one of endemic typhus or as one of spotted fever is based on the following criteria: The clinical manifestations and pathologic anatomy produced in animals by the unknown virus must be similar to those produced by the known virus; agglutinins for *Bacillus proteus*, X₁₀ are produced in the serum of the rabbit and the monkey; definite and complete cross immunity is produced with a known strain of the suspected virus. In addition to these criteria, the cultures of the cardiac blood of animals from which transfers are made must be consistently negative bacteriologically. In performing cross immunity tests, precautions must be taken to rule out secondary infections and nonspecific immunity.

Typhus.—Kemp attempted to cultivate the virus of typhus from the blood of ten patients with endemic typhus. He used dextrose-cystine-brain-veal agar, a medium known to be suitable for the cultivation of *Pasteurella tularensis*. Incubation was carried out aerobically and under conditions of reduced oxygen tension. Gram-positive diphtheroids were obtained from six of the ten patients, and a gram-negative rod belonging to the proteus group was obtained from two. None of these organisms produced signs or symptoms of typhus when inoculated into guinea-pigs. The same animals were not immune to typhus passage virus. Attempts to cultivate the virus from blood cultures or infected tissue (guinea-pig tunica vaginalis) on Kendall's K medium, both liquid and solid, were completely unsuccessful. A strain of *Bacillus proteus* (American type culture 881), carried through ten generations on liquid K

mediums with both daily and weekly transfers, did not become pathogenic for guinea-pigs. The same animals were found afterward not to be immune to passage virus. Evidence obtained from tissue culture seems to show that the virus is an obligatory parasite. Cultivation in the living animal body (Zinsser and Castaneda) seems to offer the best means for developing quantities of the virus.

Cicatricial Stenosis of Larynx.—Clerf reports a series of twenty-eight cases of cicatricial stenosis of the larynx found unsuitable for direct laryngoscopic dilation. All the patients had been tracheotomized for relief of dyspnea. In twenty-one, high tracheotomy had been performed; in sixteen there was an atresia of the airway. There was atresia in twelve of the thirteen cases of postdiphtheritic stenosis. Fifteen cases were treated by laryngostomy, followed by packing the larynx and using various forms of tube dilators. Atresia was present in seven of these cases and a portion of the cricoid cartilage had been destroyed in nine. One patient became discouraged and discontinued treatment. Three have not been cured, although an epithelialized airway is present. The author concludes that improperly performed tracheotomy and inadequate after-care are the most common factors in the etiology of cicatricial stenosis of the larynx. Recognition of this fact is of great importance in prophylaxis. The translaryngeal fixation operation seems to be the method of choice in the treatment of cases of cicatricial stenosis of the larynx that cannot be treated by the more conservative methods. This procedure obviates the need for frequent, time consuming, painful dressings and changes of apparatus. The duration of treatment and the period of hospitalization are shortened. Results, even in cases in which there is a loss of the normal supporting tissues of the larynx, are uniformly good.

Sympathetic Nervous System and the Internal Ear.—Murphy studied the effect on the labyrinth of interruption of the cervical sympathetic innervation in animals and in man. The first, second and third thoracic ganglions as well were interrupted in some of the cases. Spontaneous phenomena relative to the labyrinth were absent. Variations beyond normal limits in the threshold of excitability of the labyrinth could not be determined. General vasomotor changes, evidenced by pallor and sweating, were the same, regardless of the side from which they were induced. The variations in past pointing can be accounted for by the increased muscular tone in the extremity rather than by labyrinthine influence. The vaso-

dilatory innervation to the inner ear may be part of the cranio-autonomic system.

Epistaxis in Pregnancy.—Strauss reports a case of epistaxis in a pregnant woman, aged 27, in whom there was constant bleeding until ligation of the external carotid was performed on the seventh day. There was no further nose-bleed. On the ninth day the patient aborted a four to four and a half months old fetus. She was discharged on the ninth postoperative day. From the study of this case and a review of the literature the author concludes that, in a case of severe uncomplicated epistaxis when local treatment and transfusion fail, ligation of the external carotid should be performed to save the life of the patient. Severe epistaxis during pregnancy may be stopped by terminating pregnancy. Ligation of the external carotid artery to stop epistaxis in pregnancy should be preferred in order to save the life of the child.

- *Attempt to Transmit Poliomyelitis to Splenectomized Guinea-Pigs. H. Chor, St. Louis.—p. 387.

Anatomic Lesions from Salyrgan.—Rosenthal states that, although the impression of the lesser toxicity of salyrgan is probably justified, he presents a report that concerns a patient with congestive heart failure who received this mercurial diuretic shortly before death and who showed definite anatomic signs of mercurialism at necropsy. Since only a small quantity of salyrgan was given, the author's patient apparently possessed an increased susceptibility to the drug, a suggestion supported by the evidence found by Andrews in his case. In view of the increasingly widespread use of salyrgan and the numerous favorable reports from experimental and clinical studies of its action, this case is of interest, since it supports the doubt held by some authors as to the absolute harmlessness of the drug by the actual demonstration in man of structural lesions due to the presence of mercury in the tissues.

Attempt to Transmit Poliomyelitis to Splenectomized Guinea-Pigs.—According to the experiments of Chor, splenectomized guinea-pigs do not acquire the nerve lesions characteristic of poliomyelitis following inoculation with potent monkey virus, either in direct or in passage experiments. Splenectomized guinea-pigs show a decrease in resistance to such inoculation, which produces in many a condition characterized by fever, general sluggishness and lymphoid hyperplasia, with death often occurring within fourteen days.

Cancer of Cervix Uteri.—Behan states that, in cancer of the cervix, surgery, which includes endothermic removal and desiccation, does not give as good results as does surgery and irradiation. When ligation of the blood supply in addition to increased calcium intake and proper diet and hygiene is added to surgery and irradiation, there is an increase in the percentage of three and five year cures, and better results are attained than with surgery alone or in combination with irradiation. From the author's point of view, auxiliary methods of treat-

ment are only indications of one's efforts to seek other means, in addition to those usually employed, for the improvement of cancer patients.

Wound Healing in Anterior Gastro-Enterostomy.—Martzloff and Suckow present a study based on experimental observations on forty-four dogs, which they undertook in order to determine whether serosal cysts would form between apposed peritoneal surfaces and also what differences, if any, occurred in healing following the use of various suture methods. Anterior gastroduodenostomies were performed by various suture methods, while the suture material was uniform throughout. The most rapid and uncomplicated healing on the anterior aspect of the gastroduodenal ostium was obtained by the use of a single layer of serosubmucosal presection silk sutures. Separate suture of the mucosa, whether employed anteriorly or posteriorly as in the three layer suture methods, not only is unnecessary for rapid mucosal healing but is probably a retarding factor and therefore an undesirable as well as an added technical step. Mucosal healing, like healing along the line of apposition, was most rapid with one layer presection sutures. Four types of suture methods were used on the posterior aspect of the gastroduodenal ostium. The best healing was obtained either with an inner row suture passed through all coats of the stomach and intestine as an ordinary continuous stitch or with a similar suture passed through serosa and submucosa, leaving the cut edges of the mucosa free. The latter confirms the authors' observations on the anterior aspect of the ostium, that separate suture of the mucosa is not necessary for rapid mucosal healing. Good posterior healing was also obtained with the three layer suture technic, and most undesirable of all was the healing following the use of an inner row lock-stitch suture, which has a strangulating effect on the involved tissue. The authors believe that their observations warrant the conclusion that fine plain catgut, when passed through the entire thickness of the gastric or intestinal wall, does not cause the development of mucosal inclusions along the course of the suture, as in the case of improperly placed silk suture material. Their observations also indicate that when silk suture material is placed without piercing the gastro-intestinal lumen its presence causes practically no inflammatory reaction. Halsted sutures so placed tend to migrate toward the serosa, while those that pierce the mucosa become infected, are the cause of mucosal inclusions in the intestinal wall and slough into the lumen either through the intestinal wall or along the line of apposition. If silk suture material is used, it is probably preferable to use interrupted sutures.

Experimental Ileus and Sodium Chloride.—In high intestinal obstruction an important factor in the cause of death is the loss of digestive secretions. This view is supported by

Jenkins and Beswick's experiment, in which some animals lived from fifty-two to seventy days with a high obstruction. The rôle of the sodium chloride solution, administered daily through a jejunostomy opening below the obstruction, was to replace the water and important blood electrolytes, fixed base (chiefly sodium) and chloride ions, ordinarily lost through failure of resorption and vomiting. In regard to obstruction low in the intestinal tract or complicated by necrosis of the intestine, the loss of digestive secretions may be a factor in the cause of death; but this is of varying importance, depending on the length of intestine above the obstruction which would offer opportunity for some resorption of the secretions. It is in this group that toxemia probably plays the more important part, and in man operative treatment should be resorted to immediately. The beneficial effect of the administration (subcutaneously or intravenously) of saline solutions clinically in cases of intestinal obstruction appears to depend largely on the extent to which the body has suffered from the loss of digestive secretions from failure of resorption and vomiting. When toxemia is a conspicuous factor, its benefit may be masked to some extent.

Syphilis of Stomach.—Meyer and Singer state that the features that serve to distinguish syphilis of the stomach from carcinoma are as follows: There is a striking disparity in many cases between the extent of the lesion as determined roentgenologically and the extent as observed operatively by palpation. Whereas in carcinoma one generally finds at laparotomy a more extensive involvement than the roentgenogram indicates, in syphilis of the stomach there is a surprising paucity or complete absence of changes as determined by palpation. The common lesion of gastric syphilis is not a spherical prominence as in a tumor, gummatous or neoplastic, but a flat infiltrate that leads to a plaque-like thickening of the gastric wall. When thin, the infiltrate is readily overlooked. When thick, its relatively soft consistency and pliability distinguish it from carcinoma. On cross-section, the increase is seen to be due to an edematous fibrous tissue located chiefly in the submucosa. Inspection of the interior of the stomach generally discloses one or more superficial, serpiginous ulcers involving a large part of the plateau formed by the infiltrate. The base of the syphilitic ulcer, contrary to the peptic variety, is situated at a higher level than the normal mucous membrane. Fibrous and edematous thickening of the serosa and adhesions, when present, suggest an inflammatory rather than a neoplastic lesion. Associated syphilitic changes that may be detected during the course of the operation include hepatic, intestinal and splenic syphilis. Of these, the coexistence in the liver of gummas, deep stellate scars or subtotal destruction of the left lobe is of greatest aid in the recognition of the type of gastric disease present. The authors report two cases in which the gross features of the gastric lesion led to the correct diagnosis. One patient was operated on by a colleague who, on palpating the stomach, immediately apprehended that he was dealing with an unusual condition and predicted with confidence that the involvement was syphilitic. The diagnosis in the other patient was based chiefly on the observations made at operation, since from biopsy the condition was reported as simple nonspecific inflammation.

Resected Knee Joints.—Ghormley and Brav studied the clinical history, roentgenograms, lesions discovered grossly and microscopically and results of inoculation of guinea-pigs in a series of 236 resections and nine amputations of the knee joint. The preoperative diagnosis was found to be incorrect in 24.4 per cent of the cases of tuberculosis and in 13.7 per cent of the cases of nontuberculous arthritis. The gross specimens and roentgenograms were found to vary so widely as often to prevent the possibility of accurate diagnosis. The inoculation of guinea-pigs proved incorrect in 12.5 per cent of the twenty-four cases in which inoculation was made. The diagnosis made by microscopic examination of tissue removed at the time of operation has been found to be accurate in all but 3.2 per cent of the cases, an error of omission.

Stab Wound of Heart.—Beekman reports two cases of stab wounds of the chest that involved the heart. In the first there was a perforating wound of the right ventricle, which was rapidly fatal as a result of loss of blood. In the second there was a penetrating wound of the musculature of the left ventricle, a cardiac tamponade developing, which was tem-

porarily relieved by the aspiration of blood from the pericardial sac; this case later came to operation, and the wound was sutured. The patient recovered, following a stormy convalescence in which pneumonia of both lungs, an abscess of the right lung and empyema developed.

Perinephritis.—Mathé states that suppurative and nonsuppurative perinephritis occur independently in a certain number of cases, besides being secondary to diseases of the kidney and other extraneous lesions. Chronic perinephritis is divided into (1) fibrosis of the renal capsule; (2) chronic cicatrizing perinephritis with sclerosis of the perineal fat; (3) fibrolipomatous perinephritis in which the fatty capsule is sclerosed, indurated and hypertrophied, sometimes forming a veritable lipoma, which may invade the renal parenchyma, and (4) suppurative perinephritis or perinephric abscess, in which the inflammatory processes have undergone suppuration. The diagnosis of chronic perinephritis is obscure. Important points in distinguishing it are persistent pain, absence of urinary changes and (the author's sign) lack of renal mobility, as evidenced by taking a pyelogram in the standing position. This lack of renal mobility demonstrates without any doubt that there are inflammatory processes of the perinephric tissues which anchor the kidney in place. The most important points in the diagnosis of perinephric abscess are persistent fever, relative lack of urinary changes, obscuration of the roentgenologic shadow of the kidney and of the muscular and skeletal structures of the renal fossa, displacement of the ureter, and immobility of the kidney as evidenced by palpation and when making a pyelogram in the vertical position. The treatment of persistent, chronic, cicatrizing and fibrolipomatous perinephritis consists of nephrolysis and partial decapsulation by which the kidney is decompressed and liberated from its pathologic encasement, adhesions and conglutinations.

Uterine Cancer.—During a ten year study of 219 consecutive patients with cancer of the female generative organs, Miller observed that the most significant early symptom of uterine cancer is abnormal discharge. Usually this appears as bleeding or "spotting" but may take the form of an abnormal leukorrheal discharge. The spotting is intermenstrual, progressive and prone to follow trauma. Spotting is far more significant as a symptom of cervical cancer than is leukorrhea. The sudden appearance of leukorrhea in older women or its

sudden change in character is also highly significant. The real need for a definite diagnosis in all patients with suggestive symptoms must be emphasized again and again. The possibility of cancer should be ruled out in every patient presenting indicative symptoms, even to the point of doing a biopsy with microscopic examination of the tissues, if necessary. Physicians who speak on cancer of the female generative organs should avoid discussion of late symptoms, which may lead the patient astray and defeat the purpose of the talk. The early symptoms may be ignored and the patient may wait for further evidence before having her innermost fears confirmed or refuted. Emphasis should be placed on spotting and abnormal discharge. The need for more extensive use of the surer methods of diagnosis is stressed by the high percentage of inaccurate diagnoses before admission.

Staining Bacterial Capsule.—Churchman and Emelianoff outline a new method for staining capsules. With this method appearances are produced about the somas of a number of non-capsulated organisms which resemble capsules. The best results have been obtained when young organisms (not more than 18 hours old) from a culture on solid mediums were used for study, although capsules have also been stained in smears from broth cultures and (in the case of *Diplococcus pneumoniae*) from sputum. Use is made only of stain and fixative, which are applied together. No steps are taken (like preliminary treatment with serum, acetic acid, nutrose), which are designed to render the capsule more readily demonstrable but are likely also to produce somewhat more artificial conditions. Films are made from aqueous suspensions of the bacteria and are air dried. They are then covered with 10 drops of freshly filtered Wright's stain, which is left on until it has evaporated nearly, but not quite, to dryness, when a purplish pink replaces the original color of the Wright's stain. It is probable that staining of the capsule occurs just at this instant. The evaporation usually requires about three minutes. The stain is washed off as rapidly as possible with Clark and Lubs' buffer pH 6.4

to 6.5 and immediately dried with a fan without blotting. Sometimes the capsule is more satisfactorily stained if the film is rapidly washed with distilled water after the buffer has been used. Excellent specimens may also be obtained by leaving the air dried film in Wright's stain overnight, removing and allowing the stain to evaporate as described, and then washing rapidly with buffer and drying with the electric fan.

Vitamin A Deficiency.—According to the experiments of Wolbach and Howe on white rats, in vitamin A deficiency the replacement stratified keratinizing epithelium is morphologically identical in all locations. All cells of the lowermost layer of the replacement epithelium have proliferative power as in the stratum germinativum of the epidermis. In recovery, in spite of the complete morphologic masking, the epithelium in each region returns to its normal type. The important histologic features of repair involve removal of the layers of cells irreversibly differentiated toward keratinization and direct differentiation of the stratum germinativum into the normal type. These take place simultaneously. The histologic sequences observed in the removal of cells above the stratum germinativum indicate that autolysis, as shown by vacuolar degeneration, and heterolysis, as shown by leukocytic infiltration, are involved. The cycle of metaplasia and recovery in vitamin A deficiency affords an experimental method available for the correlation of nuclear chromatin and types of cytoplasmic activities.

- Additional Note to Article "Studies on Tobacco Hypersensitivity." Marion B. Sulzberger, New York.—p. 265.

Comparison of Diphtheria Toxoid and Toxin.—Reiner prepared azodyes from crude and from purified diphtheria toxoid by coupling them with the diazonium salt of arsenic acid. The dyes obtained were purified by dialysis and precipitation with acid at about pH 4 and pH 3. The dyes had practically lost their immunizing power but retained their combining power as measured by the Ramon test. The specific toxic and the nonspecific reaction causing properties of the dye were approximately the same as those of the original toxoid or toxin. Micro-arsenic and nitrogen determinations were made on the toxoid dye. High values were obtained for the ratio of arsenic to nitrogen; hence a high content of cyclic amino acids in the toxoid or else a decomposition during the dye formation is assumed.

H and O Agglutination in Typhoid and Vaccination.—Dulaney and Wikle state that, in the usual course of typhoid, both H and O agglutinins are produced, H designating the causative organism and O expressing the body's response to infection with a member of the enteric group of bacilli. H and O agglutinins to appreciable titer (1:500) are not demonstrated in unvaccinated persons suffering from nontyphoid diseases. O agglutinins seem definitely related to infection. Their demonstration in 1:500 to 1:1,000 is highly suggestive of infection by a member of the typhoid-paratyphoid group, since neither vaccine nor other febrile diseases stimulate to such titers. Typhoid vaccine stimulates the production of H agglutinins to high titers and O agglutinins to low titers (1:40 to 1:320). The ordinary Widal test detects only H agglutinins and does not differentiate between infection and vaccination. The use of preserved formaldehyde treated and alcoholized antigens offers an easy and standardized method of demonstrating H and O agglutinins. H and O agglutination is recommended

as a laboratory procedure in typhoid, though it could never have the validity of isolation of the causative organism.

Cutaneous Epithelium in Immunity Response.—Dienes points out that the epithelium of the skin is probably sensitized in allergic (contact) dermatitis and certain cases of drug idiosyncrasy. The hypersensitiveness of the epithelium develops by contact with the injurious agent in the same manner as the usual forms of hypersensitiveness. The tuberculin type of skin reactions presents many characteristics that suggest the direct participation of the cutaneous epithelium in the reaction. The characteristic necrosis in the reactions is often limited to the epithelium and a thin layer of connective tissue below it. The epithelium is involved early before the macroscopic reaction is strong. The epithelium is often infiltrated with polymorphonuclear leukocytes even in slight tuberculin reactions. The occurrence of necrosis is in no direct connection with the size of the reaction or with the general sensitiveness.

- Emile Kraepelin, Psychiatrist and Poet. Louise Brink and S. E. Jelliffe, New York.—p. 274.

Subacute Combined Degeneration of Spinal Cord.—Olkon reports a case of severe anemia in which the final diagnosis was the Lhermitte symptom with degeneration of the spinal cord. The patient complained of numbness of the hands and fingers, tingling of the legs and arms, and electrical shock-like sensations on moving the head downward and then upward. The gait was at times dragging and spastic. The tendon reactions were exaggerated, more on the left side. The Rossolimo sign was present. The plantar reflex was suggestive of the extensor type; while not marked, it was not a negative one, particularly on the left side. The vibration sense was lost, indicating changes in the posterior columns. The Rossolimo and Babinski signs were indicative of changes in the lateral columns, particularly the pyramidal tracts. The increased lymphocytic percentage might suggest a form of leukemia, but, lacking all corroborative observations, such a possibility is negated. Multiple sclerosis and tabes were ruled out by serologic and clinical studies. The diagnosis of subacute degeneration of the cord was based on the progressive onset of the paresthesias, the dysaesthesias, the loss of vibratory sensation in the limbs, the achylia gastrica, which still persists, the progressive weakness with little loss of weight, the peculiarly lemon-tinged skin, the tachycardia without definite clinical heart involvement, and the remission under liver therapy. The author concludes that the Lhermitte phenomenon is unusual in this connection.

Anesthetic in Urology.—McKim and his associates used piperidinopropanediol diphenyl urethane hydrochloride for local infiltration anesthesia in concentrations varying from 0.25 to 1 per cent in a total of fifty-nine cases comprising fourteen cystotomies, six scrotal varicectomies, four operations for hydrocele, one epididymectomy, one orchidectomy, nine vasectomies, twelve urethral caruncles, one urethral varicotomy and eleven adult circumcisions. With one exception the results were

superior to those obtained in similar cases when using other local anesthetizing agents. The failure in a suprapubic cystotomy may have been due to a poor infiltration technic in an extremely nervous and apprehensive person. The authors injected 75 cc. of a 1 per cent solution of piperidinopropanediol diphenyl urethane hydrochloride but they made no subsequent check on the concentration of this solution. A light supplemental gas anesthesia permitted the satisfactory completion of the cystotomy. The amount of solution injected has varied with the type of surgical procedure contemplated. There has been no suggestion of toxic symptoms or local tissue irritation. A definite delay in the appearance of postoperative pain has been noted and the authors have been impressed with its mildness when it has appeared. They conclude that piperidinopropanediol diphenyl urethane hydrochloride commends itself to urologists because of its lack of local irritation, relatively high anesthetic properties, extremely low toxicity, prolonged anesthesia and ease of sterilization.

Traumatic Rupture of Urethra.—Haines feels that conservative treatment, especially in the hands of the less experienced, is a more satisfactory method of handling cases of incomplete or complete rupture of the urethra, whether in the bulbous portion or posterior to it, than is the more radical method advocated by many authors. He believes that each case is a case unto itself: no two cases will present the same identical injury, nor will any two show the same amount of shock or the same ability to combat it. Whether one relies on catheter drainage, suprapubic cystotomy, perineal section, end-to-end anastomosis, or a combination of all four depends entirely on the individual case, the length of time following the injury, and its severity. The condition of the patient should be the guiding factor in one's choice and method of treatment.

Stricture of Female Urethra.—Briggs points out that stricture of the female urethra is common in patients presenting urinary symptoms. Its incidence as estimated by various authors shows a wide variation but is probably not less than 10 per cent. Aside from congenital narrowing of the meatus and the atresia of age, most strictures are the result of trauma, regardless of whether the trauma is mechanical, surgical, chemical or bacterial. The pathologic changes that take place in the urethra account for the local symptoms, which in many cases are severe enough to throw the whole body out of balance, especially the nervous system. Aside from prostatitis, prostatic abscess and extravasation of urine, the symptomatology is identical to that in the male. More than 50 per cent of the author's cases presented a bacterial cystitis, which probably accounted for some of the bladder symptoms, especially when the stricture was of wide caliber. Diagnosis of stricture at the meatus can often be made at a glance. In deeper strictures, large catheters or bougies of graduated sizes should be used. The author made the diagnosis in most of his cases by the routine use of a number 18 F. glass catheter. Except in resilient strictures requiring repeated dilations, the prognosis

is good; but complete recovery is rare. A stricture of the meatus should be cut, and the prognosis is unusually good. In deeper strictures, gradual dilation is the treatment of choice.

Aschheim-Zondek Test in Teratoma Testis.—Lindsay believes that the term "early" in its application to the diagnosis and treatment of malignant disease is given a new significance by the appropriate use of the Aschheim-Zondek test. The application of the Aschheim-Zondek test to the study of malignant disease, including teratoma testis, sets apart another group of tumors which may be followed by graphic methods. He believes that this delineation of special groups amenable to special methods of diagnosis and control constitutes the most important phase of the attack on the cancer problem while one awaits improvements in the recognized procedures already available. A most important factor in the value of the Aschheim-Zondek test is its clear demonstration of significant general principles in relation to the local manifestations of cancer. The evidence resulting from the work so far accomplished in connection with the Aschheim-Zondek test appears to offer a most hopeful outlook for the development of other biologic procedures which may broaden the field of precisely studied neoplasms and lay the foundation for further improvement in both diagnosis and therapy.

Skin Testing in Asthma and Hay Fever.—O'Keefe and Burgin state that, in children with hay fever, the cutaneous or scratch method gave a high proportion (91 per cent) of positive reactions. The intradermal test is only slightly superior to the scratch test. In children with asthma, however, scratch tests showed a low proportion (30 per cent) of positive results. The intradermal test brings the proportion of positive reactions much higher (87 per cent). The scratch test is reliable in the hay fever of children, but in the asthma of children it should be followed by the intradermal test in all cases in which the scratch test is negative.

Relation of Bacterial Endocarditis to Rheumatic Endocarditis.—Davis and Weiss point out that the incidence of subacute and acute bacterial endocarditis among 5,215 consecutive necropsy examinations was 0.9 per cent and 0.4 per cent, respectively. A study of the interrelation between rheumatic and bacterial endocarditis revealed that approximately one case of subacute bacterial endocarditis occurred to every ten cases of rheumatic heart disease, and approximately one case of acute bacterial endocarditis to every twenty-five cases of rheumatic heart disease. One case of subacute bacterial endocarditis occurred to approximately every four cases of fatal rheumatic heart disease, and one case of acute bacterial endocarditis to approximately every nine cases of fatal rheumatic heart disease. Rheumatic heart disease occurred more frequently among women, but subacute and acute endocarditis superimposed on rheumatic heart disease developed considerably more often in men (ratio 3:1). The distribution of the degree of rheumatic valvular damage in the forty-seven cases of subacute bacterial endocarditis corresponded with that for 474 cases of rheumatic heart disease, indicating that the development of subacute bacterial endocarditis is independent of the degree of underlying rheumatic endocarditis. The apparent infrequency of advanced mitral stenosis with subacute bacterial endocarditis is explained by the fact that slight or severe "non-active" rheumatic valvular lesions predispose equally to the development of subacute bacterial endocarditis, and slight lesions are much more common than advanced ones. The same factor is held responsible for the relatively rare occurrence of severe congestive heart failure and auricular fibrillation in the course of subacute bacterial endocarditis. Instances of morphologic

evidence of varying grades of healing of the valves were encountered in subacute bacterial endocarditis.

Atropine in Appendicitis.—Findlay found the use of atropine to be of great value in differentiating the pain and tenderness due to acute appendicitis from that due to other conditions. In any suspected case of appendicitis, the patient, if an adult, is given $\frac{1}{400}$ grain (0.00065 Gm.) of atropine sulphate by mouth unless nauseated, in which case the drug is administered subcutaneously. A half hour later he is given an enema of 2 quarts of warm soap suds. After the enema is expelled the abdomen is carefully palpated and, if an area of distinct localized tenderness persists in the region of the appendix, a positive diagnosis should be made. If the enema has been only partially expelled and the entire cecum feels full or emits a gurgling sound on palpation, the atropine and enema may be repeated to ensure a thorough emptying of the large intestine. If either pain or local tenderness persists after this procedure, one is justified in making a diagnosis of appendicitis. The author has used this method for four years in a series of more than 300 cases of acute abdominal pain. Of the eighty-six patients operated on on the basis of the test, all but one have shown definite evidence of acute appendicitis. Acute appendicitis did not develop in any of the cases with negative observations in which operation was not performed. Patients suffering from food poisoning, infectious colitis and other forms of gastroenteritis have been given prompt relief from their discomfort by the administration of atropine, which has often been repeated two or three times.

Ruptured Aneurysm of Hepatic Artery.—Taylor reports a case of ruptured aneurysm of the hepatic artery in a man, aged 22, who entered the hospital suffering from a severe hemorrhage from the stomach and acute pain in the epigastrium. There was a history of some pain and distress in the epigastrium about a year before. Four months before admission he had an attack of acute pain in the right lower quadrant, followed by the removal of a gangrenous appendix. Otherwise his previous history was not important. He died eight months later. At necropsy there was no evidence of a malignant condition in any part of the body, or of ulceration in the stomach or duodenum, or of any way, macroscopically, by which bleeding could have occurred into the stomach. It is believed that because the aneurysmal sac communicated with the gallbladder the bleeding occurred into this organ and from there was transmitted to the duodenum and to the stomach.

Treatment of Bone Tumors.—Friedman states that, of the eight types of primary bone tumors, four are radiosensitive in varying degrees. They are, in the order of their radiosensitivity: endothelial myeloma, multiple myeloma, giant cell tumor and chondroblastic osteogenic sarcoma. This fact is helpful when employed as a therapeutic test to aid diagnosis in a doubtful case. Radiation therapy should be discontinued in favor of surgery if definite results are not obtained in six weeks. Malignant bone tumors are curable under proper therapy. The more differentiated the tumor (i. e., sclerosing osteogenic sarcoma), the higher is the percentage of five year cures. The more undifferentiated the tumor (i. e., osteolytic osteogenic sarcoma), the lower is the percentage of five year cures. The scope of radium and roentgen therapy in the treatment of bone tumors is still to be accurately delineated. No osteogenic sarcoma of any type should ever be curetted.

Radiotherapy of Thyrotoxicosis.—According to May, radiotherapy in the different types of hyperthyroidism should be recognized as one of the most powerful remedies. In plain hyperthyroidism and small toxic goiters it is superior to other methods. It is also indicated in cases of poor surgical risk. The mortality is less than 1 per cent and recurrences are fewer than with surgery. Surgery should be resorted to in acute cases of large toxic goiters with impending heart failure and in persons more than 60 years of age. Preoperative roentgen treatments will lessen the surgical risk and prepare the patient for thyroidectomy better than ligation of the blood vessels, in all cases in which surgery is given preference. Previous irradiation does not render the operation more difficult. Recurrences after operation respond well to radiotherapy. Of 160 patients treated with radiotherapy alone, 132 (82.2 per cent) were cured; 25 (15.6 per cent) were much improved, and 3 (1.9 per cent) were unimproved. Of these, 6 patients included (5 as improved and 1 as unimproved) with large toxic goiters were later operated on and are now cured.

Nutritional Anemia.—Scott and Delor present experimental proof that the nutritional anemia of the white rat may be relieved by either the feeding of milk from cows fed on a diet consisting of a warm malted and hydrolyzed hay and grain mixture to which a complex formula of mineral was added, or by the addition of an iron and copper free extract of alfalfa or of a liver oil high in vitamin A to the deficient milk diet. This growth promoting factor is absent or insufficient in the milk of cattle fed on the usual winter dairy ration. This factor, when present in milk following the special feeding of the cattle, is thermolabile. Further evidence has been obtained of the intimate relationship existing between the feed of the cow and the hematopoietic factor or factors in the milk. Milk, to be of the highest nutritive value, must contain the factors resulting from the presence of the vegetable pigments in the food of the cow. The rapidly growing belief in the close association between the vegetable pigments carotene and chlorophyll and vitamin A or its associated factors is strengthened by these experiments.

Evaluating Remissions in Dementia Paralytica.—Stout made a study of the speech, handwriting and tremor of 110 dementia paralytic patients. He noted the rate and degree of improvement following malaria, and the degree of synchronism between this improvement and improvement in the mental and emotional status. Improvement in the objective neurologic signs of dementia paralytica, especially in those due to cortical disease, is a most reliable sign of improvement in the physiologic state of the cortex. Improvement in dysarthria, in involuntary movement, and in the mental and emotional status of dementia paralytica patients becomes evident concurrently following therapeutic malaria. The spontaneous handwriting of these patients discloses not only involuntary movement but also by its content incoordination of thought. Improvement both in form and in thought content occurs following malaria and is evidence of clinical remission. By means of Whipple's steadiness tester, involuntary movements can be recorded and graphically compared. This affords a reliable objective test

for the degree of recovery. Advanced optic atrophy and profound dementia have been the only contraindications to this type of examination.

*Allergy in Tuberculosis: Study of Twenty Cases. B. Thompson, Tucson, Ariz.—p. 100.

Allergy in Tuberculosis.—In an attempt to study the part allergy plays in tuberculosis, Thompson tested the skin in twenty unselected cases of active pulmonary tuberculosis by the cutaneous and the intradermal method, utilizing extracts of 140 different antigens. The list of allergens used in testing comprised every known protein of possible allergic significance which may have come in contact with the body tissues of these patients by ingestion or inhalation. Of the twenty patients, fourteen retrogressed and six remained clinically stationary during the six-months period prior to the beginning of attempted desensitization, under a regimen of rest and of hygienic, dietary and conservative symptomatic treatment. On roentgenographic and physical examination, twelve patients showed advanced involvement with cavitation, two advanced involvement without cavitation, four moderately advanced disease, and two indications of incipient tuberculosis. Of these patients, seven had been diagnosed tuberculous for a period of five years or more, eleven for a period of from one to five years, and two for a period of less than one year. Of the twenty patients treated by antigen inoculation, eleven showed symptomatic improvement in an average period of 14.2 days, and nine were relieved of symptoms in an average period of 8.5 days. From this study the author concludes that chronic pulmonary tuberculosis may be a scavenger infection, progressing only in tissues rendered hypersensitive and inflamed by a variety of extrinsic and intrinsic allergens, or that tuberculosis may be a primary infection of the tubercle bacillus, producing a hypersensitivity not only to the tubercle bacillus itself but to other allergens, and that the repeated inoculation of these allergens, by crossed reaction, may produce a tissue immunity against the tuberculous

infection. The author's experiment suggests a mode of investigation and treatment in cases of pulmonary tuberculosis which have failed to respond to the time tested conservative methods. Its trial does not contraindicate the continuance of conventional therapy. By relieving irritative symptoms, with the object of putting the chest at rest, it may, however, be possible to shorten the period of tuberculous activity.

*Simple Inflammatory Ulceration and Stricture of Jejunum: Report of Case Successfully Treated by Operation. G. W. Nagel, San Francisco.—p. 159.

Inflammatory Ulceration and Stricture of Jejunum.—Nagel reports a case of stricture of the intestine with granulomatous ulceration and perforation and states that the actual causative agent in the nonspecific variety of primary jejunal ulcer has not been determined. The primary event that has brought many of these cases to light has been an obstruction of the intestine with ulceration and perforation above the stricture. Pressure necrosis and ulceration commonly occur above intestinal strictures, whatever the cause of the stricture may be. In the author's case, the large ulcer and the necrotic intestine resulting in perforation appear to be this type of lesion. Stricture of the small intestine, often double, has been observed as a result of temporary incarceration in a hernial sac. Although his patient had been operated on previously for bilateral inguinal hernia, there was no history suggesting such a causative factor; in any event, the location of the strictures high in the jejunum appear to rule out this possible mode of origin. The most likely cause of these strictures seems to be the contraction of cicatricial tissue produced in healing ulcers. The possibility of congenital strictures playing a part in the cause of these lesions must also be considered. Congenital points of narrowing of varying degree are occasionally found in the intestinal tract, especially in the small intestine. Whether or not a stricture of the intestine produces abnormal symptoms depends on the degree of the stricture and the extent and nature of the primary lesion. Congenital stenoses of quite marked degree frequently cause little or no apparent trouble. The author believes that it is possible that the strictures in his case were congenital, as the inflammatory reaction at these points was not marked.

Treatment of Hypopyon Ulcer.—Reid presents a series of 100 cases of hypopyon ulcer comprising only those cases which, when first seen by him, presented a hypopyon visible to the naked eye. He has come to the conclusion that the most satisfactory method of treating all hypopyon ulcers at whatever stage they present themselves is with one or more applications of a cautery of the Wessely type, along with certain adjuvant methods. The author has all patients presenting ulcers put to bed, even mild cases. He insists that the patient lie on his back, using but one pillow. The patient is instructed to bathe the eye freely every half hour during the day, and as often at night as he wishes, with a 1:10,000 solution of mercuric chloride. Drops of mild silver protein, 20 per cent, are instilled by a nurse every two hours. This is kept up for forty-eight hours. If there is no advance of the ulcer, the patient is allowed to sit up in bed, followed by getting up in the ward in another forty-eight hours; and two days later, if there is no advance and the surface takes the silver stain all over, the patient is sent home. The most favorable cases thus demand six days in the hospital. Corneal section was reserved for the worst cases, after other methods had failed. The author adopted this method in only two patients after the Wessely cautery.

Radiation in Treatment of Psoriasis.—Goeckerman believes that the symptomatic treatment of psoriasis by the use of crude coal tar and ultraviolet irradiation is the most effective method of treatment. It is probable that the superior results are effected by substances produced by photochemical changes in the tar. Removing the psoriatic patches by this method has had a striking symptomatic effect on an associated arthritis in about 50 per cent of the cases treated. Exfoliative dermatitis secondary to psoriasis responds as well to this method of treatment as typical psoriasis. This complication usually develops as the result of intercurrent infection, arsenic preparations internally, or irritants locally. The results of treatment by tar and ultraviolet irradiation do not warrant the assumption that the skin has undergone a form of degeneration in this form of exfoliative dermatitis. Under hospital conditions, an ointment containing from 1 to 5 per cent of crude coal tar is applied about one-eighth inch (3 mm.) thick to the various patches, whether large or small. The ointment used by the author consists of an incorporation of the proper percentage of crude tar in about the equivalent of Lassar's paste without salicylic acid. The ointment remains in contact with the patches until the next day. The excess of ointment is then removed with olive oil; a thin film, enough to look like a

brown stain, is purposely allowed to remain. These patches are then exposed to quartz lamp radiation, beginning with a small dose to avoid any reaction. The ointment is reapplied and the exposure given daily. As the patient becomes accustomed to the exposure, the dosage may be rapidly increased. Gradual tanning is the object desired. Following daily exposure to the light, the patient may take a soap and water, or, if his skin is sensitive, an oatmeal and soda bath. He is then permitted to spend several hours in comfort, before the procedure is repeated. Mild conditions clear up in from two to three weeks.

Neuroparalytic Accidents in Antirabic Treatment.—Stuart and Krikorian state that paralytic accidents are a rare complication of antirabic treatment but exhibit a certain periodicity in their occurrence. Since 1928 the condition has been observed in Palestine on five occasions: the three patients showing Landry's syndrome died and the two with dorsomyelitis recovered. The incidence is now, for the first time, recorded among members of the age group from 0 to 5 years. The proportion of cases to the number of treated persons varies according to the method of vaccination employed. In this connection, statistics have proved the superiority of phenolized vaccines over all others, but now the safeguards thereby afforded are shown to be far from absolute. The histopathology now described does not agree with that previously published. In the authors' cases the microscopic appearances of the brain and the spinal cord showed little more than varying degrees of degenerative changes in the nerve cells, together with considerable vascular congestion and occasional hemorrhage. Evidence of perivascular demyelination or of perivascular cuffing was altogether wanting, and therefore the type of paralytic accident represented by their cases cannot, on histologic grounds, be included among the group of diseases termed "acute disseminated encephalomyelitis" or "acute perivascular myelinoclasia." Further, the absence of Negri bodies and of perivascular and periganglionic infiltrations differentiates the condition from rabies. The authors again advance a cytotoxin rather than a virus theory of origin. Thus, in the basic nerve substance of all antirabic vaccines there seems to exist some deleterious component which, though adversely affected by various physical and chemical agencies, is still capable, in peculiarly susceptible persons, of producing neuroparalytic disorders.

Tuberculosis and Tuberculous Glands.—From a series of 221 patients, divided into twelve groups according to the month of the year in which pus was evacuated, Simpson and

Clayson observed that there is a strongly marked tendency to the seasonal occurrence of pus formation in tuberculous lesions, as exemplified by a study of glandular tuberculosis. The maximum tendency to pus formation is in the month of March, while the minimum is in August, September and October. This seasonal variation is as strongly marked—if not more so—in the recurrences of the disease as it is in the initial change from caseation to pus formation. There is no appreciable difference between the tendency to pus formation, observable in patients treated at a sanatorium, and that noted in patients residing at home and treated at outpatient clinics.

Urobilinuria and Malaria.—Lal and Singh point out that the four important conditions in the tropics in which urobilin is present in large amount are, in the order of their importance, malarial fever, lobar pneumonia in the resolution stage, internal hemorrhage, and cholecystitis. The presence of a large amount of urobilin in the urine differentiates cholecystitis from kidney lesions, appendicitis and other abdominal conditions. The condition in which urobilin is present in the largest amounts is malarial infection. In the 296 cases in which specimens of urine were received along with blood films, malarial parasites and urobilin were present in 85; malarial parasites were present but urobilin was absent in 11; no malarial parasites were observed but urobilin was present in 40, and no urobilin or malarial parasites were found in 160. In the forty patients in whom no malarial parasites were found but the urine was strongly positive for urobilin, quinine was given in curative doses for the fever and in all such cases the fever yielded to the drug.

Treatment of Toxemia of Pregnancy.—In treating toxemias of pregnancy, it has been Daly's object to raise the plasma bicarbonate, to increase the calcium content of the serum, and also, in the severe cases, to obtain a relatively rapid action by the intravenous introduction of a suitable diuretic. In all cases of albuminuria, preeclamptic, severe and mild, he administers an alkaline compound tablet orally three times a day. The tablet is composed of 40 grains (2.6 Gm.) of potassium citrate, 20 grains (1.3 Gm.) of sodium bicarbonate, and $7\frac{1}{2}$ grains (0.5 Gm.) of calcium sodium lactate. In cases of severe albuminuria, in addition to the oral administration of the tablet, the author administers intravenously one ampule of 20 cc. of a sterile aqueous solution of 20 grains (1.3 Gm.) of sodium bicarbonate and 20 grains of the diuretic sodium

acetate, and one ampule containing $5\frac{1}{2}$ grains (0.37 Gm.) of anhydrous calcium acetate, 1 minim (0.06 cc.) of glacial acetic acid and enough sterile distilled water to make 2 cc. For intravenous administration the contents of the alkali ampule are added to about 140 cc. of sterile water, the 2 cc. of the calcium ampule is then added and the volume made up to 170 cc. with sterile water, the resulting isotonic solution being introduced by the funnel and tube. The effect of this treatment has been dramatic in many instances. The albumin reading falls rapidly in all cases and is almost invariably small by the third or fourth day; in many cases the urine is clear, and remains clear. If the albumin in the urine rises again, as may occur in the more severe cases, another intravenous injection of the alkali in dilution, followed by the calcium salt, is indicated. The author concludes that his treatment has the advantage over other methods in that the patients are allowed an ordinary diet, thus conserving their energies until the termination of the pregnancy. The treatment also has the advantage that the loss of child life is greatly diminished, for his investigations show that only 2 per cent of cases required induction, whereas, in the control series treated on the usual lines, labor was induced in 66 per cent of patients because of failure to respond to the treatment. The total number of cases in the control series was 131. In addition, only 11 per cent of births were premature, whereas 63 per cent in the control series terminated prematurely.

Bacteriologic Control in Puerperal Sepsis.—Rose states that a study of the various groups of cases shows that there is an increased morbidity rate for all groups having hemolytic streptococci in the fauces or vagina during the lying-in period. In throat infections, the increase is due chiefly to diseases of the respiratory system and to mastitis. In vaginal cases, morbidity is usually of genital origin. Hemolytic streptococci may in some cases be normal inhabitants of the lower vagina in the pregnant woman, but when they are present during the last month they should be regarded as a potential danger. Hemolytic streptococci were found in the genital passages in 6.8 per cent of hospital patients and in 9.6 per cent of district patients. Streptococcal infection giving rise to pyrexia occurred in 0.6 per cent of hospital cases and in 1.4 per cent of district cases. A knowledge of the bacteriology of the genital tract, especially during the last month of pregnancy and in the early days of the puerperium, is of value, as special precautions may be adopted if pathogenic organisms are present. Preventive measures should include treatment of positive fauces in patients and attendants, treatment of positive vaginas during the late antenatal period and throughout labor, also all measures that can be devised for protecting the patient from contact with acute or subacute infection at home or in the hospital. The technic of the obstetric attendant should be adequate to prevent the risk of contagion from all sources, including droplet infection. Owing to the bacteriologic examination, it has been possible to reduce the risk of puerperal infection in 3,000 consecutive cases by 75 per cent. Pyrexia due to *Streptococcus hemolyticus* has not entirely disappeared, but there have been few severe cases and, when isolated cases have occurred, there has been no spread of infection. It would appear, therefore, that the risk of contagion which is commonly associated with the congregation of patients in institutions has in the past three years been practically eliminated.

Tuberculous Infection of Uterine Endometrioma.—Stewart reports a case of tuberculosis in association with endometriosis uteri. The case is of particular interest in that there was a discrete nodule of adenomyoma as well as a general diffuse endometriosis, and that the two lesions were the site of active tuberculosis. The adnexa were not examined microscopically. Only those of one side were removed at the operation and they appeared to be normal on macroscopic examination, while the tuberculous lesion of the uterus was unsuspected until the specimen had been submitted to microscopic examination. In the clinical history there was no indication of the time of infection. As often happens, the symptoms had apparently no reference to the tuberculosis. Pain associated with and between menstruation was the only symptom so far as the patient could recall.

Traumatic Purpura.—Stubbs and Martin observed a case of traumatic purpura occurring during parturition, in which systolic and diastolic blood pressures were 100 and 65 mm.

of mercury, respectively. The blood count was as follows: red cells 3,568,000, white cells 7,000, hemoglobin 55 per cent, color index 0.75, polymorphonuclear leukocytes 70 per cent, lymphocytes 25 per cent, large mononuclears 3 per cent, eosinophils 1 per cent, and mast cells 1 per cent. The blood platelets were plentiful. The bleeding time estimated by Duke's method was four minutes. The blood coagulation time was not increased. The authors believe that their case differs markedly from those of purpura in pregnancy previously reported. Except for some hyperemesis occurring early, the pregnancy, labor and puerperium were normal, and a healthy child was obtained. The eruption was unaccompanied by any disturbance of the patient's general health and occurred during labor. The rash was distributed over the upper part of the body, which is unusual. The peculiarities which might predispose to traumatic purpura are that the prolonged bleeding time and the history of purpuric spots occurring during the hyperemesis of a previous pregnancy suggest that the patient had a hemorrhagic diathesis; the long standing mitral stenosis would tend to increase the intravenous and intracapillary pressure, and the large doses of potassium citrate that had been administered for four months prior to the labor might influence the coagulability of the blood.

- **Bacterium Dispar* (Andrewes) and Its Association with Dysentery. W. L. Forsyth.—p. 65.
Metadysentery Observed in Eritrea: Cases. A. Marmo.—p. 69.

Bacterium Dispar and Dysentery.—In the past two years, Forsyth succeeded in collecting and investigating twenty-one strains of *Bacillus dispar* isolated from the intestinal tract in cases of clinical dysentery. The author fed rabbits with this organism without their showing evidence of infection. Young, recently isolated strains have been introduced by rubber catheter in the rectum of rabbits without any harmful result to the animals. A monkey (*Macacus rhesus*) was fed each morning on vegetable impregnated with young broth culture and on sugar soaked in the culture, before other food was allowed. This was continued for a fortnight without signs of enteritis intervening. The stools of the animal were sown on three occasions on MacConkey's medium and yielded large crops of colonies of *Bacillus dispar*. A laboratory attendant indulged in some of the vegetable soaked in culture without further incident. It has proved a good antigen on injection into a patient for the clinical purposes of protein shock. The author states that some observers have, by parenteral, usually intravenous, introduction of living culture, shown selective inflammation of the mucosa of the large intestine in the rabbit. It will be admitted by those who have had considerable experience of this maneuver that enteritis does not always follow the injection of what is undoubtedly a living dysentery antigen. It is not rare to find the ureters of the animal ballooned with blood produced by an acute hemorrhagic nephritis. However, certain strains of Flexner's bacillus may, in small doses, produce on occasion enterotropism of the large intestine, as evidenced by the accumulation of blood and mucus therein and the presence of small ulcers or areas of hemorrhage. In regard to *Bacillus dispar*, the author has not been able to produce evidence of inflammation of the lower intestine in the rabbit. Doses of from one twelfth to one half of an agar slope in saline solution have been injected into the ear vein of a rabbit, resulting in the death of the animal at periods varying with the dose, one sixth of a slope killing the rabbit in forty-eight hours. Postmortem examination discloses

the first 5 cm. of the duodenum acutely inflamed and hemorrhagic, the contents being bile-stained bloody mucus, serous effusion in the peritoneal cavity, and pure culture of the organism recoverable from the heart blood, gallbladder and upper part of the small intestine. The organism does not produce a soluble exotoxin, as shown by the intravenous injection of 5 cc. of a twelve hour growth, drawn through a Seitz filter, in a rabbit that did not eat for twenty-four hours but was alive at the end of a month. The author concludes that *Bacterium dispar* (Andrewes) would appear to belong to the larger group of organisms described as *Bacillus coli-anaerogenes*. The *dispar* group is serologically heterogenous, and, as a group, distinct from the bacillus variously known as *Sonne's bacillus*, or *Bacillus ceylonensis* A, or *Bacillus kruse-castellani*. It is probably a commensal which becomes a concomitant when the normal flora of the blood is disturbed by the entry of an intestinal pathogen. It cannot be accepted as a dysenterogenic organism until further serologic evidence is obtained from the study of many strains.

Actinomycosis.—Bates presents an analysis of twenty-nine consecutive cases of actinomycosis seen in the London Hospital over a period of five and a half years. In every case the presence of the streptothrix was verified by the bacteriologic examination of pus obtained at operation or at necropsy. In his series none of the patients were under the age of 10, twenty-one were under the age of 40, and seven of these were under the age of 20. Clinically, the infections may be divided into two main groups: the superficial group, which includes the cervicofacial variety and subcutaneous infections of the limbs; and the deep group, which includes the thoracic and abdominal cases. In the first group the infection does not endanger life, but in the second it only too frequently proves fatal. The author concludes that human actinomycosis appears to be invariably an infection with the non-acid-fast anaerobic streptothrix *Actinomyces bovis*. The superficial variety of actinomycosis occurs more commonly than is usually supposed. In cervicofacial cases, before the formation of pus, trismus is the most important sign. Early diagnosis by a bacteriologic examination of pus in all cases of alveolar abscess, and early treatment with iodides will prevent the terrible scarring and repeated relapses associated with the disease. If a test tube containing actinomycotic pus is tilted, the granules are visible to the naked eye as greenish gray specks adhering to the glass. When a routine bacteriologic examination of all pus is impossible, this method of tilting the test tube and examination through a hand lens would indicate the more suggestive cases which need fuller investigation. In the deep variety there is such a high mortality that a routine bacteriologic examination of the pus in cases of empyema, appendicular abscess and subdiaphragmatic abscess is imperative. When the disease is suggested by its chronicity, it has usually spread beyond human aid. In both types of the disease adequate drainage, with the resulting increase in oxygen tension of the part affected, and massive dosage with iodides appear to give the best results. Prognosis depends on the anatomic site of the lesion and early recognition of the disease.

Pyemic Conditions and Acute Osteomyelitis.—Benians treated with benzene four cases of acute osteomyelitis presenting septicopyemia, with the object of diminishing the leukocytic reaction. In three of them there was a marked fall in the white cell count, and in the fourth a profound leukopenia set in. The purulent discharge diminished and became more watery. The patients all recovered and no after-effects due to the benzene have been noted. The most recent of the cases quoted was two years ago. There was an artificial restriction of the output of leukocytes in the later stages of the disease, and the author claims that this was an advantage rather than

a disadvantage. In each of his patients an opening in the bone had been made and drainage established. After the operation, as soon as the blood count was found to be actively rising, the patients were given 10 minims (0.6 cc.) of benzene by mouth two or three times a day or, for the younger children, 5 minims (0.3 cc.) three times a day, according to the degree of the white cell count and the amount of red blood available, for this may in time also be affected. The drug is given in capsules or in milk. The progress of the white cell count was followed every few days, and when the count had fallen to about 10,000 the drug was discontinued. The fall may continue after the drug has been stopped; consequently, when the administration has been continued for some time, it should be stopped while the count, though falling, is still relatively high; i. e., from 12,000 to 15,000.

Magnesium Sulphate in Angiospasm.—Pines has obtained good results in many cases of angiospasm treated with magnesium sulphate. His method is as follows: With the patient lying on a couch with the head and shoulders slightly raised, a solution of magnesium sulphate and dextrose is slowly injected into the vein. The dose is from 5 to 10 cc. of a 20 per cent solution and an equal volume of from 10 to 40 per cent dextrose. About half a minute after the commencement of the injection the patient feels an intense heat in the body. This is first experienced at the back of the pharynx, then in the face and neck, then in the thorax, and sometimes in the upper limbs, and it proceeds down to the rectum and genitalia, the lower limbs being the last to react. The face is sometimes intensely flushed and may even perspire; the skin of the limbs and body hardly alter in color or temperature. The pulse becomes moderately quickened. The blood pressure is unaltered. On ophthalmoscopic examination, the retinal vessels show no change. In the author's opinion the magnesium sulphate probably relaxes vascular spasm by direct action on the vasomotor center of the brain. If it acted directly on the arterial wall there would not be the constant sensation of heat. The more spastic or the more clogged the vessel, the less is the sensation of heat and the less effective is the injection. The patient can tell exactly where the sensation of heat ceases, and the author has found that the oscillometric index invariably corresponds to the patient's sensations. If the intravenous mode of injection is for some reason impracticable, the solution of magnesium sulphate without dextrose is well tolerated intramuscularly, but the intravenous route is the one recommended. He did not observe any discomfort in any of his patients, although several of them were more than 60 years of age, and he thinks that the alarming signs of respiratory distress that have been seen in the cases of tetanus treated with magnesium sulphate may be explained as due either to the intrathecal method of injection or to excessive dosage. He usually administers the treatment to his patients twice a week.

Some Clinical Types of Tuberculosis. L. S. T. Burrell.—p. 263.

Complications of Artificial Pneumothorax.—Harris classifies and discusses the various complications of artificial pneumothorax under the following headings: (1) accidents occurring during the process of induction or during a refill, (2) complications occurring usually after the induction, (3) cardiac complications, (4) complications in the opposite lung, (5) tuberculous disease in other organs and (6) complications from general diseases. He concludes that the complications of artificial pneumothorax are numerous; some are rare and should not occur if sufficient care is taken; others, such as serous effusions, are common and their occurrence is difficult to prevent. The type of gas used is immaterial; carbon dioxide

is most rapidly absorbed, but air filtered through wool is generally the choice. Full anesthetization of the subcutaneous tissues and pleura should be carried out on every patient and before every refill. High intrapleural pressures are best avoided. The correct spacing of refills is important, as is control by roentgen examinations. Effusions occur in at least 50 per cent of cases, and amounts demonstrable only by roentgen rays occur in 100 per cent of cases. Various methods of dealing with the large and purulent effusions are in vogue, but a really satisfactory treatment has yet to be devised. Hemoptysis is sometimes increased by artificial pneumothorax. Tuberculous disease occurring elsewhere in the body and the presence of any other serious disease, such as diabetes, seriously complicate the case. Artificial pneumothorax, safely used, is of definite therapeutic value in properly selected cases. In cases not suitable for this form of treatment, complications are more liable to occur.

Chemical Sympathectomy in Gynecology.—Binet states that chemical sympathectomy in its gynecologic applications is an easier and more rapid operation than surgical sympathectomy. By this method the sympathetic can be easily reached at the level of the superior hypogastric plexus innervating the uterus and the ovarian plexus innervating the ovaries, thereby permitting a complete action on the genital tract, which is desired in most cases. The author uses a 6 per cent solution of tricrosol as the chemical agent. It is innocuous for the tissues, is nontoxic and has a selective action on the sympathetic fibers. He employs two methods: one consists of applying tampons with tricrosol solution to the nerve plexus after incision of the peritoneum, and the other consists in subperitoneal injection of the tricrosol solution. After laparotomy, an injection of not more than 20 cc. of the tricrosol solution is made under the posterior parietal peritoneum in the region of the promontory. Care must be taken not to pierce a vein. Similar injections of not more than 15 cc. are made in the region of the mesovarium and, if necessary, the broad ligaments. Chemical sympathectomy, like the surgical method, is indicated in disturbances of the vagosympathetic equilibrium. The principal indication for it in gynecology is pain. If pain is linked with an organic lesion, chemical sympathectomy may be used to supplement the causal therapy which does not always stop the pain, as in ventrosuspension, and in painful syndromes without distinct macroscopic substratum it often attains remarkable results. The immediate results obtained by the author were always favorable, but it is too early to discuss the late results as his experiences cover less than two years.

Quantity of Amniotic Fluid.—By retrograde ovarian functions Albano means the power of the ovum to expel from its cavity waste matters and substances useless to the function of the amniotic fluid. An easy and clinically exact method for the study of this function consists in the intra-ovular injection of 0.006 Gm. of phenolsulphonphthalein sodium and the control of its appearance in the urine, the duration of its elimination, the quantity eliminated and the time of its disappearance from the amniotic cavity. The injection is made by transabdominal puncture with a needle 10 or 12 cm. long. The needle, provided with a stylet to prevent the entrance of blood into the lumen, is inserted in the hypogastrium immediately above the fetal chin. To prevent piercing the bladder it should be voided before the injection. An assistant holds the fundus of the uterus to fix it against the abdominal wall. The phenolsulphonphthalein is diluted with the amniotic fluid, to assure its rapid diffusion through the cavity. The patient alternates from left to right lateral decubitus every five minutes for twenty minutes and then walks for ten minutes, after which an indwelling catheter is introduced for detection of the appearance of dye in the urine. The amount of amniotic fluid present can be calculated after dilution of the phenolsulphonphthalein and

before its resorption. The first appearance of dye in the urine of the pregnant woman occurs normally between forty-five and seventy-five minutes after the injection. The amount of phenolsulphonphthalein eliminated in the first twenty-four hours (determined colorimetrically) is about 30 per cent. Elimination of the dye in traces continues for from seventy to eighty hours. After twenty-four hours the residue of dye in the amniotic cavity is about 30 per cent, and after forty-eight hours only traces of it are found. In diseases having a repercussion on the ovum there is a deviation from the normal excretory cycle. In noncompensated cardiopathies the appearance of the dye is retarded and its elimination is prolonged; this is also true in women with toxemia. In pulmonary tuberculosis the cycle of elimination is shortened. In case of death of the fetus the elimination is prolonged for days. The ovarian function can be easily studied in the maternofetal sense by determining what percentage of 2 Gm. of potassium iodide injected intravenously into the pregnant woman has passed into the amniotic fluid one hour later. The mechanism of resorption (not excluding the deglutition of the fetus) must reside essentially in the passage through the wall of the ovum and especially through the extraplacental chorial and amniotic surface.

Electrical Treatment of Cavernous Angiomas.—Bordier prefers diathermy to electrolysis for the treatment of cavernous angiomas which are covered by normal skin, because coagulation is obtained more quickly and fewer treatments are required; it is also less painful. He employs chiefly the bipolar method. In this method both needles are introduced into the tumor and the current is localized in the tumor itself. The coagulation occurs not only around the needle but in the interpolar space. He uses a bipolar diathermic fork in which the distance between the prongs can be varied according to the size of the tumor and which possesses two sets of insulated needles, one large and one small, to be fitted into the insulated handle. The needles are insulated all the way down to the point, as it is of the utmost importance not to coagulate the healthy skin covering the angioma. The fork is so introduced that the largest part of the tumor is situated between the two needles. The strength of the current varies in each case: the greater the distance between the needles, the more current is required. Coagulation is obtained in several seconds. When the volume of the clot is sufficient, the current is stopped and the fork withdrawn. This intervention does not require anesthesia. One coagulation sometimes suffices, but usually two are necessary to reduce the tumor completely. If a small elevation remains after coagulation, it can be coagulated by the monopolar method. With this technic the mark made by the needles is almost invisible.

Value of Mechanical Study of Lung in Phthisiology. F. Dumarest and P. Lefèvre.—p. 839.

Ventriculography.—Martel and his associates have performed 300 ventriculographies in the last three years with only four deaths. Two of these occurred prior to the perfecting of their present technic and two occurred in patients so ill that death could not be attributed, with certainty, to the ventriculography. Frequently the ventriculography permitted precise localization of the tumor and even the determination of its size. In less satisfactory cases it permitted differentiation between a cerebral tumor and a cerebellar tumor and, when a cerebral tumor was concerned, the hemisphere in which it was located could be determined. In several cases it ruled out the diagnosis of brain tumor and spared the patient a useless trepanation. Ventriculography is indicated in all cases of

suspected brain tumor in which the clinical examination is not sufficient to affirm the existence of a cerebral tumor or permit an accurate localization of the tumor.

Latent Cancer of Pharynx. P.-C. Huet.—p. 908.

*Trigemino-cardiopulmonary Reflex. P. Caryophyllis.—p. 909.

Red Spots on Cheeks of Tuberculous Patients.—Caryophyllis says that the red spots which appear on the cheeks of some patients with pulmonary tuberculosis on the side corresponding to the lesion are observed only in patients with extensive lesions and are due to a trigeminocardiopulmonary reflex. The pulmonary lesion by irritation of the centripetal neurosympathetic fibers of the lungs determines a reflex irritation of the centrifugal fibers which, if strong enough, manifests itself in a vasodilatation of the cheek homolateral to the diseased lung or, if not strong enough, causes a latent disturbance of the sympathetic tonus. In such cases, the author found that the application of hot water bottles to the cheeks by provoking an irritation of the sympathetic ganglion cells of the external tunic of the vessels causes a greater vasodilatation on the side of the latent neurosympathetic disturbance. The reflex is useful for determining on which side a unilateral pulmonary lesion or the more extensive of a bilateral lesion is located. Besides the local response there is a general response manifesting itself in an acceleration of the pulse and an increase of the arterial tension when the reaction is sympathicotonic. Investigation of a large number of patients with a neurosympathetic dystonia showed that the reaction was always parasympathicotonic in patients clinically parasympathicotonic and that the opposite reaction occurred in patients clinically sympathicotonic. A study of the trigeminocardiopulmonary reflex is therefore valuable for the study of the sympathetic nervous tonus. Certain rules must be observed in studying the reflex. The patient must be in dorsal decubitus fifteen minutes before the examination. The room must not be overheated. The water containers must be of equal size and weight and filled with equal quantities of water of the same temperature. They must be applied and removed at the same time. They should occupy the same place on the cheek, preferably the entire cheek. The patient should be warned in advance not to rub his cheek. The reflex should be studied only by daylight. If the patient is a man, his cheek should be well shaved.

Pneumonic Lesion as Basis of Pulmonary Tuberculosis. I. Fischer.—p. 550.

Calcium Metabolism in Rickets and Caries.—On the basis of experimental and clinical studies on calcium metabolism and its significance for rickets and dental caries, Rothlin reaches the following conclusions: 1. The calcium metabolism and its regulation by the parathyroids and by vitamin D is the physiologic foundation for the normal development of bones and teeth. 2. The pathologic changes in bones and teeth, rickets and caries, are caused by the same disturbances in the calcium metabolism, particularly by a deficiency of calcium, phosphorus and vitamin D, by a dysfunction of the parathyroids and by giving children a diet rich in cereals. 3. To obtain a physiologically homogeneous calcification of the deciduous and of the permanent teeth, as well as their regular spacing in well developed bones, a suitable dietetic prophylaxis is necessary. This prophylaxis should begin at the time of beginning calcification of the bones and of the teeth, that is, in the mother, during the time of gestation and lactation, and it must be continued in the growing child. Inadequate diet of the woman during pregnancy and lactation creates a predisposition for rickets and caries, and a deficient diet in the growing child leads to their manifestation. 4. Rickets as well as caries can be therapeutically influenced by a suitable diet; rickets can be completely cured, active caries can be checked, and the resistance against external

chemical and bacterial influences that are contributing causes of caries can be increased.

Arsphenamine Pannmyelophthisis.—Merkelbach gives the clinical history of a woman who, in the course of antisyphilitic therapy, showed hypersusceptibility to arsphenamine. In spite of this, further antisyphilitic treatment was possible fifteen months later, but five months after the conclusion of this treatment the patient required treatment for anemia. The author points out that blood diseases developing as sequelae of arsphenamine therapy generally become manifest immediately or shortly after the injections, and he therefore considers the latent period of five months worthy of note. He gives a tabular report indicating the blood status at the time treatment was begun and its gradual improvement under the influence of blood transfusions and other therapeutic measures. With the exception of a slight eosinophilia and a rather severe thrombopenia the blood status is now almost normal, but at the beginning of treatment the hemoglobin content and the form elements were greatly reduced. Whether the present status is only a remission or a complete cure cannot be decided as yet. The author considers the reported case as a connecting link between the fatally ending and the mild forms of toxic injury of the bone marrow. The impairment may involve only a partial function or all functions of the bone marrow. The fact that, one year after the beginning of the symptoms of anemia and more than eighteen months after the last arsphenamine injection, there still existed a thrombopenia seems to prove that arsenic preparations may cause myelotoxicoses of varying severity but also that there is a gradual transition between thrombopenia, thrombopenic anemia, agranulocytosis and pannmyelophthisis. The sensitive megakaryocytes, however, are damaged first, most severely and longest.

*Action of Cardiac Hormones on Lactic Acid and Dextrose Content in Blood. J. A. Collazo, J. Puyal and Isabel Torres.—p. 599.

Action of Cardiac Hormones.—Collazo and his collaborators state that the action of organic extracts on the mechanism of circulation is due to their content in cardiac hormones. Cardiac hormones may be divided into true cardiac hormones and arterial hormones. True cardiac hormones have a cardiac, muscular or visceral origin. Their active principle is adenylic-phosphoric acid. Arterial hormones are of pancreatic origin. Their active principle is still unknown, although it is believed that it is also adenylic-phosphoric acid. In order to ascertain the significance of adenylic-phosphoric acid in muscular metabolism, the authors first determined the normal glycemia and the normal content of lactic acid of the blood of two groups of normal rabbits. Then the animals of one group received an injection of 1 cc. per kilogram of body weight of a cardio-kinetic muscular extract, while those of the other group received the same dose of a pancreatic extract. The glycemia and the content of lactic acid in the blood of the animals were then determined at various intervals. The authors conclude that only the hormone contained in the muscular extract may be identified with adenylic-phosphoric acid. This hormone acts on the neuromuscular system, bringing about a dilatation of the coronary and peripheral vessels. It had a constant action on the lactic acid content of the blood, which decreased from 31 mg. per hundred cubic centimeters of blood before the injection to 26, 24 and 27 mg. per hundred cubic centimeters of blood, 30, 60 and 120 minutes, respectively, after the injection. Glycemia increased from 94 mg. per hundred cubic centimeters of blood before the injection to 95, 101 and 97 mg. per hundred cubic centimeters of blood in the same periods. The action of the pancreatic hormone deprived of insulin on glycemia and on the lactic acid content of the blood is less marked than that of the hormones contained in the muscular extracts, either because its active principle is a specific hormone and not adenylic-phosphoric acid, or because its content of adenylic-phosphoric acid is not equal to that of the muscular extracts. In the majority of the cases, the lactic acid content of the blood showed oscillations from 28 mg. of lactic acid per hundred cubic centimeters of blood before the injection to 30, 27 and 29 mg. per hundred cubic centimeters of blood after 30,

60 and 120 minutes, respectively, after the injection. Glycemia followed the variations with a tendency to a diminution, that is from 85 mg. per hundred cubic centimeters of blood before the injection to 80, 76 and 92 mg. per hundred cubic centimeters of blood in the same periods. The results justify the hypothesis that the action of cardiac hormones is primarily on the metabolism of carbohydrates and phosphorus of the peripheral muscles and of the cardiac muscle and, mostly, in the muscular layers of the vessels, thus favoring the energetic output of the vessels.

Complication of Simultaneous Bilateral Pneumothorax.

—Pollerbeck reports observations on a patient with bilateral pneumothorax in whom the roentgenogram revealed a displacement of the mediastinal organs to the left. A pneumothorax on the left side could not completely offset this displacement. Several hours after the pneumothorax had been induced also on the right side, there developed symptoms that seemed to indicate a spontaneous pneumothorax. However, the slowly progressing development of the condition, the negative pressure in the pneumothorax and the disappearance of the painful symptoms following the withdrawal of some of the air indicated that the disorder was not a spontaneous pneumothorax. The author agrees with Alexander who, in the *Deutsche medizinische Wochenschrift* (58:1351 [Aug. 26] 1932; abstr. THE JOURNAL, Nov. 5, 1932, p. 1642), called attention to the significance of the yielding mediastinum, and he thinks that the described disorder was the result of such a mediastinal displacement. The same symptoms developed several months later in the course of a simultaneous bilateral filling, while the refillings in the meantime had remained free from complications. A condition that can be considered a spontaneous pneumothorax developed several weeks later in the course of a unilateral filling.

Tests of Cardiac Function in Pulmonary Tuberculosis.

—Witzentrath calls attention to the fact that the extensive use of collapse therapy in patients with pulmonary tuberculosis has given greater importance to the tests for the estimation of the circulatory function, particularly the heart action, because the cardiac function is taxed severely, especially in the course of plastic operations. Since there is no single method that permits an adequate estimate of the function of the heart, the author employed several methods. In addition to the clinical and roentgenologic examination of the heart and of the respiratory conditions, he examined the blood pressure and the pulse, employed Kauffmann's water test, resorted to the photographic registration of the pulse of the jugular vein, which, according to Weber, gives better information about the cardiac function than any other graphic method and, in some of the patients, he also did electrocardiography. The photographic registration of the pulse of the jugular vein in 220 patients with open tuberculosis gave normal results in 2.3 per cent, slight changes in 58.2 per cent, medium changes in 23.6 per cent, and severe changes in 15.9 per cent. In 110 patients with open tuberculosis, the blood pressure and the pulse were taken and photographic registration of the venous pulse and Kauffmann's water test were made, and in twenty-seven cases electrocardiography was done in addition to these tests. The blood pressure was normal in 31.8 per cent of the patients, slightly changed in 48.2 per cent and greatly changed in 20 per cent. The

pulse was normal in 13.6 per cent, slightly changed in 65.5 per cent and considerably changed in 20.9 per cent. Photography of the venous pulse gave practically the same results as indicated for the 220 cases. Kauffmann's water test was negative in 85.4 per cent and positive in 14.6 per cent. Electrocardiography revealed abnormal conditions in only one patient. That the simultaneous use of several test methods gives reliable information about the cardiac function became evident in operative interventions on seventy-four patients.

Demonstration of Tubercle Bacillæmia.—Schramek reports his observations with Löwenstein's method for the culture of tubercle bacilli from the blood. He found that Löwenstein's culture medium is one of the best. Tests with human, bovine and avian types of tubercle bacilli revealed that the latter type grew best and that the bovine type showed the least favorable growth in this medium. Tubercle bacilli introduced into the blood in vitro are always demonstrable in the culture, but their detection is difficult in the blood sediment. Blood constituents impair growth in the culture: the greater the withdrawal of hemoglobin, the better the growth. Hemolysis with distilled water is to be preferred to hemolysis with acetic acid. Artefacts of various types are often present in the smears from the blood sediments and from the blood cultures and, since they readily cause errors, must be differentiated. Only two of 522 blood cultures from 332 patients with pulmonary tuberculosis gave positive results. The microscopic demonstration of tubercle bacilli from the blood sediment smears of these blood tests was never possible. For the certain identification of tubercle bacilli from cultures of the blood, it is not only necessary to produce the characteristic stain in the smear but to prove transferability by inoculation. In patients with extrapulmonary complications, the results of the blood culture were always negative. The author's tests show that the demonstration of tubercle bacilli in the blood is an extremely rare occurrence.

Tic as Result of Muscular Gummy. N. Szcenderowicz.—p. 708.
*Functional Changes of Thyroid in Florid Secondary Syphilis Determined by Kottmann Reaction. A. D. Troitzkaja.—p. 709.
*Local Immunization Manifestations in Gonorrhea Cutireaction. C. Engel and H. Grundmann.—p. 716.

Functional Changes of Thyroid in Secondary Syphilis.

—Troitzkaja points out that, whereas in gummatous and congenital syphilis the endocrine glands may present gummatous or fibrous processes, secondary syphilis causes only temporary changes that do not lead to anatomic changes but are more of a functional character. Clinical observations often reveal an irritative swelling of the organ, but the functional changes are not so easily recognized. To determine the functional changes the author employed the Kottmann reaction, a photochemical colloid reaction, which indicates the functional activity of the thyroid on the dispersion capacity of the serum. Since women are more subject than are men to disturbances of the thyroid, tests were made on 100 female syphilitic patients, of whom 15 were in the primary stage of syphilis, 50 in the beginning secondary stage, and 35 had relapses. None of the patients had received treatment before the test. The results indicate that the spreading syphilitic infection involves the thyroid and that the impairment usually becomes manifest in a reduction of its functional activity, although its function may be increased in a small percentage of cases. The Kottmann reaction, in revealing the smallest functional changes, also proved that the swelling of the gland generally concurred with hypofunction and not with hyperfunction, as is the case in exophthalmic goiter. This concurrence of the swelling of the thyroid with hypofunction is the result of a temporary inflammation. The syphilitic character of the thyroid changes is proved by the efficacy of the antisyphilitic treatment.

Local Immunization in Gonorrhea Cutireaction.

—Formerly reported investigations had proved to Engel and Grundmann that by means of an intracutaneous test with a gonococcus vaccine an existing or a former gonorrhea could be detected in a large percentage of patients. But whereas before they had observed only local reactions following intra-

cutaneous as well as subcutaneous (for therapeutic purposes) injections, they now found that under certain conditions the repeated administration of the gonococcus vaccine may cause a generalized toxic urticaria in which only the area of the first vaccination is spared. The authors think that this manifestation was produced because of the unusual time of reinjection, for in former cases the injections had always been continued immediately after the intracutaneous test, whereas in the reported case two weeks had intervened between the test and the vaccine treatment. They believe that, if the injections are continued, the local reactions become steadily weaker, even after increased doses of antigen, because of a gradually progressing desensitization. The immunity of the site of the primary injection is particularly noteworthy. Experiments in which the reactions following reinjection into the site of the first vaccination were compared with reactions in other areas indicated that the preliminary vaccination had produced such an increase in antibodies that the repeated administration of the antigen led to a partial saturation. Thus the process seems to be the expression of a positive anergic phase. A second series of tests corroborated this assumption. A refractory behavior of the papillary body at the site of the first vaccination can be excluded, since in the experiments the differences generally became manifest only after forty-eight hours, whereas after twenty-four hours the cutaneous reactions were practically equivalent at the previously treated and the untreated sites. The complete immunity of the site of vaccination to the generalized exanthem can be explained by the small amount of the resorbed antigen. These local immunity reactions explain the therapeutic results of local vaccinations, such as the vaccination of the portio vaginalis, the vulvovaginal gland and the rectal mucous membrane.

Clinical Significance of Q Wave.—In studying the significance of the deep Q wave, Freundlich found that the enlargement of the Q wave always concurs with a change in the intermediate portion (RS up to T) or in the T wave in at least one of the three leads. The isolated appearance of the enlarged Q wave in the third lead is not necessarily pathologic, since it is observed occasionally in patients who have a high diaphragm but who are free from other cardiac changes. However, if an enlarged Q₃ concurs with an enlarged Q₂ or with an enlargement of the T wave or of the intermediate portion in leads 1 and 2, it is a symptom of myocardial infarct or of severe myocardial damage and usually indicates a coronary sclerosis (or stenosis of the coronary ostium resulting from syphilis). The appearance of a deep Q in the first lead has the same significance, even if there is no change in the ventricular complex in the first and second leads. In disturbances that are not the result of a coronary sclerosis (in rheumatic endocarditis and myocarditis and in thyrotoxicosis) an enlargement of the Q wave is extremely rare. The most frequent change in the ventricular complex during myocardial damage is an enlargement of the Q wave in the second and third leads (Q₂ larger than Q₃) combined with negativity of the T wave or with depression of the intermediate portion in the same leads.

Treatment of Gastric Ulcer by Means of Jejunal Catheter.—To determine the therapeutic value of jejunal catheter feeding in patients with gastric ulcer, Scholtz and

Brugsch determined the acidity of the secretion of the fasting stomach and compared it with the acidity during periods when the patients received a porridge diet. They also tested the acidity of the urine. The results of the investigations indicate that feeding by means of the jejunal catheter produces a greater secretory rest for the stomach than does the customary porridge diet. Scholtz also tested the effect of jejunal feeding on the gastric motility and found that this method rests the stomach greatly.

Central Regulation of Red Blood Picture.—Salus describes the clinical histories of five patients with polyglobulism. In three the condition concurred with narcolepsy, in one with postencephalitic obesity and slight parkinsonism, and in the fifth with sarcoma of the frontal brain and mesencephalohypophyseal symptoms. He thinks that the concurrence of narcolepsy and polyglobulism, or of narcolepsy, polyglobulism and mesencephalohypophyseal disturbances indicates that in the gray matter of the mesencephalon there is a center which regulates the formation and the disintegration of the erythrocytes. He cites other investigators whose observations indicate such a regulatory center.

- Intravenous Continuous Drop Infusion. J. Schnitzler.—p. 659.

Sciatica.—Silbermann calls attention to a form of sciatica refractory to the usual modes of treatment. Its most important symptom is that the percussion of the lumbar or of the thoracic portions of the vertebral column results in the radiation of pain to the region of the sciatic nerve. Bending of the vertebral column laterally and slightly forward or backward, and movements of the head, particularly to the side opposite to the affected leg, likewise produce the radiating pains. Roentgenoscopy of the vertebral column reveals mostly normal conditions. The cell count and the protein values of the spinal fluid are generally normal. The anamnesis reveals that a cold or an influenza has preceded the sciatica. The discovery of arachnoiditic adhesions convinced the author that this form of chronic sciatica is caused by an inflammation of the soft spinal meninges; that is, by a chronic arachnoiditis. The nerve roots that otherwise move freely in the foramen spinale have become fixed by inflamed and edematous tissues and, by painful defense mechanisms, resist the stretching that results from movements. For the treatment of this form the author recommends injection of a vaccine, roentgen irradiation of the involved parts of the vertebral column and prolonged rest in bed.

Pyuria of Children.—Siegl states that in recent years the term pyuria, which simply designates the main symptom and dispenses with exact differentiation and topical diagnosis, has been widely accepted. In nurslings and small children, the acute form of pyuria predominates. The clinical aspects are usually those of a severe infectious disease. Some of the symptoms may easily lead to an erroneous diagnosis; for instance, the accelerated respiration may lead to the diagnosis of pneumonia or, if diarrhea exists, typhoid may be thought of, and, in older children who can describe their pains, the condition may be mistaken for appendicitis. To avoid such erroneous diagnoses, the examination of the urine is of the greatest importance. However, besides the misleading symptoms, children with acute pyuria also show a behavior and an appearance that is characteristic for this disturbance. They are restless, have a frightened look and present an ashy pallor which may appear somewhat icteric. Besides these acute forms, pyuria may also occur as an accompanying symptom in dystrophic and atrophic nurslings. In discussing the pathogenesis of pyuria, the author evaluates vitamin deficiency, malformations of the urinary tract, calculi and urogenital tuberculosis. In the secondary pyurias the prognosis depends on the primary disorder, and in the acute forms on the general condition and on the development of complications. Death from urosepsis is comparatively rare. The treatment should consider the various

causal factors. In the acute forms the improvement of the general condition, an adequate fluid supply and a correct diet are essential.

Tumor Growth and Vitamins.—By feeding animals with excessive amounts of vitamins A, B, C and D, Fränkel and Geréb succeeded in transplanting the Jensen rat sarcoma to twelve out of thirty-two mice; this was possible only in two of thirty mice receiving an ordinary diet, and the heterologic transplantation was never successful in thirty-nine mice receiving food deficient in vitamin and mineral contents. The tumors reached considerable size under the influence of the excessive amounts of vitamins and, as a result, some of the animals died. Preliminary feeding with a diet of high vitamin content made it possible in one out of ten animals to transplant the rat tumor in the second generation from mouse to mouse, and in a second experiment this was possible in two out of eleven animals. This was never possible in mice that had received a normal or a vitamin deficient diet. The heterologic mouse tumor that developed in animals receiving a normal diet could not be transplanted further, not even to hypervitaminotic animals. Vaccination of the tumor from the mouse back again to the rat was always possible, irrespective of the diet. The inhibiting influence exerted on the growth of vaccination tumors by gestation or lactation could be nullified by feeding with large amounts of vitamins. A diet with high vitamin content also promoted relapse after incomplete removal of the Jensen rat sarcoma. For this reason the authors consider it advisable that patients who have been operated on for malignant tumors should receive a diet that, although providing a sufficient amount of calories, has a low vitamin content.

Influence of Vitamin E on Inoculation Tumors.—Engel found that the growth of vaccination tumors is not noticeably influenced by parenterally administered wheat germ oil with its high vitamin E content. The life span of the carcinomatous animals was reduced by this substance, and the growth of their neoplasms was not promoted. The sarcomatous animals were considerably less impaired. This is the more surprising since, according to the observations of Evans, a more pronounced modification is to be expected in tumors of mesodermal origin.

Primary Carcinoma in Meckel's Diverticulum.—Franke relates the history of a man, aged 54, who was operated on because of ileus symptoms. A Meckel's diverticulum the size of a fist was found. Its surface was ulcerated and it exuded jelly-like, mucous matter. The histologic examination revealed an adenocarcinoma with marked formation of mucus but without metastases. The patient recovered. The author points out that primary carcinoma of Meckel's diverticulum is extremely rare. He found only one other case, reported by Wissely in the American literature. He assumes that the primary carcinomas of Meckel's diverticulum develop from scattered embryonal traces; that for a long time they take an entirely benign course, and that, when they are removed early enough, they show a better tendency to heal than do other carcinomas.

- *Apiol Poisoning. J. Seiffert.—p. 1223.
- *Modification of Cleidotomy. N. A. Pautschenko.—p. 1227.

Closed Ovarian Actinomycosis.—Rumpf presents the clinical history of a woman, aged 40, who, about a year after an appendectomy, underwent a laparotomy on account of ovarian cysts and a uterine myoma. Histologic examination revealed a closed ovarian actinomycosis. The woman died five days after the operation. The case differs from most of the previously reported ones in that there was no absolute growth tendency and the content of the tumors was not suppurative. The author assumes an intestinal mode of infection.

Apiol Poisoning.—Seiffert discusses the form of polyneuritis that in recent years has been observed frequently following the use of the abortifacient apiol. He points out that the intoxication is not caused by the pure apiol but rather by an admixture, the triorthocresyl phosphate. Since little has been said about the outcome of the apiol intoxications, the author reports a case which was under his observation more than a year. Following ingestion of apiol, the patient had attacks of vertigo, nausea and vomiting, and a feeling of weakness in the extremities, particularly the legs. The neurologic examination revealed a reduced electrical reactivity of the muscles of the hand, particularly in the region of the median nerve. These muscles appeared atrophied, and all the nerves of the arm were painful to pressure. The tendon reflexes of the knee were hardly elicitable and the achilles tendon reflexes were abolished. The movements of the hip and of the knee were impaired and the motor power was considerably reduced. The peroneal and tibial nerves and the muscles of the leg were extremely sensitive to pressure. The patient could not stand or walk without the aid of other persons. The increase in pain, the unbearable headaches and the continuous vomiting induced the author to interrupt the pregnancy, but instead of improvement of the symptoms a considerable exacerbation was noticeable. Electrical treatments, massage and muscular exercises had no effect. The patient was not able to walk again without assistance until ten months after the poisoning. After twelve months, most of the symptoms had disappeared.

Modification of Cleidotomy.—Pantschenko directs attention to Chatunzew's modification of cleidotomy in which the incision is made deeper and the entire shoulder girdle is divided. If the resistance is especially great, the division should be followed by extraction of the arm, after which maneuver the delivery is readily accomplished. Compared to ordinary cleidotomy, this modification has the advantage that its technic is not more difficult but reduces the width of the shoulder girdle considerably more. The author states that the method can be employed in head presentations as well as in breech presentations, when the fetus is dead and the extraction of the arms is difficult. It is indicated in cases of narrow pelvis, large fetuses, obstructions on the soft parts of the parturient canal, and when rapid delivery is necessary in cases of insufficiently dilated os uteri.

- Grave Urticaria Treated with Insulin. O. Wedel-Brandt.—p. 590.
- Shoulder-Blade Shadow in Pulmonary Roentgenogram. O. Bouet.—p. 590.

Circular Resection in Chronic Gastric or Duodenal Ulcer.—Roholm reports 130 cases in which operation was performed between 1909 and 1931, of which 40 were transverse resections of the corpus of the stomach and 90 were pylororesections. After-examination was made in 105 cases, from one and one-fourth to twenty-two years later. Transverse resection of the corpus was abandoned because of the frequent development of new ulcers corresponding to the scar formation of the operation. Preliminary pylororesection in eighty-two cases resulted in recovery in 69.2 per cent, recovery or improvement in 81.5 per cent and poor results in 18.5 per cent. The mortality was 12.2 per cent. Polya's method seems to give better results than the first method of Billroth. Comparison between pylororesection and gastro-enterostomy, on the basis of Nielsen's after-examination in 101 cases of gastro-enterostomy done in the same hospital division from 1906 to 1916, fails to show any definite difference in the value of the two operative procedures when they are used as the normal method.

THE RURAL TUBERCULOSIS PROBLEM IN THE SOUTH

CHAIRMAN'S ADDRESS

J. N. BAKER, M.D.
MONTGOMERY, ALA.

Just fifty years ago, Koch discovered the tubercle bacillus. This "find" proved epoch making and comparable to the discovery of gun powder, the printing press, the steam engine, the cotton gin and the pneumatic tire, in that each of these has perceptibly modified man's previous mode of living. Within the brief span of a half century and because of this discovery, the world's outlook on tuberculosis has completely changed.

Tuberculosis as "captain of the hosts of death" has been dethroned. Be the cause what may—and the contributing factors have been legion—this disease has been deposed from its high pinnacle by "heart disease" and now sulkily sits as the seventh chief offender in this regard. From 1898 to 1908 the death rate from tuberculosis dropped one fourth; in the next decade, that is, from 1908 to 1918, it dropped one third; from 1918 to 1928 it dropped one half. Since 1918 the rate in the United States has dropped from 150 to 70.7 per hundred thousand and that of the Southern conference area from 140 to 80.4.

The reason for the higher mortality rate in the Southern conference area is, of course, the fact that 80 per cent of the Negroes in the United States are to be found in this area. It is a well known fact—the possible causes of which need not here be argued—that the Negro death rate is from two and one-half to three times that among the white population. Unquestionably, the general living conditions and the economic status of the Negro population is poor and has contributed in no small measure to the propagation of tuberculosis. Dublin states that in the fifteen-year period prior to 1926 the reduction in the tuberculosis mortality rate for Negroes was 44 per cent. This should offer encouragement as to the possibilities of improving the tuberculosis situation among Negroes, when the comparatively small amount of work that has been immediately directed to this population group is realized.

It is estimated that there are 250,000 people in the Southern conference area afflicted with tuberculosis. An analysis by McCain of figures available for cases in adults admitted to sanatoriums in the Southern area

during 1930 and 1931 indicates that, of the 9,785 studied, 11.4 per cent were minimal, 42.2 per cent were moderately advanced and 46.4 per cent far advanced. Do not these figures speak volumes? From these facts must be deduced two simple conclusions, to wit: The problem is big and the necessity for early diagnosis is paramount. The keynote of subsequent further progress in the control of tuberculosis must be "early diagnosis," and this keynote has been clearly struck in our fifty years of experience. We stand today not only at the half century mark but also at a point half way up the steep incline where we may well look back over the years of battle and, profiting by the errors and failures of our predecessors, vigorously press forward to a complete solution of this problem.

The status of tuberculosis as a communicable disease is so well founded as to call for no argument on this point. Particular attention, and properly so, has been given in recent years to the relation of the family unit in the propagation of the disease. All factors that are presented in poverty, such as overcrowding, undernourishment and poor environment, of necessity play an important part in the widespread exposure and tubercularization of the population. It requires the spark, a positive sputum, to set off the conflagration, and the intimate contact of the members of a family unit is most favorable for immediate and intensive spread. While extrafamilial contact may be an important factor, the problem is reduced to the family unit with the appearance of manifest tuberculosis in one of its members.

The widespread exposure over considerable periods and consequent tubercularization of the population has been repeatedly demonstrated. Aronson, in a recent survey of the Southern states, found an average of 55 per cent reactors among Negro and white children in rural areas in which all factors are carefully controlled. The Mantoux test, a potent and standardized old tuberculin being used, has proved quite satisfactory. The application of the test on family groups has given valuable information as to the intensity of exposure and source of exposure for each family member. The value of the tuberculin test has been so well proved that it must be included in any comprehensive program for the study and control of tuberculosis.

If, therefore, in the South, tuberculosis is a family problem, as I believe largely it is, its proper solution and control must revolve about the family physician as the pivotal point in such control. Until recent years the private practitioner has had a most difficult and unpleasant task in the handling of this disease in its many phases. The discouragingly low economic status of the population groups in which most of his cases have occurred has been a tremendous handicap.

The physician has been forced to depend on his own ability to diagnose and treat these cases without the facilities for confirmation or assistance with roentgen examination or expert consultation. State and municipal laboratories have been of considerable aid in sputum analysis; but when the records of these laboratories show an average of 20 per cent positive of specimens submitted, this would seem to indicate that this procedure has not been fully or intelligently applied.

The experience of Southern physicians shows that many cases are seen by them but a short time prior to death. This is particularly true in the case of the Negro. With this experience, coupled with the low economic status of the average patient and feeling that death is the usual and immediate outcome, the physician naturally does not wax enthusiastic over either diagnosis or treatment. Such cases cannot bring prestige even though all may have been done that is humanly possible in a short period of time. In the absence of proper institutional facilities, where surgical procedures might be used in selected cases and where cases are too far advanced for rest to be a possible factor in recovery, a physician may do very little in the way of medical skill, except to relieve final suffering.

Organized effort, therefore, which appreciates and strives to overcome the difficulties experienced by the key man—the family physician—seems to offer much hope for success. Teamwork of the finest sort and a sympathetic understanding should exist between each physician of the organized medical profession and the official county or municipal health department. The extent and complexity of the local problem must be presented to both the medical profession and the lay organizations. A study and summary should be made from existing records and presented in acceptable form to each group. It is only in this manner that a broad program acceptable to both physicians and lay groups may be prepared and executed which will have the whole-hearted and financial backing of all concerned. The official health organization should sponsor and lead in the education of the people and in the publicity and organization necessary to promote the effort. The methods of control advanced and stressed should be early diagnosis and treatment, isolation of all open cases, social investigation and adjustment of unfavorable environment, and intensive education of the public, especially those closely associated with the disease.

PROGRAM BASED ON LOCAL RESPONSIBILITY

A reasonable program which might be adopted for joint effort on the part of the physicians and the health organization should be laid down along the following lines:

1. A program of education, participated in by all interested agencies, the leadership to be furnished by the organized medical profession and the recognized official health bodies. Such a program should embrace newspaper publicity, lectures, radio talks, promotional work with families and contacts, tuberculin testing of family groups, arrangement for distribution of sputum cups, laboratory containers and pamphlets, and the institution of isolation procedures.

2. The investigation and study of the families in all deaths on record in any given community or area. This would include tuberculin testing of all contacts and examination of selected persons or families.

3. A complete survey of all families in which there exists a known, manifest case of tuberculosis, with the

inauguration of all recommended procedures for prevention of spread.

4. Classification of all suspects on record through local diagnostic facilities. This rather large group can thus be considerably reduced and permits of more intelligent effort where needed.

5. The stressing of the needs for local hospital and diagnostic facilities and the provision of funds necessary for their maintenance.

6. In the absence of proper hospital facilities, as is the case in many of the rural sections of the South, treatment of domiciliary tuberculous cases by the local medical profession, with the recognized agencies giving all possible aid in the matter of nursing and control services. This broad plan of cooperative effort is proving helpful in many sections in Alabama and is worthy of more extended trial.

These views, briefly and imperfectly expressed, spring from the concept of local responsibility on the part of each community, be it a township, county or what not, in regard to its own tuberculosis problem, as much so as the building of its almshouses, its jails, its schools or its roads. Spurred on by the insistent urge of its populace, many states have seen fit to take over, almost in toto, all their tuberculosis problems in much the same fashion as they have assumed the insane and eleemosynary burden. This is a financial load which many states, and more particularly in the South, in their present impoverished plight, will certainly experience difficulty in shouldering. When one considers the slow turnover in such institutions and the comparatively small percentage, usually not more than 15 or 20, of the total tuberculosis problem actually solved through this plan of state cooperation, one can but wonder whether this is either the sounder or the more economic channel of approach. No one, today, would question an important degree of responsibility on the part of the state; the question is rather how best this responsibility may be discharged. To assume the entire burden, as many states have already done, is one, but an expensive, way. For a state to form a partnership with its various political subdivisions whereby it participates both financially and in the stimulation of a local program of self aid certainly has much to commend it. The autonomy of local self government is thereby preserved and the initiative and independence of each political unit correspondingly enhanced. For these reasons, the development of the county or the district sanatorium plan, in which the state participates in both a financial and a supervisory way, seems to offer a method of approach which is sound, economically and basically, and which should form at least a beginning for those states whose finances will not justify a more pretentious program.

To such a modest approach in hospitalization can be added a statewide program of consultative and x-ray service such as is now being sponsored at many points. Such a scheme, as outlined, which seeks to attack the problem of control from the periphery rather than from the center, has been planned for Alabama.

PLAN OF LOCAL CONTROL

The problem of tuberculosis control within the several states presents so many variants and is of such complexity as to defy uniformity of approach or standardization of practice. What might apply to one state in affluent circumstances and with a largely urban population would not at all apply to another with a large rural or agricultural population and with cramped

financial resources. Into the latter category most of the Southern states fall. Because, also, of the fact that the county forms the political unit of government in the South to a greater extent than prevails in many Eastern states where the township dominates the political picture, organization for many types of health service has been simplified and expedited. In Alabama, for example, where up to now 80 per cent of the counties have been provided with all time health service, it is felt that the possibilities are promising of further expanding and superimposing on an already existing county setup a simple and workable plan of local tuberculosis control. Up to the present time, so far as my knowledge goes, no one has succeeded in clearly defining the salient points that should be incorporated into such a plan, nor has there been pointed out the superfluous things that need not be so incorporated. Some two years ago and because of the many shapeless gropings in which we were floundering, Alabama's health department set for itself this rather pretentious task. A tentative plan, embracing the cardinal points enumerated, was submitted to the International Health Board of the Rockefeller Foundation and an appeal made for financial aid in its prosecution. After an exhaustive study of every detail, including the proposed field of operation and the personnel to be employed, the foundation generously consented to make such a study financially possible. This study has been in progress now for one year.

In essence, its purposes are:

1. To determine the incidence of all manifestations of tuberculous infection under conditions that exist in a rural community and their potential significance in relation to clinically manifest tuberculosis.

2. To ascertain the principal channels of spread in a rural community and the factors that modify its transmission.

3. On the basis of the information thus obtained, to devise practical preventive measures suitable to local conditions.

The general plan of procedure will be as follows:

1. The family or household is the unit of study and all families in which there now exists, or where at some time a member has suffered with tuberculosis, will be the nucleus for the study of the disease.

2. The search for new cases will be conducted on a countywide basis, all available means being used.

3. A complete tuberculin survey will be undertaken to include (a) all school children, both white and colored; (b) adults and preschool children by precincts or beats; (c) municipal and industrial groups. This should serve to indicate the difference in the incidence of infection in town and rural areas.

4. In areas selected, on the result of tuberculin tests, an epidemiologic survey of the families within the areas will be made, with follow-up roentgen examination of selected positive reactors.

5. The clinic is mobile and equipped with portable x-ray apparatus. Seven convenient points within the county, where electric current is accessible, have been selected as clinic centers. Provision is always made in preparation of schedules to render prompt service in all cases referred by physicians. Such physician is provided with cards and stamped envelopes to facilitate the immediate reporting of cases.

6. A fully equipped laboratory is set up in the central clinic, located in Opelika. The value of frequent sputum examinations is emphasized to physicians and

patients. A minimum series of ten negative sputums or two successive positives is the strict policy. In all positive sputum cases, bimonthly specimens must be submitted. Specimen containers are stamped, six being given on the first visit, and are submitted by the patient on a prearranged schedule.

7. All families in which manifest tuberculosis exists are recorded individually, by family, and the observations for each family kept up to date on a family graph.

8. General educational measures are carried on both by the clinic and by the county health staff. Each manifest case is under the care of the physician chosen by the patient, and excellent cooperation is being had through the organized local profession.

9. When a sufficiently large group of manifest, sputum positive, tuberculosis cases have been discovered, over the age of 18 years, the preventive phase of the program will be initiated. This will consist of a division of these families into a study and control series. The only variant in procedure with the two groups will be the initiation of isolation of cases in the study group, the portable, screened cottage, separate screened porches and separate rooms being used when possible. All patients and contacts will be reexamined and serially roentgenographed at intervals.

10. The administration problem of rural tuberculosis control will be studied intensively in the entire county where hospital facilities are not available.

Department of Public Health.

A BENIGN FORM OF OSTEOMYELITIS OF THE SPINE

ALAN DEFOREST SMITH, M.D.

NEW YORK

Although osteomyelitis of the vertebral column generally is considered to be relatively uncommon, numerous case reports and descriptions of the condition have been published. With very few exceptions they have dealt with the very acute form associated with high temperature, marked prostration, frequent paralysis from involvement of the spinal cord, and with a high mortality. The impression is had from reading the textbooks and most of the articles on the subject that this is the generally accepted picture of the disease. Steindler¹ describes a milder form of infection, and Kidner² has reported three cases which ran a relatively benign course. From August, 1924, to December, 1932, sixteen cases of osteomyelitis of the spine have been collected from the records of the New York Orthopaedic Dispensary and Hospital and one other was seen in consultation. They indicate the occurrence of a milder form of the disease which, in this small series, was more frequent than the severe fulminating type. In eleven of the seventeen cases a diagnosis of tuberculosis of the spine was made either in the New York Orthopaedic Dispensary and Hospital or by orthopedists of recognized standing elsewhere. It seems probable that, just as many cases of pyogenic infections of joints are mistaken for tuberculosis, similar errors are made in osteomyelitis of the spine. Often it is difficult or impossible to obtain positive proof of the etiology of

From the clinic of the New York Orthopaedic Dispensary and Hospital.

1. Steindler, Arthur: *Diseases and Deformities of the Spine and Thorax*, St. Louis, C. V. Mosby Company, 1929.

2. Kidner, F. C.: *Low Grade Infections of the Vertebral Bodies*. Probably Staphylococcal, *J. Orthop. Surg.* 3: 459-464 (Sept.) 1921.

a vertebral infection, but other factors may make the assumption practically a certainty.

Of these seventeen cases, the vertebral bodies were involved in fourteen and the posterior arches in three. The course of the disease and the indications for treatment in the two groups are so dissimilar as to warrant their separate consideration. The average age of the patients when first seen was 31.5 years and the ages varied from 5 to 58 years. The average age at the onset of the infection was 29.5 years. This is a distinct point of difference from tuberculosis of the spine, which usually begins in early childhood. The lesions extended from the fifth dorsal to the fifth lumbar vertebra and tended to be grouped in the middorsal and midlumbar regions. One patient had two separate foci of infection in the spine and another had three.

The recognition of the condition offers no particular difficulty in the fulminating cases nor in those with posterior arch involvement, often with abscesses and sinuses. It is the type with a lesion in one or more bodies, with only slight or moderate elevation in temperature and with pain that may be described as being little more than a backache, which may be overlooked entirely or diagnosed as tuberculosis. These infections commonly follow others in different parts of the body for which the patient has been confined to bed, and when backache is complained of it is thought to be from some unimportant cause and no more attention is paid to it. As has been stated, in eleven of these patients a diagnosis of tuberculosis of the spine was made in this hospital or by orthopedists of wide repute in other cities. Suspicion that the lesions were caused by some other infection was aroused by the fact that they followed, or in one or two cases preceded, pyogenic lesions in other parts of the body. The diagnosis is further supported by evidence of a productive bone reaction about the lesion and tendency for early bony ankylosis of the bodies.

Laboratory proof of the etiology necessarily is lacking in many. Six patients had a high leukocytosis with an increase in polymorphonuclear cells. Since a number of the patients were not seen until some months after the onset, their blood picture during the early stage is unknown. A culture of *Staphylococcus aureus* was obtained from sinuses in four cases and directly from the bone in two. A growth of *staphylococcus* was obtained from the spinal fluid in two patients, both of whom had a paraplegia. Sections of tissue from abscess walls showed the picture of a nontuberculous chronic inflammation in four. Guinea-pig tests were done in two cases and were negative. The Mantoux test was positive and the Wassermann reaction was negative in eleven patients. Seven patients had draining sinuses and three had a psoas abscess. Abscesses in six cases required incision and drainage. Small sequestrums were extruded in two cases. Osteomyelitis occurred in other bones in four cases and other suppurative lesions in eight. One case followed typhoid and presumably was caused by this bacillus.

The onset was sudden in thirteen cases and gradual in four. In all, pain was the outstanding symptom. In some cases it was severe and in others it was described as hardly more than a backache. It was not relieved by rest. In this respect the symptoms were unlike those of tuberculosis of the spine. There was a history of fever in ten cases. Physical examination revealed a kyphos in only three cases and in none was it as prominent as in the average case of tuberculosis of the spine. This is accounted for by the fact that there rarely ever

is as much destruction of the vertebral bodies in osteomyelitis as in Pott's disease. Two patients had a spastic paralysis of the lower extremities soon after onset. In one it was severe and permanent. In the other it disappeared almost entirely.

As in tuberculosis, one of the earliest evidences of osteomyelitis in the roentgenogram is a thinning of the intervertebral disk. A slight haziness and indistinctness of the bone structure also may occur quite early. Especially in the dorsal region, a fusiform paravertebral abscess shadow, resembling that in tuberculosis, is to be seen in the roentgenogram. Somewhat later, productive bone changes usually are seen about the periphery of the bodies and across the margins of the intervertebral space. There is a strong tendency for bony fusion of the bodies to take place. The important roentgen observations in this group of cases were: thin intervertebral disk, two; thin disk with partial destruction of bodies, five; partial destruction of bodies with bony ankylosis, six; partial destruction of bodies with probable ankylosis, four; destructive lesions of posterior arches, three.

It thus will be seen that while the evidence that these infections were caused by a pyogenic organism was in most cases circumstantial, it was so strong as to make the diagnosis of tuberculosis highly improbable.

The problem of treatment is now to be considered, first in the group of patients with lesions of the vertebral bodies, fourteen in number. One patient, a girl of 14 with a very severe infection and early involvement of the spinal cord, had a laminectomy performed in another hospital. She survived but remained completely paralyzed and bedridden.

Eight patients had an operation for fusion of the spine, most of them on the assumption that they had tuberculosis of the spine. One still has draining sinuses and advanced amyloidosis nine years after operation. Another still had discharging sinuses when last seen, one year after operation, but his general condition was much improved. The remaining six were in good health with no symptoms from their backs and with wounds healed. The patient with the typhoid infection had severe pain in his back for twelve years until his spine was fused, after which it ceased.

Four patients who were treated conservatively with braces and rest also are free from symptoms and are carrying on their normal activities without wearing any supports. In three, the bodies have fused and in the fourth they have almost done so. A fifth patient in whom psoas abscess was the prominent initial symptom and whose spinal lesion was not discovered until eight years later still has a lumbar abscess and draining sinus. The bodies became fused spontaneously. One of the patients in the spine-fusion group was operated on because of pain which really was caused by fracture of a spinous process at the apex of the kyphos. The bodies and laminae in one area already were fused spontaneously and the laminae in the area of the dorsal focus were partly fused. It is fair to say, therefore, that she had a spontaneous cure of her osteomyelitis.

The results in the three patients with lesions of the posterior arches were less encouraging. The roentgenograms of one showed large irregular masses of bone arising from the transverse processes and infiltrating the psoas muscle. One lateral articulation had been destroyed. He was relieved for several months after fusion of the spine, but, following a return of symptoms, an abscess was drained in the right psoas muscle and the infiltrating masses of bone were removed. His

sinuses have been closed and he has been free from symptoms for one year. The two remaining patients have draining sinuses which repeatedly block up and which have required frequent incisions for drainage.

CONCLUSIONS

1. Osteomyelitis of the vertebral bodies occurs quite frequently in a comparatively mild form which may easily be mistaken for tuberculosis.

2. These lesions have a marked tendency to cause spontaneous bony fusion of the vertebral bodies. They should be treated conservatively until it is certain that a cure will not result in this way.

REPORT OF CASES

Two typical case histories follow:

CASE 1.—A. S., a man, aged 58, had a series of infections in January, 1925, including osteomyelitis of the right humerus and left tibia, and suppurative arthritis of the left knee following a furuncle on the scalp. Empyema developed on the left side and was drained. Later an abscess in the right sixth rib was drained. Staphylococcus aureus was recovered from each of these lesions. In October, he was admitted to St. Luke's Hospital for a partial intestinal obstruction, which was relieved by conservative measures. He had complained of pain in the dorsal region of the back since April, 1925. Examination in October revealed a small kyphos at the tenth dorsal vertebra and a roentgenogram showed destruction of the disk between the ninth and tenth dorsal vertebrae and cavitation of the bodies. There was slight swelling of the soft parts about the lesion and marked osteo-arthritic changes throughout the dorsal region. It was thought that he had tuberculosis of the spine and he was transferred to the New York Orthopaedic Dispensary and Hospital.

The patient was fairly well nourished; all his movements were protective. His temperature was slightly elevated; the Mantoux test was positive, and the Wassermann test was negative; the red blood count was 4,480,000; white blood count, 11,900; polymorphonuclears, 65; eosinophils, 4; lymphocytes, 31. An operation for fusion of the spine from the ninth to the twelfth dorsal vertebra, inclusive, was done, November 16. The wound healed by primary union but several weeks later a sinus appeared at the lower end of a scar, from which a culture of Staphylococcus aureus was obtained. This closed in January, 1926, after the extrusion of two small sequestrums. He was last seen in January, 1932, at which time he was in good health; all wounds were closed with the exception of a sinus leading to the sixth right rib. A roentgenogram showed solid fusion of the bodies of the ninth and tenth dorsal vertebrae, as well as of the posterior arches of the ninth to the twelfth dorsal.

CASE 2.—J. D., a woman, aged 50, had a carbuncle on her scalp in January, 1929. Shortly afterward, an infection developed in her right foot, necessitating incision and drainage. It was discovered that she had diabetes, which was controlled with insulin and diet. In February, a cholecystectomy was performed for an empyema of the gallbladder. The cultures from all these infections grew Staphylococcus aureus. While in the hospital, she complained of pain in the back, which was attributed to the cholecystitis. It continued after her discharge from the hospital, however, and became more severe. In the latter part of May, roentgenograms were taken which showed destruction of the disk between the ninth and tenth dorsal vertebrae and of the adjacent portions of the bodies with slight kyphosis. There was a soft part swelling adjacent to the vertebral bodies extending up and down from the site of the lesion. Arthritic lipping was present in the dorsal spine. All movements of the trunk caused pain in the dorsal region. The red blood cells were 4,720,000 per cubic millimeter; hemoglobin, 73 per cent; white blood count, 6,500; polymorphonuclears, 77.5; lymphocytes, 22.5. The roentgenograms were thought to be typical of tuberculosis but it was decided that because of the other lesions and the persistent quite severe pain, the condition was probably osteomyelitis of the spine. A Taylor back brace was applied and she was kept in bed for

four months. The pain gradually subsided and subsequent roentgenograms showed increasing density of the ninth and tenth dorsal bodies and diminution in the surrounding swelling. The last roentgen examination, in January, 1930, showed apparent bony ankylosis of the ninth and tenth bodies. The patient was then in good general condition, free from pain, and was up and about with only a corset for support.

420 East Fifty-Ninth Street.

THE RELATION OF DIPHYLLOBOTHRIUM LATUM INFESTATION TO THE PUBLIC HEALTH

THOMAS B. MAGATH, M.D.

ROCHESTER, MINN.

If there be glory in prophesying an evil event, the honor in one instance belongs to Stiles,¹ who, the year following the published record of the first case of infestation with *Diphyllbothrium latum* native to the United States, and six years after the report of the first Canadian case, predicted that infestation with this parasite, the broad tapeworm, would become endemic in the United States. That this has come to pass can be readily demonstrated from the record here to be given and from previously published records; at least forty-one persons born and residing in the United States, and two in Canada, are definitely known to have harbored the parasite (table 1). Numerous other native cases are unrecorded, while many persons, although born in foreign countries, have surely acquired the worm in North America. In addition to this, it has been proved by Magath² and by Essex³ and confirmed by Vergeer⁴ and by Nicholson⁵ that the life history of the parasite is completed both in the United States and in Canada. The infestation of certain fishes in North American waters has been demonstrated by these observers.

From the experimental results of Magath and Essex,⁶ one may conclude that in North America the life history of the parasite takes place in the colder lakes of the country. The major first intermediate hosts are diaptomi and such species as abound in the northern belt of lakes; these species include *Diaptomus oregonensis*, *sicilis* and *siciloides*. It is possible that some cyclops also can serve because of the proof that *Cyclops strenuus* in Europe is a suitable host.

The fish hosts for the main part are *Esox lucius*, the pickerel or great northern pike; *Stizostedion vitreum*, the wall-eyed pike, and *Perca flavescens*, the perch.

It can be seen from table 2 and the map that the lakes from which infested fish have been procured are in the north central portion of the United States and adjacent to the infested lakes of the south central por-

tion of Canada. These lakes belong to restricted water sheds, one of which includes northern Minnesota and southern Manitoba, draining north to Hudson Bay. A second embraces lakes in northern Minnesota, southern Ontario and Michigan and drains into Lake Superior, while a third includes two lakes in Alberta which drain northwestward. There is direct continuity of the waters of the first two areas.

TABLE 1.—List of Forty-Three North American Native Cases

| Author | Date | No. of Cases | Residence or Region |
|-------------------------|------|--------------|---------------------------------------|
| Hamilton..... | 1901 | 1 | Montreal |
| Nickerson..... | 1906 | 1 | Ely, Minn. |
| | 1911 | 1 | Hennepin County, Minn. |
| Warthin..... | 1912 | 1 | Hancock, Mich. |
| Riley..... | 1919 | 1 | White Earth Indian Reservation, Minn. |

| | 1933 | 1 | Chisholm, Minn. |

At first sight one might think that the native cases reported are quite widely scattered; yet in reality such is not the case from the standpoint of their possible source of infestation. Three fourths of the cases reported were located in the central lake region of North America, coincident with the source of infested fish. With the exception of one case, the others were reported from two metropolitan regions in the East. While it is possible that Eastern lakes are infested, the evidence suggests that the Eastern patients acquired their infestation from fish shipped into their markets from the infested lakes of the Central region. Indeed, this is probably true of many of the other cases. The evidence for this is contained in two considerations. First, more than 75 per cent of pike and pickerel sold in the markets of the United States are caught in the Canadian lakes which harbor heavily infested fish; second, the persons reported infested are practically exclusively Jewish women, who have been shown by Barron⁷ and by Nicholson to acquire the infestation by tasting gefüllte fish as it is being prepared. For this dish, pike and pickerel are frequently used. Most of the patients in the unreported native cases are presumably males and females of the Finnish and Scandinavian races. These patients almost exclusively dwell about the infested lakes and have acquired their infestation by eating their own catch either raw, with or without seasoning, or cold smoked.

There is no evidence to support a theory that the worm has been indigenous to this continent for more than a comparatively short time. The first cases reported were after the beginning of emigration from the Baltic region and other European endemic areas. Leidy first identified the worm in this country in 1879 from one of Walker's patients. Although cases have

been reported fairly regularly from then on, no native case was reported until 1901; this is a little more than a decade after the rather sudden and large emigration from Baltic countries to the iron mining areas of Michigan and Minnesota and the first wave of Jewish emigration to Winnipeg from Lithuania, countries in which the infestation of *D. latum* runs from 15 to even 95 per cent of samples of the population studied. It is definitely known that many of these people brought, besides their baggage, anywhere from one to five or six healthy tapeworms.

The method by which our natural waters have become infested is evident. Both intermediate hosts are present in the areas settled by these peoples in the past, and even today in most of these regions raw sewage is emptied from the towns into the lakes. Lyon⁸ has estimated that more than 1,000,000 ova are discharged each day by a *Diphyllbothrium* carrier. Even when settling equipment is present it does not operate against the eggs in some instances and certainly not against the hatched larvae. The people, maintaining their European custom in regard to tasting or eating raw fish, have kept the parasitic life cycle constantly going and growing until in some lakes almost every susceptible fish is infested.

The exact method by which the infested fish are spread to other lakes and the method by which new lakes are infested is of great importance. There are clearly two ways in which this can take place. Fish may migrate from one lake to another through continuous water passages and this may account for the occasional finding of infested fish in some lakes. The degree of migration of fish is unknown but it is known that some seasonal migration does take place. The second method is economically important. Certain fish hatcheries are situated on infested lakes and, since plankton are readily eaten by the hatchery fish, some fish may become infested and thus be transported to lakes in which otherwise no infestation would occur. This may account for the isolated finding made in East Okoboji Lake. What part the migration of infested plankton plays is unknown.

TABLE 2.—List of North American Lakes Known to Harbor Infested Fishes

| Author | Lake | Region, State or Province | Degree of Infestation |
|------------------|-------------------|---------------------------|-----------------------|
| Magath..... | Burntside | Ely, Minn. | Medium |
| | Long | Ely, Minn. | Heavy |
| | Winnipeg | Manitoba | Heavy |
| Magath and Essex | Vermillion | Tower, Minn. | Light |
| | Devil's Track | Minnesota | Medium |
| | Fall | Winton, Minn. | Heavy |
| Vergeer..... | Portage | Michigan | Medium |
| | Superior (shore) | Michigan | Light |
| | Lake of the Woods | Minnesota | Very light |
| | Basswood | Minnesota | Very light |
| | Nipigon | Ontario | Heavy (?) |
| | Manitoba | Manitoba | Light |
| | Lac La Biche | Alberta | Very light |
| | Lesser Slave Lake | Alberta | Very light |
| Ward..... | East Okoboji | Iowa | Very light |

However, for the most part fish in lakes have become infested and the infestation maintained through the agency of sewage containing human excreta. The evidence for this is that only those lakes are heavily infested into which sewage is emptied from towns in which people reside whose custom it is to eat fish, either raw or underdone. These are the people from the European countries in which a large percentage of

7. Barron, Moses: Infestation with *Diphyllbothrium Latum*, Fish Tapeworm, with Especial Reference to Native Cases, J. A. M. A. 92: 1587-1593 (May 11) 1929.

8. Lyon, M. W.: Native Case of Infestation by the Fish Tapeworm, *Diphyllbothrium Latum*, J. A. M. A. 86: 264-265 (Jan. 23) 1926.

infestation occurs. The survey of Magath and Essex and the work of Vergeer⁹ clearly have demonstrated that.

Closely associated with this problem is the part played in dissemination of the parasite by wild and tame animals, such as the wolf, fox, bear and dog, in which the worm will grow. If wild canines and bears spread the disease, one should find lakes off the beaten path infested. This is not the case. The heaviest infestation occurs in lakes on the banks of which towns or cities or lumber and fishing camps are situated; lakes of which the fish are least infested are in remote places.

The specific part played by the bear is still a matter of speculation. Ward¹⁰ has by several sentences implied he has found *D. latum* in bears but his evidence has not been produced. Skinner¹¹ reported that she obtained such worms from bears of Alaska and Rush¹² from bears of Yellowstone Park. These are the only positive statements that *D. latum* has been found in wild bears. Vergeer reported finding eggs in feces of bears in nature. That these were *D. latum* cannot be proved, since the ova of members of the genus are too nearly alike to allow species to be distinguished. Scott¹³ has carefully studied the worms collected by Rush and also those in his collection from Yellowstone Park and feels sure that they are not *D. latum*. They may be *D. cordatum*, according to him, or more likely a newly recognized species. Plerocercoids from trout of the Yellowstone have been fed to human beings¹⁴ without success. In view of these observations, considerable doubt is cast on the previous records of the occurrence of *D. latum* in wild bears and no one knows how viable ova from this source would be.

The part the dog plays is clear and has been pointed out by Essex and Magath.¹⁵ A large number of heavily infested dogs roam around Burntside Lake and Long Lake, both near Ely, Minn., yet the fish of Burntside Lake are not more than one-tenth as heavily infested as those in Long Lake. The former receives practically no sewage, the latter the sewage from the city of Ely. There are three reasons why the dog cannot be a large factor in this problem, although he must play some part. In the first place these tapeworm eggs from the dog are of low viability; as compared to those from man, about 1 to 80. In the second place, these eggs are readily killed by drying and by cold. Both actions affect the eggs in feces of dogs, since they are deposited in situations which do not protect them. Although dogs are used on northern lakes for running supplies in the winter, freezing of their feces kills the ova in a few hours. Lastly, it is only chance when the feces of dogs are so deposited that rains wash the eggs into the proper lakes before the time limit for their hatching is past. As contrasted with these conditions, one must recall that feces of man are deliberately passed into the lakes by the sewage systems of towns and from the toilets of boats.

Why are not all bodies of natural waters polluted into which eggs of this tapeworm pass? It will be at once evident that no lake or stream will be a source of these tapeworm larvae unless the proper species of fish are present, and, secondly, unless the proper first intermediate hosts are also in abundance. So far as is known, these species of copopods are primarily northern lake forms and that explains the absence of the larvae in susceptible fish in rivers and streams. Aside from these considerations and those having to do with the chance elements in this intricate life cycle, the type of lake must be a tremendous factor.

In the Great Lakes, where there is a modified thermocline but no turnover, there is little or no infestation of fishes, yet it is reasonable to suppose that countless viable eggs have been deposited in them. The eggs are relatively very heavy and settle to the bottom, where the temperature is constantly so low that hatching never takes place. That no development takes place at such temperatures has been proved experimentally. In shallow lakes in wind-blown areas, such as Lake Winnipeg, the temperature of the water is practically the same throughout and the eggs can hatch during many months

Distribution of reported native cases of *Diphyllbothrium latum* and lakes known to harbor infested fish. Situation and number of cases are recorded by circles enclosing numerals, whereas lakes with infested fish are indicated by solid black areas.

in the year. In deeper lakes, even where there is a thermocline, if a spring and fall turnover exists development can also take place.

The question of the effect of the tapeworm on the human host is important. Birkeland¹⁶ has, in a masterful manner, presented this phase of the problem. In general it is evident that the effect has been greatly overemphasized, chiefly by those who have not had clinical experience with the patients. As an illustration, recently Faust¹⁷ stated: "The presence of *Diphyllbothrium latum* in man produces a more or less profound secondary anemia." He then gave the definite impression that this was the rule and that the anemia is severe. The fact is that when anemia occurs it is of the "primary" type but this is extremely rare. One must search the literature very carefully to find examples of such cases unless the Finland literature is examined. Even then the incidence will be of the order

of only 0.01 per cent and mathematically a negative correlation exists. In all literature only about 550 cases of anemia have been reported, of which about 400 affected Finlanders, yet Finland has no higher incidence of infestation than certain parts of Sweden. In Amer-

even mild anemia. The evidence is clear that other factors are at work to produce the syndrome of anemia in the presence of infestation with *Diphyllobothrium*, and the worm can at best be considered only a trigger to set off the illness.

TABLE 3.—Cases of Infestation with *Diphyllobothrium* Encountered at the Mayo Clinic

| Case Sex and Age, Years | Previous Residence | Present Residence | Years in North America | Date of Admission at Clinic | Time Before This Writing | | Symptoms and Complaints | Attending Conditions | Hemoglobin, per Cent (Dare) | Erythrocytes, Millions | Leukocytes, Thousands | Eosinophils, per Cent | Comment |

ica thirty-six cases have been reported; none of these have affected native Americans but twenty-one, Finlanders. None of the infested patients who have come to the Mayo Clinic (table 3) have exhibited any degree of anemia which could not be explained on other grounds than the infestation, and only two have had

The worm may, on the other hand, give rise to other symptoms. These are not different from those caused by other tapeworms and are just as indefinite. The patient's knowledge of the infestation is the keynote in most of the symptoms, which as a rule have to do with nervous manifestations.

With a knowledge of the fundamental facts concerning this disease, measures of control should be instituted along the following lines:

1. All sewage should be treated with some killing solution, such as formaldehyde or chlorine, before being discharged into lakes or streams.

2. People should be taught the necessity of thorough cooking of fish. "Gefüllte" fish should not be tasted during preparation for the table.

3. It has been demonstrated by Kjava¹⁸ and by Magath and Essex that submitting infested fish to temperatures of -10°C . for from twenty-four to forty-eight hours kills the larvae. Therefore freezing methods should be instituted in commercial houses that pack susceptible fish obtained from lakes known to be polluted.

4. Some system should be inaugurated for reporting human cases of infestation and isolating the infested persons until they are freed of the worm.

5. Stools of all Baltic immigrants should be examined.

6. A campaign should be undertaken to prevent feeding dogs with raw fish of the varieties known to be susceptible to infestation with *Diphyllbothrium latum*.

7. Further surveys of lakes and streams should be made in order to discover the extent of infestation of fishes.

ABSTRACT OF DISCUSSION

DR. MOSES BARROW, Minneapolis: Dr. Magath, along with Essex, Nicholson and Vergeer, has definitely proved that fish tapeworm infestation has become native in America. In 1928 I reported nineteen cases of this infestation, four of which were definitely native cases. Since then I have seen four or five cases a year, so that I could now add another twenty-five or thirty cases. The suggestions made by Dr. Magath are important in the control of this disease. Perhaps the fish-eating population could be reached by circulars passed out with each order of fish, stating that some of the fish may be infested and that the fish should be cooked thoroughly before being tasted. The disposal of sewage is a very important matter. I was interested in Dr. Magath's statement that many of the lakes in which there are fish hatcheries are infested. That certainly ought to be stopped at once. No fish hatcheries should be located in lakes that have already proved to be infested. It is simple to free patients from infestation. The present method of treatment is so simple, takes so little time of the patient, only perhaps three or four hours in the hospital, that all patients can be convinced that they should be freed of this infestation immediately. The possibility of further infestation in human beings could be eliminated later on by the freeing of all those known to be carriers at the present time and by proper isolation of the lakes known to be infested. As Dr. Magath stated, there are no definite symptoms.

DR. M. W. LYON, JR., South Bend, Ind.: From my limited experience I have seen no harm result from infestation; in fact, the presence of the fish tapeworm seems to be as harmless as that of the more common beef tapeworm. Dr. Magath has probably erred on the side of conservatism in calling cases native infestations. Many native cases occur in adult foreigners who were free of infestation when they left home. The last case I reported was in a well nourished Jewish woman who had been in the United States many years and only recently had noticed the parasite. She frequently made gefüllte fish and described the process of making it to me. Dr. Magath has pointed out the simple measures to be employed in protecting the northern lakes from sewage, as well as how to handle and prepare fish in order to destroy the larval forms of the tape-

worm. The latter measures are probably more practicable than the sterilization of sewage, especially in these days of limited municipal finances. If fully carried out, it would lead to extinction of the fish tapeworm. Dr. Magath's recommendation that the stools of Baltic immigrants be examined for this parasite is a good one. That the parasite requires a cold climate for its life cycle is well shown by the seasonal incidence of *Diaptomus oregonensis* in the St. Joseph River at South Bend, Ind. Mr. John Dolley of the University of Illinois did considerable work on studying the plankton and other life of this river. Several summer collections failed to reveal any *D. oregonensis*, but November and December collections yielded numerous examples of this species. The St. Joseph River is so polluted in the immediate vicinity of South Bend that the intermediate fish hosts cannot live in it. I wish that Dr. Magath would say something in his concluding remarks on the subject of heavy infestation of adult fish hosts. If I understand the matter correctly, the adults do not become infested by eating the diaptomi directly but by eating smaller fishes that have eaten them.

DR. THOMAS MYERS, St. Paul: I have seen five instances of this infestation in native born American children in St. Paul, all of them of Jewish parentage. They were all infested in the same manner; that is, they were permitted to taste particles of this incompletely cooked gefüllte fish. In every case the diagnosis was made by the appearance of large segments of the worm in the stools. The children have practically no symptoms aside from occasional cramps. I have yet to see a case of anemia occurring in children, nor has any been mentioned in the literature. There have been several reports of this infestation in children by Rodda and Wilder of Minneapolis and by Pilot of Chicago, who observed a fairly large series. Many instances are called tapeworm infestation without an attempt to differentiate between the beef tapeworm and the fish tapeworm. Oleoresin of aspidium is employed, sometimes pelletterine. It would seem that active propaganda in teaching people not to eat uncooked fish would rapidly eliminate this parasite, as the fish must indirectly be infested by human excreta.

DR. W. S. LEATHERS, Nashville, Tenn.: How many parasites may be found in one person? Reference was made to the number of eggs discharged from a person per day and it would be of interest to know the approximate number of parasites responsible for the number mentioned. I have had no experience with this parasite and an answer to this question would be of interest to me.

DR. THOMAS B. MAGATH, Rochester, Minn.: In regard to the last question, I have seen one patient with four worms; more than four have been reported. The vast majority of patients have one or two worms and that makes a difference in the number of eggs passed in the feces. Dr. Lyon's finding of 1,000,000 eggs per patient is a conservative figure. I have had occasion to estimate the number of eggs on several occasions and it has run much higher. The figure was published by Dr. Lyon; he is a competent observer and certainly his estimate is not too great; if anything it is too low, and many patients will excrete many more than 1,000,000 eggs a day. Concerning the habits of the Finlanders and other Europeans in eating raw and insufficiently cooked fish, the subsequent generations in this country are doing it less and less; however, the Finlander is still fond of this food, sometimes ripened a bit, then seasoned with vinegar and salt. The number of larvae that are found per fish varies from a few to as many as seventy-five or eighty larvae per fish. Apparently the older the fish gets, the more larvae he gets, although information is not complete. The plankton forms, diaptomi and cyclops, are eaten by young fish. The larger fish can become infested by eating smaller fish, the smaller fish having infective larvae in the stomach at the time. That has been demonstrated experimentally and it undoubtedly happens, how frequently I do not know; but the great northern pike is often found with the stomach literally loaded with smaller fish, and in the stomachs of the smaller fish, in turn, one may find infested diaptomi. The treatment is very simple, very satisfactory, and there is no reason why it should not be employed as a routine in these cases.

PUBLIC MEDICAL CARE IN NEW
YORK STATE

THOMAS PARRAN, JR., M.D.

ALBANY, N. Y.

To what extent does the state now assume responsibility for the medical care of its citizens? In this paper I attempt to answer the question through an analysis of existing laws and current practices in the state of New York.

Through a succession of far-reaching laws for human welfare, the state and local governments in New York already have become responsible for many and diverse types of medical care, supplementing traditional preventive health functions.

The treatment of mental disease, for example, has been a state function since 1890. There has been built up an excellent system of hospitals, with a patient population of nearly 55,000, maintained at a cost of about \$20,000,000 a year. Appearing frequently in old laws was the term "pauper insane," a term which now is replaced by "persons with mental disease." This well illustrates the change in public concept toward this problem. Supplementing the excellent system of hos-

pitals are state-operated child guidance clinics and clinics for the after-care of paroled mental patients, which served more than 10,000 patients last year.

The control of tuberculosis furnishes another example of care and treatment as well as preventive services for patients supplied through public action. When the sanatorium construction program now under way is completed, a bed will be available for every tuberculous patient in need of such care. State and local sanatoriums now built or in process of construction provide a total capacity of 8,300 beds. Tuberculosis sanatoriums represent a capital investment of \$19,000,000 and an annual operating cost of \$3,553,000. Moreover, in every county of the state, diagnostic clinics and clinics for the follow-up care of discharged patients are being conducted. The state itself operates such clinics in the smaller counties which are unable to provide these services, while in the larger counties the service is available through the county tuberculosis sanatoriums.

State and local governments also have assumed a large measure of responsibility for medical care of children. In theory, and to a considerable extent in practice, educational authorities have accepted responsibility for the physical well being of all children of

school age. As a part of this program, an annual medical inspection is required, and "if the parents or guardians are unable or unwilling to provide the necessary relief and treatment for such pupils, such fact shall be reported by the principal or teacher to the medical inspector, whose duty it shall be to provide relief for such pupils."¹ The annual cost of school health services is \$2,537,184.

The state itself also has assumed much of the burden of care and treatment of crippled children. Under the provisions of the Education Law² and the Children's Court Act³ the state has declared its intention that no child shall be handicapped in acquiring an education or in engaging in a remunerative occupation by reason of correctable physical defect or disease. It is estimated that about 3,000 such handicapped children will be treated this year, requiring a total expenditure of more than a million dollars, one half of which will be paid by the state. This law is administered through joint actions by the departments of health and education, a large state reconstruction home, private orthopedic hospitals and homes, a field staff of orthopedic surgeons and nurses, and many local orthopedists and hospitals.

Counties and cities are authorized to construct and maintain public general hospitals⁴ at which all citizens are entitled to admission free or at a rate they are able to pay. There are thirty such hospitals now in operation in the state. In table 1 are given the detailed data concerning the number and size of public hospitals in various categories as compared with similar data for the private hospitals in the state.

The volume of dispensary service, in both public and private hospitals, has grown rapidly in recent years. In 1931 more than two and one-quarter million individuals were treated in clinics and dispensaries (public and private). Data for 1932 are incomplete but indicate a considerable increase over previous totals. Table 2 summarizes the volume of dispensary care and shows the large increase in the use of public facilities.

The control of the venereal diseases is another field in which public action in recent years has supplemented, and to some extent supplanted, private endeavor. Surveys of cases of venereal disease under treatment indicate that between 40 and 50 per cent of all cases of syphilis and a somewhat smaller percentage of gonorrhea cases are now being treated at public expense. In the venereal disease clinics upstate last year, 23,000 patients were given 230,000 treatments. Accurate data for New York City are lacking, but the cases more than double the upstate total. All these clinic treatments are included in the total given under dispensary service.

Traditionally, government has provided needed medical care for paupers and indigents, although such care rests on a statutory rather than a common law basis. A long step beyond this concept was recorded in New York by the passage in 1929 of a public welfare law, which makes it the obligation of municipalities to provide all necessary medical, nursing and hospital care for those citizens, normally self supporting, who are unable temporarily to provide themselves with such service. The state is divided into public welfare districts, one for each county and each large city. The law⁵ requires that

The public welfare district shall be responsible for providing necessary medical care for all persons under its care, and for

2. Article 47.

3. Section 486.

4. General Municipal Law, sections 126-134.

5. Sections 83, 84 and 85, Public Welfare Law.

such persons otherwise able to maintain themselves, who are unable to secure necessary medical care . . . Such care may be given in dispensaries, hospitals, the person's home or other suitable place.

When a legislative body shall make an appropriation for the purpose, one or more physicians shall be appointed to care for sick persons in their homes. . . . Where no physician is so appointed, the public welfare official shall employ a physician or physicians to visit sick persons in their homes whenever necessary.

Further,

A public welfare district shall provide needed care for sick and disabled persons in a hospital. . . . It may contract with such . . . hospital to pay such sum for the care of sick persons as may be agreed upon.

It will be noted that this law definitely removes the stigma of pauperism from recipients of public medical relief. It is based on the theory that a person otherwise self supporting may be unable to provide medical treatment for himself and his family; that the lack of medical care may result in unnecessary illness with resulting

of New York, rules and regulations have been formulated and put into effect to provide uniform standards and procedures for medical relief.⁷ In some welfare districts, "outdoor medical relief"—the term includes home and office care—constitutes as high as from 15 to 20 per cent of the total relief load. For the state, exclusive of New York City, it constituted 3.2 per cent for April, 1933. While this percentage may seem small, it will amount to about a million dollars a year at the current rate of expenditure. All this money is being paid to local physicians on a fee basis for service rendered in accordance with rules laid down by the state. The physicians have been very generous in accepting lower rates of pay than those prevailing in private practice.

Desirable as it may seem for the practice of medicine to be exclusively a private matter between the physician and his patient, the payment to physicians from public funds during the last year probably has meant the difference between solvency and insolvency for a great many doctors, particularly in rural areas. It has meant

dependence and pauperism. In other words the law, in addition to requiring medical care for persons already indigent, seeks to prevent others from becoming public charges for lack of medical care.

A further example of the interest of the state, expressed in law, in the personal health of citizens is found in the Temporary Emergency Relief Act, passed in 1931.⁶ This law, the first of its kind in this country to meet the unemployment emergency, was based on the public health powers of the state. By its terms, medical care, food, clothing and shelter are listed as "necessities of life." The provision of such care is made an obligation on state and local agencies charged with unemployment relief. Under the terms of this law the state establishes relief standards and reimburses the local welfare districts for approved expenditures on account of unemployment relief, including medical relief. The state department of health has acted as the medical adviser to the Temporary Emergency Relief Administration.

In cooperation with and with the approval of a special committee of the Medical Society of the State

also that needed medical care has been furnished to persons who otherwise would not have received such care.

The current unemployment emergency has given an opportunity to provide nursing and dental care by utilizing nurses and dentists who themselves are in need of public assistance on a "work relief" basis. More than 200 nurses are being employed by the state department of health with relief funds allocated for the purpose, and assigned to work under the supervision of local health departments, visiting nurse associations or similar agencies. These nurses render bedside nursing care and public health nursing service, principally to families receiving public relief funds. About the same number of dentists similarly are being employed to provide dental service in existing and newly established dental clinics in New York City. The current annual rate of expenditure for these services is approximately \$250,000.

The volume of public medical relief under the Public Welfare Law and the unemployment relief act can be visualized by the fact that in April, 1933, 396,884

6. Laws of 1931, chapter 798; amended by Laws of 1932, chapter 567.

7. Health News, March 13, 1933 (10, No. 11).

families were on the relief rolls. This constitutes 15 per cent of the population of the state. Medical care for the unemployed, "state medicine," if you like, for a considerable part of the population has been superimposed on a volume of public medical service already large.

It should be explained that medical care under public welfare laws is provided in several ways:

(a) In New York City, medical relief is given in hospitals and dispensaries. Until last year that city had not provided "outdoor medical relief." Under an arrangement agreed on by the county medical societies of New York City, home medical care was provided on a fee basis for needy persons under regulations comparable to those in the rest of the state. At the present time about \$35,000 per month is being spent for this outdoor medical relief. This is supplemented by home nursing care, likewise paid for from relief funds, and by an annual appropriation of \$16,985,410 for the city department of hospitals.

(b) In the larger upstate cities, hospital and dispensary care is provided; also home medical care through salaried physicians employed for that purpose. Home nursing service also is furnished through visiting nurse associations, supplemented by emergency relief nurses.

(c) In the smaller cities and rural areas, local welfare officials in general have not employed physicians on a salary basis, although there are some notable exceptions to this rule. The more usual arrangement is for local physicians to be employed on a per visit basis, subject to the state regulations already outlined. Bedside nursing care in rural districts has not been developed extensively, although local welfare officials are authorized to and frequently do employ nurses to give such care to ill persons.

Time permits only casual mention also of such state or local public health activities as prenatal and infant welfare clinics; clinics for immunization of children against diphtheria and smallpox; communicable disease hospitals; the state institute for the study of malignant disease, with an extensive service in making free diagnoses of pathologic specimens for any physician or hospital and with a limited tumor diagnostic and treatment service; the state-wide system of approved or state-aided local laboratories, many of them tax supported and available free for clinical no less than public health examinations; and the free distribution by the state of biologic products to all citizens regardless of ability to pay.

Recent discussions of the need or lack of need for reorganizing our existing system of medical care frequently start from a mistaken assumption. The impression seems to prevail that a choice must be made between the present system of private and completely individualistic medical care and a very different collectivized system. As a matter of fact the present system is far from being completely individualistic. With two thirds of the hospital beds in New York State owned by the public and supported through taxes; with 15 per cent of the population of the state receiving all necessities of life from public funds, including medical care; with practically all cases of mental disease and a large proportion of tuberculosis being hospitalized at public expense; with one half of the burden of syphilis treatment a public responsibility; with the care of crippled children an actual obligation, and medical care of school children a legal obligation of the public; and with blanket authority existing for any city or county to

construct and operate public general hospitals available to all citizens, it will be seen that, to a considerable extent, medical care already has become a matter of public participation.

The only opinion I shall venture, as to the implication of trends in public medicine in New York in determining medical care to be provided in the future, is that the interest of the public in this problem, that action by municipalities under one or another provision of existing laws, that public expenditures and control for preventive and curative medicine seem as likely to increase in the future as in the past.

State Office Building.

ABSTRACT OF DISCUSSION

DR. W. H. ROSS, Brentwood, N. Y.: How far can the state go in activities hitherto largely dependent on private initiative for leadership? One can easily visualize increasing difficulty for the taxpayer if the state increases its public medical care. The state has no money except that which comes from the taxpayer. We as a nation cannot spend money indefinitely. Any increase in public medicine means an increase in paternalism. Is this for the best interests of society? The cost of work relief in New York State has increased from two and a half millions to more than one hundred millions in two years. We have accepted for a long time the obligation of providing food and shelter and clothing for every individual and now we have added to these medical care. If the number of individuals requiring these things grows, a redistribution of wealth will be necessary and a reorganization of that which was thought to be standard. I am not objecting to public medicine if we as taxpayers can pay the bill. Can all these things continue without bringing about taxpayers' bankruptcy? The state has become tremendously powerful. It has come to have vast resources. There is an alarming tendency to have the state do things and the result may be a disturbance of our social formation. We have today in government controls of all kinds—commerce, currency, industry. I doubt whether it can go much further without imposing an impossible burden on the taxpayer. If state intervention goes too far into the realm of private initiative, is there danger that it will absorb social effort which has hitherto been thought to be the most effective means for advancing public welfare? One wonders whether emotionalism is playing a part in public medicine. We need the assistance of the state in medicine but do we need the state as a dictator in medicine? The indications are plain of the trends in public medical care at the taxpayers' expense, but is it the best thing for society to have its personal initiative diminished by giving more than it can get for itself?

DR. NATHAN B. VAN ETTEV, New York: The housing of sufferers from mental diseases at an annual cost of \$20,000,000 presents a serious tax problem. The intensive effort in the prevention and care of venereal diseases, and clinical research in the field of personality, of endocrinology, of psychiatry, of social maladjustments and of eugenics, may open an opportunity profitable to the medical profession and to the taxpayer. Forty-two per cent of all hospital beds are now occupied by mentally sick people, many of whom might be caring for themselves if they had been able to profit by early diagnosis and preventive treatment. Control of tuberculosis in the last twenty-five years justifies the provision of sanatoriums. The governmental care of the health of school children through supervision of preventive immunizations promises dividends. The city hospital has long been the stage on which has been enacted a continuous performance, the title of which might well be "Demoralization." Yearly the plot thickens with an increasingly large cast. The city dispenses an unintelligent hospitality which defrauds the taxpayer. Physicians have always been willing to serve the sick poor without fee, and the city hospital always will be served by physicians without complaint, if the hospital is limited to the service of the really indigent. All classes of citizens, regardless of financial status, have been demoralized into thinking that usage has created a right to enjoy privileges for which they do not pay. Many people have crowded wards and clinics

who have never had a moral right to be there. Government hospitals are in unfair competition with private practitioners and in ruinous competition with nongovernmental hospitals and are defrauding the taxpayer. Last month a patient in our hospital on the day before his free operation made a will distributing an estate of \$100,000. Such abuses of medical charity are no doubt common everywhere and must be corrected.

TYPES OF CHRONIC RHEUMATISM

RALPH A. KINSELLA, M.D.

ST. LOUIS

A remarkable increase in interest in chronic rheumatism has been shown in recent years. As a matter of fact, a student in this field may find the review of important work of older writers and the descriptions of results of modern investigators within the current literature of the past two years.

The formation of the American Committee for the Control of Rheumatism might be regarded as a symptom of this increased interest. The classification of chronic rheumatism which was issued under the auspices of this committee proved to be a challenge which has been met in the studies of many workers and which has been useful in leading to a clearer statement of the problems that must be understood before treatment can be improved.

The multiplicity of names previously in vogue led the average practitioner to believe that as many different forms of rheumatic disease were prevalent as there were names employed by various writers. It is my purpose in this paper to look at the question from the standpoint of a practitioner and attempt to come to an attitude that will make designation simple and the understanding of problems involved more clear.

The American Committee on the Control of Rheumatism suggested that the various types of chronic rheumatism be grouped under two varieties called atrophic and hypertrophic arthritis. It became necessary at once to study the evidence that led earlier writers to employ different names. It is apparent that a single disease was receiving numerous designations, such as proliferative, atrophic or chronic infectious or rheumatoid arthritis. The expression "proliferative arthritis" was used in the classic description of Nichols and Richardson when they described the changes in the joints in the disease previously known as arthritis deformans. The reasons for using the expression "proliferative" were valid, and these investigators traced the progress of the reaction in a joint with remarkable clearness. The term had the disadvantage of being indefinite and not sufficiently exclusive in character. To these changes appeared to be of bone substance, and this gave rise to the expression "atrophic." The expression "atrophic arthritis" has become widespread in use because it is popular not only with the internist but also with the roentgenologist. It is objectionable because the chief pathologic process is not atrophy and the real process is entirely overlooked in such an expression. Within the past ten years there has been much bacteriologic study, the results of which implied that arthritis deformans was an infectious process, and many writers use the expression "chronic infectious" arthritis as synonymous with proliferative arthritis or

atrophic arthritis. The fact that many other forms of chronic infection about the joints produce clinical pictures strikingly different from the picture of arthritis deformans makes the expression "chronic infectious" arthritis too indefinite. In the meantime, the expression rheumatoid arthritis has continued from the writers of the earliest reports, and in many prominent clinics in the country the disease which has been variously referred to by the aforementioned names is classified as rheumatoid arthritis. The expression rheumatoid arthritis may be said to represent an escape from inaccuracy as much as an approach to better definition. It has the added advantage, however, of suggesting a connection with rheumatic fever, which is reflected not only in recent studies but even in very early reports.

For the purpose of classification, therefore, in this paper the expression rheumatoid arthritis will be used to describe that disease which the average practitioner of today learned about under the name arthritis deformans.

The other variety of chronic arthritis, which is common in everyday practice, was designated as hypertrophic in the report of the American Committee for the Control of Rheumatism. There is much evidence in favor of the accuracy of this term, because changes that take place in the bones of patients with this condition sometimes show evidence of hypertrophy. Here again the influence of the roentgenologist is felt because, while Nichols and Richardson described the changes found in this condition as essentially degenerative, the appearance under the x-rays were suggestive of hypertrophy and exostosis.

The recent studies of Keefer and his associates and those of Bauer would indicate that these degenerative changes are incidental to the effects of trauma and senescence, and to the wearing out of movable parts, and that the hypertrophic changes and exostoses represent attempts on the part of the tissue to repair damages produced by such trauma. A consideration that complicates this argument arises from the fact that Heberden's nodes, so frequent in degenerative arthritis, appear definitely to be associated with certain involutional changes, particularly those occurring in women at the time of the menopause. This creates the impression that some constitutional influence besides trauma is important in producing this type of rheumatism. The expression "osteo-arthritis" describes the clinical picture and is perhaps as popular as the expression "hypertrophic"; it is the term of choice in some clinics. There is not much reason to prefer any one of the three terms degenerative, hypertrophic or osteo-arthritis. For the purpose of description in this paper, the expression rheumatoid will apply to the first type of chronic rheumatism, and the expression degenerative arthritis will be used to designate the other type of chronic rheumatism. The expression "arthritis deformans" is discarded because it refers only to "rheumatism with deformity"—a condition which may exist in both of the chief varieties mentioned.

RHEUMATOID ARTHRITIS

It is not my purpose in this paper to describe again the clinical picture so well known by every practitioner. Extensive descriptions have already been written. Until comparatively recent times no theory concerning the etiology of rheumatoid arthritis gained much popularity. In their descriptions of the pathologic changes, Nichols and Richardson were careful to disclaim any knowledge of etiology and particularly held that there

was no evidence to support the idea that the streptococcus was responsible for the disease. During the past ten years the chief discussion concerning the etiology has centered about the streptococcus. On the one hand, there have been reports by Cecil, Nichols, Stainsby, Clawson and others of positive cultures of various types of streptococci recovered from blood and synovial fluid. On the other hand, very painstaking work by Dawson tends to refute the positive reports, and this negative attitude is strengthened by further studies of Lichtman and Gross. Besides the approach to the question of bacterial infection by means of cultures, studies of serologic features have been made which are both interesting and important.

Many workers agree that patients with rheumatoid arthritis possess a peculiar capacity on the part of their serum to agglutinate streptococci. Dawson, Olmstead and Boots found that this capacity to agglutinate was possessed in common by patients with rheumatoid arthritis and those with acute rheumatic fever. Keefer and his associates found that while a little over 50 per cent of patients with rheumatoid arthritis possessed the capacity to agglutinate hemolytic streptococcus, patients with rheumatic fever possessed this capacity in less than 25 per cent of the cases. Finally, Nichols and Stainsby, while agreeing that the majority of patients with rheumatoid arthritis displayed such capacity to agglutinate hemolytic streptococcus, found that patients with acute rheumatic fever as a rule did not possess such a reaction. A point of great interest lies in the fact that patients with rheumatoid arthritis, according to Dawson, yield positive agglutination reactions not only for *Streptococcus hemolyticus* but also for the *R. pneumococcus*.

It is not easy to interpret these results as meaning that rheumatoid arthritis is an infection by streptococcus. One is reminded of the Kahn test for syphilis, according to which patients with this infection show agglutination reaction with extract of beef heart. The streptococcus may be as remote to rheumatoid arthritis as beef heart is to syphilis. Nevertheless, the fact that patients with rheumatoid arthritis do show a strongly positive tendency to agglutinate hemolytic streptococci might be taken as an argument in favor of the infectious nature of the disease.

Pathologic changes about the joints in rheumatoid arthritis were first fully described by Nichols and Richardson and more recently descriptions in greater detail have been given by Allison and Ghormley. The pathogenesis of the disease as described by all of these workers places the initial lesion in the synovia, with a spread of the process into the joint cavity and into the interspaces of the ends of the bones. The process itself consists of round cell infiltration, which is characterized, according to Allison and Ghormley, by the formation of small tubercle-like collections. This picture is particularly interesting when considered in connection with the description of the subcutaneous nodules that are found in this disease and that are similarly described by Dawson, and in the older literature by McCrae. Both the lesions in the joints and in the nodules resemble the lesions of acute rheumatic fever.

It is perhaps interesting at this point to consider the pathogenesis of experimental streptococcal arthritis in rabbits. In this study, rabbits were inoculated intravenously with suitable doses of virulent hemolytic streptococci. At twenty-four hourly intervals the joint tissues were obtained at autopsy and investigated, to

determine the point at which initial inflammations might be beginning. It was found that at twenty-four hours initial lesions could be detected in the synovial membrane as a hemorrhagic collection, which quickly became purulent and extended into the joint at about the fifth day. An attack on the substance of the bone was made on the lateral aspect of the joint and a purulent infiltration was established which spread like a pannus over the joint surfaces and into the heads of the apposing bones. This infiltration became organized, and ankylosis was finally established by fibrosis.

This series of events is analogous to the pathogenesis as described by Nichols and Richardson and perhaps is additional support to the idea that the process in rheumatoid arthritis is an infectious one. The nature of the reaction in streptococcal arthritis, however, is so different from that of rheumatoid arthritis as to throw doubt on the conception that rheumatoid arthritis is related to infection by the hemolytic streptococcus. The occurrence of subcutaneous nodules both in acute rheumatic fever and in rheumatoid arthritis was noted by McCrae, and painstaking comparative study by Dawson has suggested that there is a striking resemblance between the microscopic evidence in the nodules in acute rheumatic fever and in rheumatoid arthritis. That there is a sharp clinical difference in the patterns of the two diseases is obvious, and the invariable attack on the heart seen in acute rheumatic fever is not encountered in rheumatoid arthritis. This point has been excellently emphasized by Master and Jaffe.

TREATMENT

As a result of the studies, which point to a possible connection between the hemolytic streptococcus and rheumatoid arthritis, numerous workers have employed the method of vaccination with these organisms in an effort to bring about successful treatment. The most noteworthy contribution in this field is the work of Clawson and Wetherby, who have treated many patients with chronic arthritis by intravenous injection of these bacteria. Unfortunately, these writers do not clearly separate cases of rheumatoid arthritis from other cases of chronic arthritis, and it is difficult accurately to criticize their results, because the prognosis in the two groups is so different.

In a much smaller experience at the arthritis clinic at Desloge Hospital in St. Louis, the use of streptococcus vaccines and streptococcus extracts has not been followed by encouraging improvement. Other forms of treatment include the use of hyperthermia, and other physical therapeutic devices have been used without more than temporary relief.

The operation of sympathectomy, while producing curious relief from pain in some instances, has not in our experience proved sufficiently valuable to justify its continued use. In this connection, it is very interesting to mention that many operations, such as the removal of an infected gallbladder, will produce not only a temporary benefit to the patient but even a vasomotor effect in the hands and feet similar to that seen after sympathectomy.

The clinical course of this disease presents one feature that is extremely important in estimating the effect of any treatment. This feature is the tendency of the patient to enjoy remissions. These remissions are much more likely to occur in the early months or years of the disease and may last from a few weeks to a few years. This fact makes it impossible to be certain that a given treatment is producing the remission which

might occur if no treatment were given. But, on the other hand, it constitutes an important reminder that improvement is possible could the key to its production be captured. In my experience, as in the experience of many others, the prognosis of rheumatoid arthritis is extremely discouraging. The need is great for searching for the etiologic agent in hitherto unexplored fields, and the treatment that any physician employs had better be some reasonable treatment worked out along new lines.

DEGENERATIVE ARTHRITIS

One of the reasons why the expression arthritis deformans is no longer used to describe rheumatoid arthritis lies in the fact that deformity is also produced by the disease known variously as degenerative, hypertrophic or osteo-arthritis. No two diseases could be more unlike than rheumatoid arthritis and degenerative arthritis. While there is an argument concerning the bacteriology of rheumatoid arthritis, it is apparently universally agreed that there is no bacteriology whatever in osteo-arthritis. The disease about the bones was well described by Nichols and Richardson. More recently, Keefer and his associates have undertaken to study the changes in the bones of a group of 100 knee joints of patients coming to necropsy as a result of a variety of diseases and without the symptoms of rheumatism in the knees in 90 per cent of the cases. They came to the conclusion that the process of aging and the trauma incident to motion and weight bearing produced primary degenerative changes in the joint surfaces which often led to stripping of the cartilage. They felt that the deformed excrescences were the result of an effort to repair damages locally. It is peculiar that persons who show these signs most readily are of a physical type in which small nodular swellings about the joints of the fingers occur frequently. These swellings have been called Heberden's nodes, and the question of their nature raised by Heberden himself has never been adequately answered. They do not occur about the joints of the toes and it is possible that they may represent a process in the fingers due to traumatic use similar to the process which has been described by Keefer and by Nichols and Richardson in other parts of the body. It is a question whether the changes about the bones just described deserve the name "arthritis." Such persons need not be patients. Whether or not they are patients apparently depends on the occurrence either of injury or of inflammatory changes about these previously degenerated joints. These inflammatory changes are most often the result of an infection and might be referred to as focal infection. The injury may be produced by new and sudden trauma or from the trauma incident to obesity. The experience of every clinician and clinic includes cases of this type in which, in one or several joints, painful swellings occur that have an apparent though often unproved relationship with a focus of infection elsewhere in the body. This is the field in which the idea of focal infection is well established. The treatment of such patients will depend on the nature of the exciting cause. In joints already the site of extensive excrescences and deformities provoked by years of trauma, slight injuries may produce effects calling for energetic orthopedic treatment. Such patients should be referred to the orthopedist and are most likely to be benefited by the various physical therapeutic measures as well as by orthopedic maneuvers. In that group of patients in which infection seems clearly to

play a rôle, careful search for infected foci must be made and appropriate clearing out of such places instituted. In connection with such infection, it must be remembered that syphilis may produce many kinds of inflamed joints in such patients. It is useful in many cases to employ colchicum in medication. An occasional patient having a low basal metabolic rate is benefited by the use of thyroid extract, but many patients experience an accentuation of pain following the use of this drug. In all patients with chronic arthritis, the restriction of carbohydrates seems beneficial. Many patients also report improvement when constipation is relieved either by ordinary remedies or by colonic lavage. Reduction in weight naturally lessens trauma in obese persons.

PROGNOSIS

The prognosis in degenerative arthritis is generally favorable. The nodes on the fingers are sometimes distressing and unsightly, and the symptoms of pain usually subside without special treatment. Patients who have evidence of acute infection of one or more joints usually suffer the most protracted course, but even in these patients limited improvement is to be expected. Long continued use of orthopedic and physical therapeutic measures may be needed, but here, too, success usually follows diligent effort.

When one considers the contrast that exists between the prognosis of degenerative arthritis and rheumatoid arthritis, it is apparent that the success of no treatment may be accurately estimated if this treatment is applied indiscriminately to the two types of disease.

SUMMARY

There are two main types of chronic rheumatism: the one known as rheumatoid arthritis, of apparently infectious nature, caused by some as yet undiscovered agent and without successful treatment at the present time; the other, known as degenerative arthritis, in which the factors of production are fairly well recognized and in which subsequent injury or superimposed focal infection constitute the reasons for bringing such persons under medical care. In this second disease, recovery is much more likely to occur.

3720 Washington Boulevard.

ABSTRACT OF DISCUSSION

DR. JAMES S. McLESTER, Birmingham, Ala.: Interest in chronic arthritis lies in the fact that the disease is widespread and that little is known about it. I have been impressed with the fact that many patients with roentgenologic evidence of hypertrophic arthritis will experience no discomfort whatever and that not until something happens, a minor accident or a passing infection, does pain appear. In addition to the tissue changes of wear and tear and of age, it would appear that some other factor is operative in such instances. Not so much rheumatoid arthritis is seen in the South as in the North. This is understandable if one accepts Dr. Kinsella's suggestion that this disease is perhaps in some way related to rheumatic fever, for in the South comparatively little of the joint manifestations of true rheumatism is seen. The admission of the author that he sees little promise in any of the present methods of treatment of arthritis strikes a responsive cord in most physicians. Dietary regulation, in my experience, has never seemed to influence the course of chronic arthritis, except in the case of the obese and the near obese. In the present state of knowledge of the treatment in chronic arthritis, the patient should be treated rather than the disease. Persistent, long continued attention to those things that add to the patient's comfort, including the various forms of physical therapy, will frequently bring genuine improvement.

DR. WALTER BAUER, Boston: In order to treat more intelligently each patient with chronic arthritis, the following requisites are fundamental: A simple classification must be employed. The term chronic rheumatism serves as a "blanket term" for all joint aches and pains, is too indefinite, and should not be used. Chronic rheumatism can be divided into definite types. Dr. Kinsella has chosen the terms rheumatoid arthritis and degenerative arthritis. The terms rheumatoid arthritis and degenerative arthritis convey visual pictures of two distinct diseases with characteristic symptoms, signs and pathologic changes. The characteristic pathologic changes of the rheumatoid and degenerative types of arthritis are fully described and adequately illustrated in the exhaustive monograph written by Richardson and Nichols in 1909. Every practitioner should read it. Many diseases may simulate chronic arthritis, particularly the rheumatoid type. First, there are the joint diseases due to known bacteriologic agents. The most important one in this group is gonorrheal arthritis, because it can mimic rheumatoid arthritis. Other diseases that should always be considered are traumatic arthritis and the various arthropathies, as well as certain constitutional diseases with joint manifestations such as hysteria, hemophilia, intermittent hydrarthrosis, anaphylactic reactions and gout. Acute gout is a disease frequently diagnosed incorrectly. At times myxedema, early acromegaly and pulmonary osteo-arthropathy are labeled chronic arthritis. There is no specific therapy for rheumatic arthritis. Therefore, every one treating these patients should study them carefully, correct all abnormalities, treat the patient as a whole and observe the effect on the course of the disease. Rheumatoid arthritis is characterized by remissions and relapses; therefore it is difficult to evaluate any therapy employed. No patient should be considered cured until he has been symptom free for five years. In the case of degenerative arthritis, the story is entirely different. Data that I have accumulated lead me to believe that this form of arthritis represents the wear and tear of life but can also be produced by repeated trauma to a joint or long continued and unusual use of an extremity. It does not necessarily bear any relation to arteriosclerosis.

DR. ARCHER O'REILLY, St. Louis: One of the lessons to be learned from the discussion is the fact that each patient must be given a careful study and a thorough examination. An attempt must be made to find the basic cause of the condition and to correct the metabolic faults that may exist. With proper living, proper diet and proper exercise, a great many patients can obtain an improvement. If rheumatism or arthritis is seen early, a good deal can be done toward correcting the condition. I am not sure whether syphilis plays any particular rôle in arthritis. Several years ago I studied a number of cases of syphilitic arthritis, and in a good many I found conditions that simulated the various types of rheumatoid arthritis. The roentgenograms were the same, the appearance of the joints was typical. Those patients under antisyphilitic treatment showed remarkable results. I think, however, that syphilis plays a part as a secondary infection or as a focal infection. I do believe that in all these cases syphilis should be looked for.

Diagnosis of Auricular Flutter.—Of singular interest is the striking abnormality of rhythm exhibited in electrocardiographic tracings in the group of cases known as auricular flutter. This peculiar rhythm is a finding strictly within the domain of electrocardiography, since the clinical signs exhibited by patients with such a condition are very difficult if not impossible of detection through any other means. The reason for diagnostic failure clinically in the majority of instances of auricular flutter are obvious to those who are at all familiar with the nature of this disturbance of rhythm. Both the ear and the palpating finger at the wrist are greeted by a perfectly regular sequence of contractions, except where there exists an inconstant degree of auriculoventricular block; in most of these the ventricular rate is only moderately accelerated. It is true that the tonal quality of the heart sounds is rather altered, but such finesse in clinical differentiation belongs to diagnostic skill and acumen of the highest order only. For all practical purposes, therefore, the recognition of auricular flutter at present rests strictly with the electrocardiogram.—Parsonnet, A. E., and Parent, Sol: *Arch. Int. Med.* 51:938 (June) 1933.

CURE OF TYPHOID CARRIERS

GEORGE H. BIGELOW, M.D.

AND

GAYLORD W. ANDERSON, M.D.

BOSTON

Typhoid carrier control presents one of the most troublesome of public health administrative problems. It is easy to say that such carriers should not be allowed to handle food for the consumption of others, yet application of this principle is often difficult if food handling is the only livelihood that the individual has. Too close surveillance may accomplish nothing further than to drive the carrier under cover, only to reappear in connection with further cases. To the administrator, therefore, any means of dealing effectively with such a carrier is just as valuable a tool as is the epidemiologic procedure that brought his existence to light.

Subsidy of carriers, the offering of an official reward for good behavior and abstinence from food handling has been attempted in some states. At best it can hardly be held out as an ideal solution, since it must always fall short of the normal earning capacity of the individual. It is an expensive procedure which must be continued year after year and is not effective with the irresponsible or the insincere. The threat of incarceration of uncooperative carriers, while often effective, can ultimately create only ill feeling and drive some carrier to cover.

The ideal solution is, of course, cure of the carrier condition; yet like most ideals this is simpler to formulate than to achieve. The site of the infection is deep seated and inaccessible to external influences. If the fortunately infrequent urinary carrier is left out of consideration, it may safely be said that the focus is in most instances the gallbladder. Here is found, as pointed out by Mallory and Lawson,¹ a characteristic pathologic condition of the mucosa, evidencing a chronic inflammatory process. Drainage, the normal means of favoring the cure of any localized infection, is at best incomplete. The presence of stones, often roughened on their surfaces, causes a chronic irritation and may offer crypts for growth of the typhoid bacilli. The almost invariable occurrence of stones in the typhoid gallbladder has led some to the belief that the carrier condition resulted from the localization of the infection on previously existing stones. This theory that stones are prerequisite to the development of the gallbladder carrier condition does not harmonize readily with the fact that small children may become carriers. We have under our observation a boy of 9 who has been a fecal carrier since his typhoid infection at the age of 4. Although we acknowledge that the existence of stones may favor the development of the carrier condition, it is hard, in view of these cases, to accept the doctrine that they are an indispensable prerequisite. The possible relationship between a typhoid infection and the subsequent development of stones gains support from the often reported isolation of typhoid bacilli from the center of such stones. Yet in this matter also few would concede the existence of a constant etiologic factor.

The necessity of considering the biliary tract as a whole in any discussion of the typhoid gallbladder has

From the Massachusetts Department of Public Health.
Read in part before the American Epidemiological Society, April 8, 1932.
1. Mallory, T. B., and Lawson, G. M., Jr.: *Am. J. Path.* 7:71 (Jan.) 1931.

been repeatedly emphasized. It must be remembered that in many instances the infection of the gallbladder has spread upward along the ramifications of the biliary ducts, so that one may be dealing with a very widespread infection. Unfortunately, it is not possible to determine in advance the extent to which the infection has extended out of the gallbladder. If a specimen of bile obtained by duodenal tube is shown to contain typhoid bacilli, one can feel reasonably assured that there is infection of the biliary tract, but one cannot determine the extent of spread outside the gallbladder.

In the hope of reaching all parts of the biliary tract and thus effecting a cure, a vast and impressive array of medical measures have been used, aimed variously at disinfection of the tract from above downward, the favoring of drainage or the production of individual resistance. Stertenbrink² recently reviewed the German literature on this subject, analyzing the results achieved by the use of more than a hundred different therapeutic agents, including laxatives, disinfectants, dyes, bile products, vaccines (specific and nonspecific), proprietary products, foreign proteins and even ultraviolet radiations. He concluded that the methods were uniformly lacking in success or even promise. Similar conclusions have been arrived at by all who have seriously undertaken to cure the typhoid carrier by purely medical means.

Surgical treatment through drainage or removal of the gallbladder was first suggested by Dehler³ as a result of the observation of Blumenthal⁴ that a previously unrecognized carrier condition disappeared in patients on whom he had operated for gallstones. Following these early articles, numerous reports have appeared of one or more carriers cured of their carrier condition through surgical means. Both Voss⁵ and Arnd⁶ have published comprehensive reviews of the early literature, concluding that removal of the gallbladder was superior to mere drainage. Unfortunately, many of the cases were so poorly controlled before and after operation that to draw definite conclusions from them was somewhat hazardous.

The Haalands⁷ in 1927 presented a series of fourteen cases in western Norway in which cure had been attempted by surgical means. Five of these were typhoid carriers, the remaining nine being infected with paratyphoid B. One of the patients had died of the operation, and two had not been cured of their carrier conditions. All but one of the patients had gallstones. In this one instance, however, the gallbladder was normal when examined after operation, and the carrier condition was still present seven years later. The remaining eleven patients were cured of their carrier condition, as shown by repeated negative specimens over a period of months, averaging about a year. Vogelsang and Haaland⁸ in 1931 bring this series up to date, reporting on twenty-five carriers, nineteen of whom were definitely cured through cholecystectomy.

Whipple⁹ has reported a series of fourteen cases of gallbladder removal to cure a typhoid carrier condition. In this series there were two deaths and two failures of cure. Unfortunately, six of the patients were operated on late in the convalescence from their typhoid infec-

tions, so that there might be some room for doubt as to whether or not they would have continued as carriers even without surgery. We have ourselves found that a patient shedding the organisms eleven months after the infection could clear up spontaneously, as attested by twelve negative stool cultures at monthly intervals seven years later, followed by two negative diarrheal specimens and finally a negative bile specimen. Such an instance will explain why in Massachusetts we have preferred to classify as permanent carriers only those still shedding the organisms a year after infection. Until that time they are considered convalescent carriers.¹⁰

During the past few years, in the course of our routine supervision of typhoid carriers we have had occasion to follow carefully a series of twelve such permanent carriers who have submitted to removal of the gallbladder.¹¹ Nine of these were operated on at our suggestion in order to be cured of their carrier condition. The other three came to operation primarily because of the clinical condition of the gallbladder. The series is small, yet it has been followed with sufficient care so that we may draw a few deductions from it:

CASE 1.—M. J., aged 50, a housewife, had typhoid nine years previously, discovered through infection of a friend five years later. Cholecystectomy was performed for relief of gallstone colic, the attending surgeon being uninformed of her carrier condition. Stones were found at the operation. During the subsequent seven years she submitted fourteen stool specimens, all of which were negative for *B. typhosus*. Two bile specimens obtained by duodenal tube four and seven years after operation were likewise negative.

CASE 2.—J. M., a man, aged 48, had typhoid four years prior. He was employed as a milker, causing an outbreak of fifty-one cases. The gallbladder was removed to cure the carrier condition. The preoperative bile specimen was positive. Two stones were removed with the gallbladder. One positive stool specimen was obtained twenty days after operation, followed by twenty-four negative specimens (two diarrheal) during the succeeding year. The bile specimen at the end of a year was negative.

CASE 3.—D. T., a practical nurse, aged 50, had typhoid four months prior, convalescence being extremely slow. The gallbladder was removed for cure of a persistent carrier condition. Two preoperative bile specimens were positive; bile from the gallbladder at operation was positive; one bile specimen in the hospital two weeks after the operation was negative. During the next seven months seven stool specimens were submitted, all of which were negative for *B. typhosus*. The patient was lost from further observation.

CASE 4.—W. R., a man, aged 48, had typhoid twelve years prior, discovered through investigation of a milk-borne outbreak of twenty-three cases and one death. He was the milker. The gallbladder was removed to cure the carrier condition. A preoperative bile specimen was positive for typhoid; bile also was positive at the operation. Multiple stones were found. During the next eighteen months, nineteen stool specimens (one following artificially induced diarrhea) and one bile specimen fourteen months after the operation were examined, all of which were found free from typhoid organisms.

10. Since the original preparation of this paper, two more excellent studies of surgical cure of carriers have been reported. Sentfner and Coughlin (*Am. J. Hyg.* 17: 711, 1933) report cure of thirty-five of fifty-three carriers through removal of the gallbladder. There were eight deaths in the series and ten not cured. Eight others had not submitted sufficient specimens to determine cure. All the deaths had occurred among persons over the age of 50. Swenson (*Tidsskr. f. d. norske lægefor.* 53: 63, 1933) reports on gallbladder removal from fourteen carriers, eleven of whom were infected with paratyphoid. In this series there were three deaths among elderly patients who had insisted on operation, one patient had been operated on too recently to determine cure, and nine of the remaining ten had been definitely cured.

11. Since the preparation of this paper, another carrier has submitted to removal of the gallbladder owing to cholelithiasis. Three negative stool specimens during a five months period since operation have been obtained.

9. Whipple, A. O.: *Ann. Surg.* 90: 631 (Oct.) 1929.

CASE 5.—R. L., aged 51, a housewife, stated that she had not had typhoid. Twelve days after an operation for cholelithiasis, stool culture was positive for typhoid organisms. Thirteen subsequent specimens during the next four years were negative. A bile tube was not passed because of chronic glaucoma, which had become acute at the time of the operation.

CASE 6.—M. T., aged 68, a farmer, had typhoid thirty years prior. Only one case of typhoid was definitely traced to him. He had, however, been selling home-made butter for several years in a small city where numerous cases of typhoid had occurred. These cases stopped suddenly after he discontinued selling it. He submitted to cholecystectomy for cure of the carrier condition. Bile specimens obtained preoperatively by duodenal tube, and directly from the gallbladder at the time of the operation, were positive for typhoid. Stones were found in the gallbladder at the time it was removed. Eight consecutive daily stool specimens during convalescence were negative, and thirteen specimens (one diarrheal) during the next sixteen months were also negative. A bile specimen thirteen months after operation was negative.

CASE 7.—I. S., a woman, aged 54, had typhoid thirteen years prior. She was a housewife on a milk farm and caused seven recognized cases. During three years following her recognition as a carrier, she submitted nine fecal specimens, all of which were positive for typhoid bacilli. The gallbladder was removed for cure of the carrier condition; one large stone was found. A specimen of bile taken at the operation was positive for typhoid. *B. typhosus* also was isolated from the gallstone. During the year following the operation, twenty-seven stool specimens (one diarrheal) were found to be negative for typhoid. A bile specimen one year after operation also was negative.

CASE 8.—W. D., aged 53, a business man, had typhoid fifteen years prior, discovered through infection of his son. The gallbladder was removed for relief of cholelithiasis. No bile specimens were obtained. Five stool specimens during the next year were all negative for typhoid. No further specimens were obtainable.

CASE 9.—A. W., aged 50, a housewife, had typhoid five years prior. She infected two family contacts. Six stool specimens over the five year period were all positive for typhoid. She submitted to operation for cure of the condition. No pre-operative bile specimen was taken, but a culture of the mucosa yielded *B. typhosus*. Four stones were found. A stool specimen eight days after the operation was positive. During the next four months, eight specimens submitted for examination were all negative. One positive specimen was then obtained. Seventeen specimens (the last two diarrheal) submitted during the next three years were consistently negative. A bile specimen three and a half years after the operation was found free of *B. typhosus*.

CASE 10.—J. D., aged 36, a housewife, had typhoid three years prior. She infected one family contact. The gallbladder was removed for cure of the carrier condition. Five stones were found. Preoperative and operative bile specimens were both positive for typhoid. The stools were positive for the first five days after operation, the first negative stool being obtained on the tenth day. Five subsequent stools in the hospital were negative and one bile specimen was negative, sixteen days after the operation. During the next three years, ten stool specimens were examined with negative results. She died following an operation for ovarian tumor three years after removal of the gallbladder.

CASE 11.—C. B., aged 30, a salesman, was found to be a carrier through routine examination of specimens during convalescence. Five years after his infection, the gallbladder was removed for cure of the carrier condition. Stones were found. A bile specimen obtained by duodenal tube prior to the operation was positive for typhoid. Twelve specimens during the next twenty months were negative for typhoid. In addition, weekly specimens submitted to the Harvard School of Public Health for five months after operation were uniformly negative. The patient has not yet consented to a second passage of the duodenal tube for a final bile specimen.

CASE 12.—R. H., a man, aged 29, an undertaker, had typhoid thirteen years prior. He infected two family contacts. The gallbladder was removed for cure of the carrier condition. Preoperative and operative bile specimens were positive for typhoid. Ten stool specimens obtained in the hospital between the sixth and the fifteenth day after operation were negative. During the sixteen months following discharge from the hospital, fourteen stool specimens (two diarrheal) were examined with negative results. A bile specimen sixteen months after operation also was negative.

With a single exception, the dates of infection ranged from four to thirty years prior to operation. In all but four instances, positive bile cultures had been obtained prior to operation, so that there was definite evidence that the infection was located either in the gallbladder or in the biliary ducts. In this way it was possible to avoid bringing to operation the carrier whose focus was elsewhere than in the biliary tract and whose condition could obviously not be affected by such surgery. Three of the patients who did not have preliminary bile cultures were operated on purely for relief of gallbladder symptoms, one of them not being recognized as a carrier at the time of the operation. Nine of the series submitted to operation primarily to cure their carrier condition, having had no symptoms serious enough to lead them to seek medical relief. They had, however, without exception had symptoms such as epigastric distress that may well have been associated with the pathologic condition of the gallbladder revealed at operation. These symptoms disappeared after operation. In all instances, stones were found. All of the patients recovered.

These twelve patients have been followed over variable lengths of time and examination of specimens from them has been consistently negative, as shown in the table. One alone, patient 9, showed a single positive specimen taken four months after operation, but this has been followed by a series of fifteen negative specimens (some diarrheal) over a period of two years. Two of the patients had negative bile cultures before leaving the hospital and seven others have had negative bile cultures taken at least one year after operation. These seven have been taken from our carrier list and have been given letters stating that in our opinion they are no longer typhoid carriers. The others having refused to have a specimen of bile taken by duodenal tube continue nominally on our list, though we have reason for believing that they are actually cured. In all instances the operation performed was removal of the gallbladder.

As this series of cases has developed, it has been possible for us to draw up standards by which we might determine the advisability of operation and judge as to cure. It has been mentioned that no person is considered a permanent carrier unless still shedding the organisms a year after the infection. We have then felt that in urging operation we were safe in predicting that the condition would not clear up without surgical intervention. It is insisted that the patient shall be a good surgical risk and not over 60 years of age. The stormy convalescence of the only carrier over 60 in the list prompted the adoption of this condition. Finally, it has been insisted that a bile culture shall have shown typhoid organisms. Through insistence on this condition it has been hoped to avoid those cases of carriers who would certainly not be benefited by cholecystectomy. If these conditions have been met we have felt that we could urge operation and in some instances defray the attendant costs. Five of the operations have

been paid for by the state. In such instances the patient has been allowed to select the surgeon and the hospital, the state paying the costs not to exceed \$250. When no preference has been expressed, the operation has been performed at the Massachusetts General Hospital.

The criteria for release of the carrier from further observation after operation have been purposely strict. We have insisted on the submission of at least twelve stool cultures, taken at intervals of not less than one month from each other. If these have all been negative, a bile culture has been obtained by a representative of the department. If this and two artificially induced diarrheal specimens are also negative, we have considered the carrier cured and have ceased further supervision.

It may be considered that we have been extremely fortunate that all of our carriers have been apparently cured and that we have not encountered instances of

sources of trouble were simultaneously effected under the most favorable conditions for the individual patient. The risk attending the operation under such circumstances is materially less than in those whose symptoms force them to seek relief through surgery.

Finally, it is interesting to consider briefly the purely administrative aspects of such a procedure. Are we justified in paying public moneys for the surgical treatment of those carriers who are willing to submit to operation? The relative cost of possible cure through operation as compared with subsidy is, in our opinion, more than ample justification for the payment of the operative and hospital fees. In one state the subsidy paid carriers varies from \$14 to \$65 a month, averaging almost \$30. This means an expenditure of about \$350 a year for each carrier so subsidized, and this expenditure continues in all probability the remainder of the carrier's life. For a sum materially smaller than a single year's subsidy we have found it possible to

Gallbladder Operations on Typhoid Carriers in Massachusetts

infection high up in the biliary ducts that has persisted. Yet the fact that five of the cases showed one or more positive cultures during the convalescence from operation suggests that cases of biliary duct infection were included in the series. Lyon¹² has recently advised prolonged biliary drainage in the treatment of cases that do not clear up after operation. It is because of their existence, our inability to make certain that the stool specimen submitted actually came from the carrier, and the possibility of missing carriers through sole reliance on stool cultures, as pointed out by Garbat,¹³ that we have insisted on the bile culture before release from supervision.

The histories of these carriers suggest that although in most instances the hope of curing the carrier condition was the determining factor in the decision of the individual to submit to surgery, the operation was in the last analysis of considerable benefit to the patient's well being. All had had symptoms suggestive of a pathologic condition of the gallbladder, and all were relieved of their symptoms. The stones that were found in all instances were certainly of no value to the patient and might well have precipitated more serious gallbladder conditions at a later date. The cure of the carrier condition and also the removal of potential

offer a procedure which carries with it a very high proportion of cures and which, if used selectively, is reasonably safe. In addition, it has been shown to be of actual benefit for the individual most vitally concerned, the carrier himself. Furthermore, the carrier so cured is obviously no further a public health menace. The subsidized carrier, on the other hand, may well continue to spread the infection. In one state which has relied on subsidy, twenty-one cases of typhoid, three of which were fatal, were traced in a single year to seven previously recognized carriers. Certainly it is preferable to cure a carrier when possible than to pay for good behavior, which is often not maintained.

The conclusions are the same if one considers the purely theoretical cost of operation on carriers as a group. We do not know exactly how many carriers there are in Massachusetts today. We know of but seventy-five. So far as possible we attempt to recognize through release cultures all of those who become carriers following current infections. Our records show that, of those cases of typhoid followed up through specimens submitted to our own laboratory, about 2 per cent continue as permanent carriers. This figure is somewhat lower than that frequently recorded in the literature, often as high as 5 per cent. Part of the discrepancy, we feel, is due to the fact, already emphasized, that the line between the convalescent and the permanent carrier is drawn at one year. Were our

12. Lyon, B. B. V.: Typhoid Hepatocholeangitis, *J. A. M. A.* 98: 885 (March 12) 1932.

13. Garbat, A. L.: Rockefeller Inst. monograph 16, 1922.

line drawn at three months, as is frequently the case, the percentage of carriers recorded would be much greater.

It has also been our experience that, contrary to the general impression derived from the literature, women do not necessarily outnumber men as carriers. Although we have a preponderance of women on our carrier list, this is largely because they handle food more frequently and are therefore more frequently discovered in connection with outbreaks. On the other hand, we have more men than women who have been shown to be carriers on the basis of release cultures taken during convalescence.

If, then, we use our own low figure of 2 per cent of the survivors remaining as permanent carriers, take the average age of our typhoid patients, which has been 22 years, and assume the average expectation of life at that age has been 40 years, we may estimate that there are in Massachusetts today about 1,100 carriers. Were we able to find all these and persuade them to submit to operation at our expense, the cost would be \$275,000. If it is assumed that the cost of a single case of typhoid is \$500 (certainly a conservative estimate when loss of wages is included), it can be calculated that, with 250 cases in Massachusetts in 1931, the typhoid bill was \$125,000. This takes no consideration of the loss of life or mental anguish. Even on this conservative estimate, it is apparent that cure of the carrier condition through operation is far less expensive than the continuance of typhoid at even a minimal rate. The cost of treatment of all the carriers would be more than saved in three years. None of the commonly accepted public health procedures yield so high a return.

Such an event is, of course, purely utopian. Discovery of typhoid carriers is becoming increasingly difficult as the cases become fewer and more sporadic in character. A single case unrelated to others presents few promising leads. Most of the carriers that are found can be sufficiently well controlled to prevent further infections and are not interested in the removal of the gallbladder. Yet in those special instances in which continued wage earning is dependent on ability to engage in food handling, or in which the individual is extremely anxious to be cured of the condition and released from supervision, surgery presents a method which in our experience has been effective, safe and for the personal benefit of the patient.

SUMMARY

1. Medical measures for the cure of typhoid carriers have not been effective.

2. In a series of twelve cases, cure of the carrier condition has apparently been effected through removal of the gallbladder.

3. In all of these instances, stones were found and the symptoms associated with the gallbladder were cured.

4. Prior to operation the bile should be shown to contain typhoid bacilli, as it is important to make certain that the infection is located in the biliary tract.

5. All carriers whose gallbladders are so removed should be followed after operation for at least a year by monthly examinations of specimens and not definitely released until a negative bile culture has been obtained.

6. The payment of cost of operation is a justifiable public health expenditure, which is cheaper and more effective than subsidy.

METHEMOGLOBINEMIA FOLLOWING THE ADMINISTRATION OF BIS- MUTH SUBNITRATE

REPORT OF A FATAL CASE

HAROLD E. ROE, M.D.

CHICAGO

The literature of a quarter of a century ago contains many reports emphasizing the hazard of nitrite poisoning, or methemoglobin formation, following the oral administration of large doses of bismuth subnitrate used either in the treatment of diarrheas or for roentgenologic studies. That these warnings still bear emphasis is evident from some of the statements in modern textbooks.

Six consecutive pediatric textbooks were consulted on the treatment of summer diarrhea. Without exception, every one recommended the use of bismuth salts without pointing out the possible dangers of poisoning following the oral administration of large doses of bismuth subnitrate. In one of these books appears the statement that "bismuth subnitrate in not less than 10 grain doses at two hour intervals has given most satisfactory results and in order to be of service it must produce black stools." No warning is given of the danger of nitrite poisoning.

These observations have prompted the following report of a fatal case:

REPORT OF CASE

History.—A male infant, aged 1 month, was admitted to the hospital, July 14, 1932, because of a severe diarrhea of three days' duration. The stools were frequent, watery, and green but contained no visible blood or pus. Fever had been present for two days. Following this, the baby vomited on two occasions and had a convulsion that lasted an hour.

The infant was of normal gestation; the mother had been delivered by cesarean section. Neither cyanosis nor convulsions were present at birth.

On admission, the patient was small, dehydrated and emaciated and appeared to be acutely ill. The temperature was 99.8 F. A heat rash was present over a large part of the body, including the buttocks and the external genitalia. No cyanosis was noted. The head was well formed and a tense fontanel was present. The pupils were equal and regular and reacted to light. Nothing abnormal was found in the nose, mouth, pharynx, ears, neck or lungs. A faint systolic murmur was heard over the base of the heart. The liver was about 1 cm. below the right costal margin. The lymph glands of the cervical and inguinal regions were moderately enlarged. A diagnosis of intestinal intoxication was made. Five days later, the temperature rose to 102 F. Following a bilateral paracentesis, pus was obtained from both ears, and the temperature returned to normal.

After twelve days of dietetic therapy, no improvement in the diarrhea having occurred, 10 grains (0.65 Gm.) of bismuth subnitrate was ordered "every two hours until the stools were black."

July 27, the day after the bismuth subnitrate was started, the temperature was 99 F. and the nurse noted at 9 a. m. that the baby was very cyanotic and that the extremities were cold.

July 28, the temperature was 107.6 F. The cyanosis persisted with only slight fluctuations in degree. The respirations were labored and the patient was put in an oxygen tent. Bismuth subnitrate was discontinued after 190 grains (13 Gm.) had been given within forty-four hours.

July 29, the respirations were slow, shallow and gasping. The cyanosis continued to be marked in spite of the continuous use of the oxygen tent. External heat was applied because

the body was cold. The nurse noted that "the thermometer did not register." At 10:15 a. m., sixty hours after the first dose of bismuth subnitrate was given, the infant died.

Laboratory Examination.—The Mantoux test (1:10,000) gave a negative reaction. Albumin was found only once in the urine; acetone was present at each examination. Microscopic analyses were repeatedly negative. The blood on admission was reported as having a hemoglobin of 110 per cent; red blood cells, 4,570,000; white blood cells, 8,800; polymorphonuclears, 78 per cent, and lymphocytes, 22 per cent. No gross blood or pus was seen in the stools at any time. The benzidine test, however, always gave a positive reaction for blood. Stool cultures yielded only a growth of the colon bacilli.

Necropsy.—The body showed a poor state of nutrition and development. The skin was very gray and cyanotic in appearance. This was true, also, of all the viscera. The blood was a dark chocolate brown, typical of methemoglobin, and spectroscopically it gave a very positive reaction for methemoglobin.

The brain was grossly normal but microscopic sections revealed a recent small superficial hemorrhage into the cortex of the cerebrum, with a moderate infiltration of lymphocytes. The right middle ear contained a small amount of thick yellow pus. Both lungs showed only a very small area of hypostatic bronchopneumonia. The bowels were moderately distended with gas. A very small quantity of green, watery, fecal material was found in the large bowel, but no blood or pus was seen, and no inflammation or ulcerations were present. Peyer's patches and the solitary lymph nodules were not hypertrophied. A few mesenteric lymph glands were moderately enlarged. The remainder of the examination revealed nothing of interest. The postmortem blood culture showed no growth after five days' incubation. A growth of *Streptococcus viridans* and *Staphylococcus aureus* was obtained from cultures of the lung tissue.

The first report of methemoglobinemia caused by the ingestion of bismuth subnitrate for roentgenologic diagnosis was published in 1906 by Bennecke and Hoffman.¹ It occurred in a 3 weeks old infant with an enteritis. Three grams of bismuth subnitrate was given by gavage in 300 cc. of buttermilk. Twelve hours later the child became markedly cyanotic and collapsed; death occurred three hours later, and methemoglobinemia was present.

Boehme,² in 1907, reported a similar case in a child, aged 18 months. A few grams of bismuth subnitrate was given by stomach for roentgenographic purposes; two days later a few grams was injected into the rectum for the same purpose and washed out. Three hours later, the child was suddenly seized with pain, cried out, became cyanotic, and died in from twenty to thirty minutes. At autopsy, methemoglobin was found in the blood.

Stieglitz,³ in 1927, cited three instances of nitrite poisoning following the oral administration of bismuth subnitrate to patients suffering from severe diarrheas. He⁴ states that complete data were not available on these individuals. One of them was an elderly woman suffering from carcinoma of the rectum who had marked methemoglobinemia. The dosage of bismuth subnitrate which she had received was not known. She died shortly afterward. No further information is available on the other two cases.

COMMENT

In the case reported here, since only four hours elapsed between death and the time of autopsy and

since the infant was markedly cyanotic before death and not prior to the administration of bismuth, it seems safe to assume that the methemoglobin formation did not occur after death. Such postmortem changes⁵ have been reported to have occurred in the blood of the body many hours after death.

While the intestinal intoxication, otitis media, and terminal hypostatic bronchopneumonia may all have been contributing factors in the fatal outcome, the methemoglobin formation was apparently the determining factor. This is supported by the fact that the infant became cyanotic without evident pulmonary involvement within twelve hours after the subnitrate was started, became progressively worse in spite of the administration of oxygen, and died within sixty hours after the first dose of the drug was given.

The death was apparently due to asphyxia because of the methemoglobin formation. Support of this statement lies in the fact that ingested nitrates are supposedly reduced to nitrites by the putrefactive bacteria of the intestine.⁶ The nitrites are absorbed by the blood and in some way oxidize hemoglobin to methemoglobin.⁷ If the individual is not overwhelmed with the intoxication, the body tissue may again reduce the pigment to normal hemoglobin.⁸ If, however, a fatal dose of the drug is given, most of the oxygen of the blood will be bound firmly in the methemoglobin. This bond is so firm that the oxygen cannot be liberated for tissue respiration, and asphyxia follows.⁹

These affirmations are further partially substantiated by the following experimental work: Haldane, Makgill and Mavrogordato¹⁰ gave rabbits sublethal doses of nitrites. In a typical instance, over half of the blood pigment had become methemoglobin in one hour and the rabbit showed signs of anoxemia. After three and one-half hours, the methemoglobin was reduced to 6 per cent and the rabbit appeared normal. Lewin and Dennig¹¹ reported similar observations.

ZoBell and Meyer¹² demonstrated that about 425 *Brucella* organisms commonly found in the intestinal tract reduce nitrates to nitric acid when grown in vitro. The same reaction may possibly take place in the bowel of a living animal.

Van den Bergh¹³ demonstrated that nitrites could form in the bowel from nitrates and subsequently be absorbed through injured intestinal walls and recovered in the blood. The nitrites are eliminated by the kidneys, and if the rate of production is greater than that of elimination, methemoglobinemia may result.⁹

Not only ingested bismuth subnitrate but also other ingested nitrates and nitrites have been reported to have produced methemoglobinemia. Eusterman, Keith and others have cited cases of methemoglobin forma-

tion following the use of ammonium nitrate as a diuretic.¹⁴

In addition to the nitrates and nitrites, many other drugs, such as nitrobenzene,¹⁵ potassium chlorate⁵ found in certain tooth pastes and mouth washes, acetylsalicylic acid¹⁶ and acetphenetidin¹⁷ used over long periods of time as headache powders may produce methemoglobinemia.

The metabolic activities of pneumococci¹⁸ and Streptococcus viridans,¹⁹ as well as the toxins of the pneumococci,²⁰ have been shown capable of producing methemoglobinemia when placed in contact with red blood cells.

In "enterogenous cyanosis,"²¹ a condition due to inflammation of the bowel and associated constipation, methemoglobin formation is not uncommon. It occurs apparently without the presence of nitrates or nitrites, and the putrefactive bacteria^{21a} of the bowel are thought to be the responsible agents.

Since most individuals can tolerate huge doses of nitrates without cyanosis¹⁴ and since methemoglobinemia is most likely to occur in patients who have intestinal putrefaction, nitrite poisoning and methemoglobinemia appear to be dependent on the presence of certain putrefactive bacteria in the intestine, or on an idiosyncrasy to certain drugs (Sollmann,²² van den Bergh,¹³ and Beck⁶). Large doses of nitrates taken by mouth may produce collapse, but rectal injections of smaller doses may cause nitrite poisoning much more quickly than that from oral administration. Children appear to be more susceptible than adults to nitrite poisoning.

The only condition that enters into the differential diagnosis is sulphhemoglobinemia.²³ This condition also produces marked cyanosis and is due to the formation of sulphhemoglobin pigment in the blood from the reduction of hemoglobin. Here, again, the putrefactive bacteria of the intestine are thought to play an important rôle by producing hydrogen sulphide,²⁴ the reducing agent that is apparently concerned in the chemical change.

In sulphhemoglobinemia, as in methemoglobinemia, the oxygen of the pathologic pigment cannot be used

in tissue respiration. In both conditions² there is usually intense cyanosis, diarrhea, weakness, dyspnea, headache and giddiness. The blood and all the organs of the body have a characteristic chocolate brown appearance. If death occurs, it is due to asphyxia.

The sulphhemoglobin and methemoglobin pigments are both found in the red blood corpuscles and can be differentiated only by spectrum analysis.¹³ The two spectral bands are in different positions; the methemoglobin band disappears on the addition of ammonium sulphide to the solution, whereas the band formed by sulphhemoglobin persists.

In a proved case of chemical methemoglobinemia, Duvoir and Goldberg²⁵ recommend the following procedures: stomach lavage, emetics, enemas, blood tests, oxygen, and the administration of alkalis. The same treatment is applicable to a case of sulphhemoglobinemia.

The deduction, finally, seems evident that since bismuth subnitrate may be occasionally, although rarely, a dangerous drug which offers no advantages over other preparations of bismuth, such as the subcarbonate, it has no legitimate place in the treatment of diarrhea.

707 Fullerton Avenue.

FORCED DRAINAGE OF THE CEREBRO-SPINAL FLUID

ITS EXPERIMENTAL BASIS, THE TECHNIC OF CLINICAL APPLICATION, AND THE INDICATIONS AND CONTRAINDICATIONS

LAWRENCE S. KUBIE, M.D.

NEW YORK

AND

GEORGE M. RETAN, M.D.

SYRACUSE, N. Y.

Recently a preliminary report was made on the clinical results of forced drainage of the cerebrospinal fluid in infectious diseases of the central nervous system.¹ Our purpose in the present communication is dual: first, to bring together and summarize the data on the experimental background of the method, data which are now available only in scattered studies; second, to outline the technic of its clinical application.

EXPERIMENTAL BACKGROUND

The physiologic laws involved are those which were demonstrated in the fundamental work of Starling² on the production of lymph, experimental work which covered two decades and which he gathered together in his book on "The Fluids of the Body" in 1909. Secondly, of course, this work is a logical extension of the classic studies of Weed and his associates³ on the special pressure conditions that obtain in the intracranial cavity.

Starling showed that the formation of lymph depended on the fact that, at the arterial end of a capillary, the intracapillary pressure was higher than the osmotic pressure of those constituents of the blood

serum which could not penetrate the capillary walls, the most important of which are the proteins. The osmotic pressure of these nondiffusing colloids of the blood is usually estimated as somewhere around 25 to 40 mm. of mercury and is a force that tends to hold fluid within the vessels. The pressure within the capillary at the arterial end must exceed this, therefore, in order that there may be any formation of lymph at all.

Starling showed, furthermore, that with the fall of pressure within the capillaries and venules, as the blood courses toward the venous end of the system, this intravascular pressure drops below the osmotic "pull" of the nondiffusing colloids, with the result that the lymph is reabsorbed into the vascular system. Thus it happens that from a limb at rest or from an organ at rest there is no flow of lymph. The only exception to this general rule is in the drainage from the abdominal viscera, where certain special conditions prevail which need not be discussed here. For the body in general, the rule holds as Starling stated it: to wit, that there is no flow of lymph from a resting organ.

There are only three ways by which more lymphatic fluid can be produced at the arterial end of a capillary system than can be reabsorbed at its venous end: The osmotic pressure of the blood must be lowered by dilution of the blood stream, the intravascular pressure at the venous end of the system must be raised above that of the nondiffusing colloids by venous obstruction, or there must be an increase of the osmotic pressure of the lymphatic fluid by accelerated processes of metabolism and oxidation which break up into smaller molecules the large molecules of the constituents of the tissue fluids, thus multiplying their osmotic effect.

When one turns to a consideration of conditions within the cranial and spinal cavities, one is faced with an apparent paradox. It is within the rigid confines of the bony skull and spinal skeleton alone that one finds normally a pressure which under ordinary circumstances is greater than atmospheric pressure. The effect of this positive pressure should be to inhibit the production of any transudate from the arterial end of capillaries and to accelerate its reabsorption at the venous end. How, then, is one to account for the fact that it is only here, in the face of this high counter-pressure, that one finds a permanent lake of extravascular fluid? The answer, of course, lies in some property of the cells of the choroid plexus. Starling's work makes it clear that under normal conditions the capillaries which are scattered throughout the parenchyma of the brain and spinal cord cannot be the source of this permanent lake. That this fluid arises primarily from the choroid plexus has, moreover, been proved beyond any doubt. Nor is it necessary to assume that the cells of the choroid plexus possess any special secretory function. The evidence in hand⁴ would suggest rather that their main function is to stand as a barrier against the reabsorption at the venous end of the vessels which Starling showed to be operative throughout the rest of the body. The evidence on this point need not be presented here, but an understanding of the principle involved is essential to the subject.

So much for normal conditions. What, however, will happen if this high intracranial or intraspinal

pressure is reduced to atmospheric pressure, thereby changing the physical conditions of intracranial fluid production to conform to those which obtain throughout the rest of the body? This can be done quite readily by performing a lumbar puncture and allowing the fluid to drain freely for some time. Clearly, under these circumstances the capillaries of the brain and spinal cord should function exactly as do the capillaries of the rest of the body; and the same procedures could then be used here to increase the production of cerebrospinal fluid from the blood stream. That is, the production of fluid could be increased either by raising intracranial venous pressure, by increasing the metabolic activity of the surrounding tissues so as to increase the number of molecules in the tissue fluid, or by lowering the osmotic pressure of the blood stream by dilution. It is the latter step that is used in the procedure which we have called forced drainage.

Forced drainage, then, consists of two steps: first, the reduction of intracranial pressure to atmospheric pressure, in order to make the intracranial conditions of fluid production conform to those of the rest of the body so as to bring into active participation all the capillary bed; second, the dilution of the blood stream by the intravenous injection of hypotonic saline solutions. Under these conditions, not only is the formation of cerebrospinal fluid accelerated⁵ but also it takes place both at the choroid plexus and by active transudation from the capillaries of the parenchyma throughout the brain and spinal cord.⁴ The fluid thus formed courses along the perivascular channels until it reaches the subarachnoid space and then emerges from the body through the drainage tract that has been provided.⁶

This, then, is the fundamental rationale of the treatment of infections of the central nervous system by forced drainage. It remains to point out that, when the formation of cerebrospinal fluid is accelerated by this procedure, no diffuse swelling or hydration of the nervous system occurs,⁴ that little or no increase in intracranial pressure takes place,^{5c} that the fluid actually courses along the perivascular channels until it reaches the subarachnoid space, and that when the perivascular or adjacent perineuronal spaces are choked with inflammatory exudate the passage of this fluid tends to mobilize this exudate and to carry it from the depths of the central nervous system to the surface, and out through the drainage tract.⁷

In experimental work, the procedure has proved to be free from risk. Both sick animals and normal animals have been subjected to this treatment repeatedly, and in no case have injurious results followed. Normal dogs have been given as much as one eighth of their body weight of hypotonic saline solution, with continuous drainage of the cerebrospinal fluid, and this procedure has been repeated at least once every two weeks throughout an entire winter; and throughout that time the dogs lost nothing in weight, vigor, health or activity.⁸ Similarly cats that had been sub-

jected to experimental meningitis by the subarachnoid injection of irritant dyes or of red blood cells have been put through this procedure many times without untoward results.^{5a} Rabbits have been given intravenous injections of as much as one fourth or one third of their body weight of hypotonic solutions. It has been shown, furthermore, that when slowly administered such massive injections as these can be given with safety and with no rise in venous pressure and no measurable increase in the circulating blood volume; so that it is safe to conclude that there is no overloading of the circulation.⁴

A further subsidiary point that is of interest is the fact that during the course of such drainage there occurs a consistent shift in the type of cell found in the cerebrospinal fluid. During the acute stage of an infection, the earlier fractions of fluid may have many polymorphonuclear leukocytes, whereas the later fractions, which are drained from deep crevices of the central nervous system, become predominantly lymphocytic.⁹

Furthermore, there is indirect evidence, which has not yet been made direct or complete, that this procedure may increase the transfer of immune bodies from the blood to the cerebrospinal fluid, just as it has been shown to increase the protein content of the cerebrospinal fluid and the transfer of certain dyes.^{5b}

It does not seem too much to assert, therefore, that this method of treatment is worthy of careful clinical trial in a wide variety of infections of the central nervous system.

TECHNIC OF CLINICAL ADMINISTRATION

1. The technical procedures that are recommended here must be looked on as tentative, although they are based on an experience of more than 100 separate drainages in more than forty cases, the drainages varying in duration from a few hours to a few days.¹⁰ There are so many variable factors, however, that no absolute laws can be laid down as yet as to the optimal duration of drainage, the optimal concentration, volume or rate of the injection, or the frequency with which the procedure should be carried out. These questions will all have to be settled in the course of further experience.

2. A simple and satisfactory arrangement of the bed and of the patient has been worked out. A Bradford frame is used, which is as long as the bedstead and about 36 to 40 inches in width. This frame is either supported on the frame of the bed with blocks of wood or else hung from the head and the foot of the bed by means of iron hooks. In either case, the hooks or the blocks are of such a size that the head of the frame is about 8 inches higher than the foot. The canvas is stretched on the frame in two pieces, with a gap of about 8 inches, which can be moved up or down in order to be opposite the lower lumbar region of the patient's back. The patient rests quite comfortably on a frame of this kind. He is rolled onto his back after the lumbar puncture is made, so that the needle is dependent through the gap in the canvas. The fluid then collects in a graduated receptacle, which rests on the bed beneath him. Blankets

are draped so as to prevent drafts, which would otherwise sweep under the frame, or an electric light can be placed between the frame and the mattress to make sure that the patient does not become chilled.

The simplest method of arranging the injection is with an ordinary gravity apparatus, only provided some warming device is used to prevent the cooling of the fluid, which would otherwise occur during a slow injection.

3. In any consideration of this procedure, three problems are presented which must be considered more or less separately: (a) the reduction of intracranial pressure; (b) the provision of a steady and constant avenue of drainage; (c) the method of fluid administration. Each of these aspects of technic will be considered in the succeeding sections.

4. Intracranial pressure is reduced by the withdrawal of cerebrospinal fluid. In some patients it is possible to allow the fluid to escape freely and rapidly until the lake of preformed fluid has flowed out to the point at which intracranial pressure and atmospheric pressure balance. At this point the rate of outflow of fluid drops to approximately 1.5 to 2 cc. per hour, and the fluid in the needle can be seen to protrude and retract with each respiration, the drops falling at a rate of one or two every five minutes. There are some patients, however, in whom the escape of even a few cubic centimeters of fluid, with a reduction of intracranial pressure of not more than 20 or 30 mm. of water, brings on a severe headache. With these patients, unless the headache is relieved by ice-water compresses, the withdrawal of fluid must frequently be interrupted by reinsertion of the stylet into the needle, or by the use of a fitted stopcock.

With patients who can be drained rapidly without developing headache or other discomforts, the drainage is allowed to flow until the fluid drops very slowly before the intravenous injection is begun. In the patients who develop headaches with even slight reduction in intracranial pressure, it has been found advisable to begin the intravenous injection even before the reduction of intracranial pressure to atmospheric pressure is complete. Under these conditions, the reduction in intracranial pressure is carried out by slow stages, with frequent interruptions of the drainage; sometimes with alternating periods of intravenous injection and subarachnoid drainage, as well as with the simultaneous administration and drainage of fluid. In this way, intracranial pressure is reduced gradually without causing the patient undue discomfort. Without such precautions, headache, nausea and retching may occasionally occur. The reasons for the differences in these responses are as yet not clear and are being investigated.

5. The administration of fluid involves several variable points; namely, the concentration, volume, rate and duration of the injection. The safest concentration to use is that which is just sufficiently strong to prevent hemolysis of the red cells in a fragility test *in vitro*. This is usually about 0.45 per cent of sodium chloride. It must be remembered, however, that during the intravenous injection the solution is diluted by the blood stream so rapidly that there is less chance for hemolysis to occur at the point of the needle than in the test tube. It is possible, therefore, to use solutions of a concentration that is materially less than that at which hemolysis begins in a fragility test. We have, in fact, injected solutions of as low a concentration as 0.3 per cent without visible hemolysis in the serum at the end

Med.* 31: 1378 (Nov. 15) 1931; Forced Spinal Drainage in Its Relation to Infections of the Central Nervous System, *J. A. M. A.* 99: 826-830 (Sept. 3) 1932. Retan, G. M., and Kubie, L. S.: Forced Drainage in the Treatment of Poliomyelitis, *Bull. Neurol. Inst. New York*, vol. 1, November, 1931. Kubie and Retan.²

of the treatment. It is clear that the more dilute the solution, the greater the caution with which it should be injected, because with solutions that are at the upper limits of the fragility of the red cells, the rate of injection makes practically no difference, whereas with more dilute solutions than this there will be a limit to the rate at which fluid can be injected without hemolyzing the red cells. It is not possible for us to say yet just where the limits of this velocity and dilution factor lie.

At the beginning of our clinical work with this method we limited ourselves to injections of about 1 liter of fluid. At present, however, we are finding that injections of 2 and 3 liters of saline solution in from one and one-half to two and one-half hours not only increase more strikingly the production of cerebrospinal fluid but lessen headache and enhance the comfort of the patient. It must be borne in mind that any headache or nausea which occurs during the course of the treatment can be eliminated by increasing the rate of fluid administration and slowing the rate of drainage.

6. For drainages of only a few hours' duration, an ordinary lumbar puncture needle is used. When it is desirable, however, to maintain drainage over many hours, as in tuberculous or pyogenic meningitis, it is necessary to use a needle that will not move or shift its position in the tissues. This is because after twenty-four hours the tissues around a needle tend to soften and hold it less firmly, necessitating the readjustment of the needle, or its withdrawal and replacement. This moving of the needle provides the greatest risk of ascending infection. The simplest way devised up to the present is to slip a Swift-wing over the shaft of the needle, screwing it in place on the shaft of the needle against the skin and strapping it firmly to the skin with adhesive plaster. It is also possible to use a specially large needle, which can be forced in around the shaft of the ordinary lumbar puncture needle after this has been inserted. This larger needle is held in place by the surrounding tissues more firmly, and, after it is inserted to the proper distance, the inner lumbar puncture needle is withdrawn, providing a drainage tract of wider bore.

On some occasions it has been found desirable to perform a laminectomy on a single lumbar vertebra and to provide for drainage through a rubber tube or cigaret drain.

It is important to have the patient lying comfortably on his back, with his head and shoulders higher than the lumbar region. At the same time, if the hips sag too much, as sometimes occurs with heavy patients, a sharp lumbar lordosis is produced and tends to obstruct materially the outflow of fluid. In such cases, it is well to support the hips by placing a firm support on the frame of the bed under the buttocks of the patient.

7. Many patients require no sedatives, but for others their use makes the procedure less of a strain. Both with and without sedatives we have had the experience of having patients fall asleep during the treatment. Several sedatives have been used, among the more satisfactory being amytal, 3 grains (0.2 Gm.) by mouth, two hours before the treatment, repeated one hour before the treatment.

For intercurrent symptoms of headache, ice-water compresses are often surprisingly effective.

8. No serious reactions have yet been observed beyond the symptoms of headache and nausea, which

have already been described and the treatment of which has been outlined. Occasionally, chills have occurred either when the patient was allowed to get cold on the Bradford frame or when fluids of too weak a concentration were administered too rapidly with resulting hemolysis. No undesirable after-effects from these chills have been encountered.

9. There remains to discuss only the method of puncture. The puncture is made with the patient on the Bradford frame, curled up on his side as for any ordinary lumbar puncture. Care is taken that the needle is approximately opposite the middle of the gap in the canvas. When fluid appears, the stylet is reinserted and the patient is allowed to straighten out slowly. As measured in lateral roentgenograms, this straightening out of the patient increases the depth from the skin to the subarachnoid space by about one-eighth to one-fourth inch. The needle is therefore thrust in this much farther after the patient is straightened out, and the stylet is withdrawn again to make sure that the fluid is flowing freely. Again the stylet is reinserted, and the patient is slowly rotated onto his back, so that the needle hangs dependent through the gap in the canvas of the frame. The patient is then covered so as to be kept warm, the receptacle is arranged under the needle, the stylet is withdrawn, and the fluid is allowed to flow out at a rate which, as previously explained, is determined by the patient's comfort and freedom from headache. If the patient develops headache rapidly, the rate of withdrawal of fluid is reduced, and the intravenous injection is begun promptly. If, however, the patient does not develop a headache, the fluid is allowed to flow freely until it drops only slowly before the intravenous injection is begun.

INDICATIONS

While our studies of the therapeutic value of this procedure are still in this tentative stage, it is impossible to speak of "indications" for the use of the method. One may say, however, that the experimental and theoretical basis of the method and its proved safety in work on animals and in clinical application justify its trial in almost all forms of acute or chronic infection of the central nervous system. Our own experience covers various forms of syphilis of the central nervous system, different types of pyogenic meningitis, acute and chronic forms of epidemic encephalitis, poliomyelitis, Sydenham's chorea, tuberculous meningitis, and disseminated sclerosis.¹⁰

This is not the place to discuss the therapeutic results that seem to have been achieved in some cases.¹⁰ It may be pointed out, however, that in all of these conditions in which adequate drainage could be established there resulted a definite influence on the course of the disease, and on many symptoms and signs. In syphilis, a modification of an Argyll Robertson reaction has been observed as well as the lessening of intractable pain and improvement in tendon reflexes. In disseminated sclerosis, similar results have been encountered, and in one case there was a return of vision after nineteen months of severe amblyopia. This occurred actually during the course of the drainage. In the acute virus infections, dramatic improvements have accompanied or followed the treatment. In the pyogenic infection, improvement seems to depend on the adequacy with which drainage can be maintained. The results with chorea have been outstanding and will be presented in a separate report. It is not our desire to imply that any

of these results can yet be considered a definite therapeutic achievement of the method. They are evidence, however, that symptoms which may have existed even for a long time do not necessarily rest on irreversible structural alterations in the central nervous system and that their pathologic basis, whatever it may be, is influenced by the procedure we have described.

CONTRAINDICATIONS

The procedure is to be avoided whenever one is dealing with a lesion into which fluid will filter from the blood stream but from which it is impossible for it to escape. It would be dangerous, therefore, in any form of obstructive hydrocephalus, in the presence of a cystic tumor, probably in the face of any area of fresh hemorrhage with engorgement and necrosis. It is also possible that, in cases of acute myelitis in which the cord is so swollen as to cause a block, the procedure would be inadvisable unless there were combined drainages at the cistern and lumbar regions or unless there was a preliminary shrinking of the cord with intravenous injections of hypertonic salt solution. It is also possible that in the presence of extremely thick gelatinous exudate, such as that which is sometimes produced by pneumococcal infections of the meninges, free drainage may be impossible. This point only future experience will settle. It is obvious, therefore, that careful differential diagnoses must be made, and the possibility of such conditions as these must be borne in mind before the method is applied.

It cannot be said that the procedure puts an undue strain of any kind on the body organs in general. There is experimental evidence that there is no material increase in blood volume, no increase in venous pressure, and in consequence no undue strain on the cardiovascular system.⁴ Nevertheless, it is our routine to make a thorough preliminary review of the cardiorenal system.

From the systemic point of view, the only important contraindication is the presence of active infectious or inflammatory processes elsewhere in the body. The increased permeability of capillary walls in such regions tends to increase the outpouring of fluid at the point of inflammation. In certain situations this may be advantageous, as in pyelitis or cystitis; on the other hand, it has given rise to some alarm in cases of severe bronchitis and the like.

SUMMARY

It is possible, therefore, to summarize briefly as follows:

1. A trial of this procedure is indicated in the presence of any acute or chronic infection of the central nervous system; but it is contraindicated whenever an intracranial lesion is suspected into which fluid can be poured without opportunity for free escape, in the presence of cardiorenal deficiency or in the presence of active inflammatory processes elsewhere in the body.

2. In essence, the purpose of all technical manipulation must be to reduce intracranial pressure to atmospheric pressure, rapidly when conditions so permit, or slowly and cautiously when this is necessary, to avoid discomfort for the patient. Throughout this procedure, hypotonic salt solution is administered in large volumes, ranging from 1 to 3 liters in the course of from one to three hours. The concentration of the salt solution varies downward from 0.45 per cent, depending on the fragility of the red cells of the

particular patient and the rate at which the fluid is to be administered. The duration of drainage varies from three hours to several days. The frequency of repetition is rarely more than once a week for the short, repeated drainages but may be maintained continuously over as long as two or three weeks in the face of more desperate and acute infectious processes.

3. The theoretical basis for the method lies in the fact that under these conditions cerebrospinal fluid is formed not only from the choroid plexus but by transudation through all the capillaries of the central nervous system, the new fluid thus formed traveling along perineuronal and perivascular spaces to the subarachnoid space and out through the lumbar needle. This affords a natural process of internal lavage, which influences the accumulation of inflammatory products and the course of infectious processes without increasing intracranial pressure or causing hydration of the parenchymatous tissues.

FATAL FUSOSPIROCHETAL ANGINA

REPORT OF SEVEN CASES

LEON GOLDMAN, M.D.

CINCINNATI

AND

HERMAN E. KULLY, M.D.

OMAHA

In discussing the differential diagnosis of diphtheria, Plaut,¹ in 1894, described another form of angina in which he found constantly fusiform bacilli and spirochetes, "Miller'schen Bacillen and Miller'schen Spirochaeten." In 1895, Vincent,² writing about the fusospirochetal etiology of hospital gangrene, related that the fusiform bacillus was very similar to a type of noncultivable bacillus found in certain "diphtheroid anginas," which he stated that he observed for the first time in 1893. However, as early as 1883, von Strümpell spoke about "angina necroticans," which in all probability was the fusospirochetal angina. For obvious reasons, fusospirochetal angina is a more descriptive name than "Plaut-Vincent angina."

That these organisms are present in the normal healthy mouth is generally known (Plaut, Vincent, Muhlens, Kolle, Onorato, Beck, Tenney and others³); moreover, in a healthy mouth they are not very numerous. The exact classification of these organisms is still somewhat doubtful (Kolle and Hetsch⁴). There is a difference of opinion regarding the relationship of the fusiform bacillus and the spirochete associated with this type of angina. Davis and Pilot⁵ showed the invariable association of both the fusiform bacillus and the wide-coiled spirochete. A difference of opinion still exists regarding the relationship of the two organisms. Tunnick⁶ advanced the idea that the spirochete is merely a highly differentiated form of the same micro-organism. Pilot and Bramer,⁷ after extensive

FUSOSPIROCHETAL ANGINA—GOLDMAN AND KULLY

VOLUME 101
NUMBER 5

experimentation, concluded that the fusiform bacillus and the spirillum are different forms in the life cycle of one organism. But whether these organisms represent a true symbiotic relationship or whether one is the transitional form of the other, has not been definitely settled.

The reason these organisms pass from a relatively saprophytic state to a definite pathogenic state is not clearly understood. Local infection, usually dental caries and pyorrhea alveolaris, local trauma, systemic infections and intoxications have been suggested. Spirochetes and fusiform bacilli have been aptly called opportunists by Pilot,⁷ becoming pathogenic only when the integrity of the tissues with which they are in contact is altered. Primary chemical factors have been implicated by Beck.⁸ The question of other and more virulent strains of the organisms has been offered by the presence of epidemics described chiefly during and after the war. Of course, it must not be forgotten that when extensive ulcerations are produced in the mouth the other organisms present, especially the staphylococci and streptococci, play a very important rôle as regards systemic invasion and involvement.

PATHOLOGY

The lesions observed due to these organisms are of a great variety, depending to a large extent on the underlying factors, the resistance of the patient, and the behavior of the pathogenic processes. In all, the tendency to necrosis and the production of a foul smelling lesion are the striking characteristics. From the standpoint of pathology, the disease presents great contrasts. In cases of pulmonary gangrene, the tissues seem unable to set up an adequate defense against the gangrene process, which spreads rapidly in every direction, destroying tissue as it goes. The microscopic picture has proved of great interest. The microscopical picture complete absence of a leukocytic reaction is conspicuous and conforms to the blood picture of an uncomplicated Vincent's infection. The number of neutrophil leukocytes is never elevated in the peripheral blood. Vincent, Krebs and Gross⁹ have studied sections of the ulcerous membranous lesions of the tonsils, and Ellerman¹⁰ of the uvula, and observed a great variety of bacteria, especially cocci, in the external necrotic layer; in the middle zone, between necrotic and normal tissue, there were a large number of fusiform bacilli, often in palisade arrangement. Spiral organisms were found in enormous numbers in the zone separating the spirilla necrotic epithelium and the living tissue, the spirilla being the more abundant and in advance of the bacilli. These organisms were not associated with cocci or other bacteria at the line of advancing necrosis.

In recent years, many successful attempts have been made to reproduce the disease experimentally. In the original investigations, neither Plaut nor Vincent succeeded in transmitting the infection to animals. Smith¹¹ succeeded in transferring infection from the pharynx of the patient to the groin of guinea-pigs. He then removed the fresh pus from the experimental abscesses in the groin of the guinea-pigs and injected it directly into the trachea of rabbits while the rabbits were under a deep ether anesthesia. Ten rabbits received injection

with pus from these abscesses produced in the guinea-pig. Of these ten animals, four developed lung abscesses, three gangrene, two pneumonia, and one bronchiectasis. Seguin¹² and Kritschewski of Paris were able to produce lesions typical of Vincent's infection, in guinea-pigs, and subsequently recovered both organisms in culture. Neither micro-organism alone was capable of producing the lesions of the disease.

In spite of isolated warnings, it has been the opinion for some time that fusospirochetal angina is rather a benign affair. As late as 1929, Kolle and Hetsch¹³ stated that the general condition of the patient is not seriously troubled. Albray,¹⁴ however, believes that "this is a condition of serious and conscientious attention." The number of reported fatal cases has been relatively few. There is every reason to believe that the fatalities are not so rare as reports of cases might indicate. In 1904, Bruce¹⁵ reported a fatal case in a girl, aged 8 years. The ulcerations extended throughout the fauces, the base of the tongue and the epiglottis. He reported another case in a boy, aged 9 years, who died after a prolonged course of thirty-seven days, with ulcerations extending to the thyroid cartilages, and with multiple lung abscesses. Halstead¹⁶ reported two fatal cases and cited the fatal cases of DiCorlis, Gilberti and also Meyer, a fusospirochetal angina developing in the latter during a bacillary dysentery. Heinemann,¹⁷ in 1917, described a large series of fatal cases, almost twenty-five, occurring in an epidemic in Adrianople, the fusospirochetal angina extending to a ulcerations and bronchopneumonia. Husik¹⁸ reported a fatal case occurring during a secondary anemia, the ulcerations extending to the upper part of the bronchial tree.

REPORT OF CASES

From 1929 through the first six months of 1932 there were twenty-one patients with fusospirochetal angina admitted to the wards of the Cincinnati General Hospital. These cases were in the medical, dermatologic and otorhinolaryngologic service. In almost every case, cooperation with the dental service was had. These patients were all admitted because of severity of their symptoms. In a busy general hospital, the ordinary case of stomatitis ulcerosa is treated in the outpatient dispensary. In 1929 there were ten admissions with one death; in 1930, six admissions with one death; in 1931, three admissions with three deaths; during the first half of 1932, two admissions with two deaths. There were, then, a total of seven fatal cases. A brief summary of the fatal cases follows:

CASE 1.—J. E., a Negro, aged 41, a laborer, was admitted with complaints of toothache and difficulty in swallowing, of ten days' duration. Two days prior to admission, his neck began to swell. The patient appeared uncomfortable but not acutely ill. The temperature was 100 F. There was marked fetor ex ore. The mouth showed dental caries and pyorrhea, with an alveolar abscess in the lower jaw. There was a diffuse cellulitis of the entire neck, with a small area of fluctuation in

the digastric triangle. Spontaneous rupture of the submandibular abscess occurred shortly after admission. The opening was enlarged with multiple incisions, and irrigations with saline solution and surgical solution of chlorinated soda were instituted. He continued to have an irregular intermittent fever. At no time was there any respiratory difficulty. His condition grew progressively worse and he died fourteen days after admission. Postmortem examination was refused. Save for a moderate leukocytosis, the blood examination had been negative. Blood cultures were repeatedly sterile. The blood Wassermann reaction was negative. Roentgen examination of the chest revealed only slight apical pleurisy and increased bronchial markings. There was no widening of the mediastinal area. Fusiform bacilli and spirochetes were found in great numbers in the mouth, in the alveolar abscess, and in the submandibular abscess. The patient had had the usual therapeutic measures.

CASE 2.—R. W., a Negro, aged 24, a laborer, had been admitted three times during the past year for a fusospirochetal angina, the last admission five months previously. Attendance at the outpatient dispensary had been very irregular. Active symptoms dated three weeks prior to entrance. On admission the patient was chronically and severely ill. The temperature was 99.8. Feter ex ore was very pronounced. There was extensive infection of the teeth and gums with numerous small, greenish gray ulcers on the mucosa of the lips. The remainder of the examination was entirely negative. The ulcerations continued to spread until the entire pharynx was involved. He had an irregular septic type of fever. No localizing signs were present in the heart or lungs. He grew progressively worse and died thirty-three days after admission. The blood examination had shown repeatedly a moderate secondary anemia (3,000,000) and a moderate leukocytosis (from 15,000 to 16,000), always with a polymorphonuclear increase. Large numbers of fusiform bacilli and spirochetes were found in the ulcers. The sputum was negative for acid-fast bacilli. Blood cultures were sterile. The blood Wassermann reaction was repeatedly negative. Roentgen examination of the thorax had shown only a slight pleurisy. Locally, the patient received applications of solution of potassium arsenite, arsphenamine, potassium permanganate and sodium perborate. Frequent intravenous injections of neoarsphenamine and intramuscular injections of sulpharsphenamine were administered. The patient received large quantities of dextrose intravenously. Postmortem section showed numerous ulcers covered with a greenish gray exudate extending throughout the entire mouth, tongue and larynx, and to the middle third of the esophagus. The bronchi were clear and the lungs showed only pulmonary edema and old fibrinous pleuritis. The remainder of the viscera showed severe toxic changes.

CASE 3.—S. T., a Negress, aged 29, a maid, was admitted with complaints of sore tongue and hoarseness of some two weeks' duration. The only other relevant details in her history were twenty-one intravenous injections for "bad blood" during the past year. However, no injections were given six months prior to admission. There had been no intramuscular therapy nor any known history of mercurial therapy. The patient appeared acutely and severely ill. The temperature was 99.4. She was not hoarse. The skin was clear. Definite feter ex ore was noted. Movement of the jaws was extremely painful. Dental caries and pyorrhea were present. The mucosa of the lips, cheeks, gums, tongue and soft palate was covered with ulcers varying in size from 0.25 to 0.5 cm. Some were covered with a serosanguineous exudate and some were covered with a thick white exudate like thrush. There was no difficulty in breathing. There was no adenopathy. The remainder of the physical examination was negative. The ulcerations continued to grow and to spread throughout the retropharynx. Several days after admission, irregular erythematous areas developed on the dorsum of each hand. These lesions developed rapidly into confluent bullae filled with a serosanguineous fluid. Similar lesions appeared in each inguinal region, but not in the vagina at that time. The bullae ruptured very shortly, and irregular shallow ulcers with a reddish base appeared. Under continual wet dressings, these were fairly "clean" yet continued to spread slowly. The lesions in the mouth also spread and became more painful. The patient lapsed into coma and died in convulsions

sixteen days after admission. Repeated smears from the mouth had shown staphylococci, streptococci, many fusiform bacilli and spirochetes. Smears from fresh lesions on the hands and in the inguinal regions had shown no organisms at all. Culture from the mouth, hands and inguinal area on meat infusion agar, dextrose ascites agar, blood agar and beerwort agar, and dextrose ascites broth showed only *Staphylococcus albus*. The cultures had been done at various oxygen tensions. Blood examination revealed normal red counts and cells. The white cells varied from 5,000 to 5,400, with an average of 32 per cent lymphocytes, 65 per cent polymorphonuclears and 3 per cent eosinophils. The urine showed numerous leukocytes and albumin. Blood cultures were repeatedly sterile. The blood Wassermann reaction was weakly positive. Locally the patient had been treated with potassium chlorate solution, gentian violet and potassium permanganate. She received frequent injections of neoarsphenamine. Postmortem section revealed extensive greenish gray ulcers involving the entire pharynx; the larynx, the trachea and bronchial tree were clear. The esophagus was a dull purplish red and showed small greenish ulcers in the lower third. The stomach and distal portion of the ileum had the same color without ulceration. The typical ulcers were found in the inguinal regions, vagina and cervix. The lungs were edematous. There was also marked cerebral edema. Toxic changes were evident in the remainder of the viscera. Smears from all these ulcers showed staphylococci, streptococci, fusiform bacilli and spirochetes. Cultures on the various mediums mentioned showed only *Staphylococcus albus*.

CASE 4.—C. J., a Negress, aged 41, a maid, had a sore mouth of three weeks' duration and, two days before admission, she began to have difficulty in breathing. Because of the patient's condition, it was difficult to obtain an adequate history. The patient was very obese and markedly dyspneic; she appeared seriously ill. The temperature was 100. There was no feter ex ore. The gums were purplish red, spongy, and covered with small grayish ulcers. The tongue was slightly edematous and covered with fine ulcerations. The tonsils were enlarged. Because of the marked respiratory difficulty, a tracheotomy was done, but the patient died shortly afterward. Smears from the ulcers showed numerous fusiform bacilli and spirochetes. The white blood count was 30,000, with 82 per cent polymorphonuclears. No additional laboratory work was done. Postmortem section disclosed numerous ulcers about the gums, tongue and buccal mucosa. The epiglottis and arytenoids were edematous and covered with a fine granular exudate. There was edema of the tracheal mucosa. The lungs were normal save for numerous petechial hemorrhages in the pleura. One portion of the right lobe of the thyroid was calcified; the left lobe was filled with blood and fibrous tissue and showed marked degeneration. The esophagus was normal, but there were numerous hemorrhagic areas throughout the rest of the gastroenteric tract. Except for a "flabby" myocardium, the heart showed no changes. The perivertebral lymph nodes were enlarged, were soft and contained areas of congestion. The hilar nodes were boggy and acanthotic. Small hemorrhagic areas were present in the spleen. The suprarenals showed no gross changes. Toxic nephrosis was evident in the kidneys. The vagina was clear. Smear from the ulcers showed numerous fusiform bacilli and spirochetes. Blood culture taken at the postmortem examination was negative.

CASE 5.—Q. A., a Negress, aged 44, a laundress, had a sudden onset of paralysis of the entire right side of the body, six days before admission. The day before admission, swelling of the right side of the face occurred, and the patient complained for the first time of a sore throat. The patient was obese and appeared severely ill. The temperature was 100.6; pulse, 102; respiration, 20. She was completely oriented; she had an indistinct, "mushy" speech. There was a complete flaccid right hemiplegia. Marked feter ex ore was noted. There was a soft cold, painless, pitting edema of the left side of the face. There was a blackish green exudate about the gum margins, palate and tongue. The retropharynx was not clearly seen. The trachea was in the midline. The heart was enlarged to the left, with a tympanitic aortic second sound and an apical systolic murmur. The peripheral blood vessels were very firm, of equal caliber and not especially tortuous. The blood pressure was 250 systolic, 130 diastolic. Rhonchi were present

throughout the lungs. No ulcers were present in the vagina. The patient continually drooled green exudate from the mouth; later there was considerable oozing of blood from various ulcerations on the lips. She had an irregular intermittent fever. She died nine days after admission. The blood examination was negative except for a moderate leukocytosis. Urinalysis revealed a trace of albumin. Smears from the mouth lesions had large quantities of fusiform bacilli and spirochetes. The blood and the spinal fluid Wassermann reactions were negative. Extensive local treatment was administered for the oral sepsis, and intramuscular injections of a bismuth compound and intravenous injections of neoarsphenamine were administered. Post-mortem section was refused.

CASE 6.—L. H., a Negress, aged 51, was admitted because of a painful mouth and a skin eruption, both of some fourteen days' duration. The previous history was entirely irrelevant. The patient appeared uncomfortable but not severely ill. There was a generalized eruption of small discrete and confluent bullous lesions, distributed chiefly on the extremities and about the navel. The lesions were most numerous on the legs. There were a few small areas about the breast, lips, nose and back. The skin adjacent to these lesions showed practically no inflammatory reaction. There was no generalized glandular enlargement. Numerous greenish gray, discrete and confluent shallow ulcers were seen about the lips, gums and tonsils. Save for a generalized arteriosclerosis, the remainder of the examination was irrelevant. The fundus examination was negative. All the ulcers spread locally, and many new areas appeared on the abdomen and also about the vagina. The patient continued to grow weaker and died nine days after admission. The blood examinations were negative. The urine showed only an albuminuria. The blood urea nitrogen and carbon dioxide were normal. The Wassermann blood and spinal fluid reactions were negative. Repeated blood cultures were sterile. Smears from the mucous membranes of the mouth, nose and vagina showed numerous fusiform bacilli and spirochetes. Smears from the skin lesions showed only staphylococci. Treatment consisted in mouth irrigations with hydrogen dioxide, potassium permanganate and potassium chlorate; peroxide and arsphenamine applications to the nose, and tannic acid dressings to the skin. Neoarsphenamine and tryparsamide were given intravenously. Post-mortem section was refused.

CASE 7.—V. C., a Negro, aged 42, a chauffeur, was admitted with a history of gradual loss of weight and "weakness" of four or five weeks' duration. Four days before admission, he complained of a sore mouth and for the first time noticed a generalized skin eruption. The remainder of the history was entirely negative. The patient appeared chronically and severely ill. The temperature was 102; pulse, 140; respiration, 40. There was a generalized eruption of small, circular, slightly elevated, dark red, painless lesions distributed over the entire body, including the palms and soles, and most marked on the thorax. Fetor ex ore was marked. There were small grayish ulcers on the gums. An irregular, easily removed, grayish white, fibrinous exudate was seen over the palate, pillars and tonsils. The lungs showed some dullness over the left apex posteriorly, with increased intensity and roughening of the breath sounds there. Except for a localized systolic murmur, the heart examination was negative. Abdominal and rectal examination was negative. No localizing neurologic signs were evident. The patient became moribund shortly after admission and died on the third day. The red blood cells numbered 2,400,000, with hemoglobin 50 per cent. The white cells varied between 3,600 and 4,200, with 14 per cent lymphocytes, 8 per cent large mononuclears and 78 per cent polymorphonuclears. The urine showed albumin and a few hyaline casts. The blood Wassermann reaction was strongly positive. The blood culture was sterile. Numerous fusiform bacilli and spirochetes were found in the exudate from the throat. Roentgen examination of the thorax was essentially normal. The patient had been given intravenous injections of neoarsphenamine and local irrigations for the mouth lesions. Post-mortem section was refused.

ANALYSIS OF CASES

1. All patients dying with a fusospirochetal angina at the Cincinnati General Hospital from 1929 to 1932 were adult Negroes.

2. The patients had been seriously ill on admission, usually with extensive ulcerations.

3. Six of the patients had extensive chronic dental infection.

4. None of the patients had had regular therapy for their dental infection. From this information, then, neglect was an important factor.

5. Extensive ulceration was active in every case except case 4, in which edema and septicemia played important rôles, out of proportion to the extent of the local lesions.

6. In some of the cases, during therapy and at the post-mortem examination, the spirochetes were rather difficult to find. Decrease of "superficial" spirochetes, then, was not associated with improvement. The spirochetes are reported to disappear from the surface rather quickly after death.

7. Syphilis was only an associated factor in two cases, and in neither of these had mercurial therapy been given.

8. Routine blood studies were not abnormal save in case 7, in which a definite secondary anemia and malignant leukopenia were found.

9. Skin eruptions were associated in three of the cases.

10. During their period in the hospital, all had practically the conventional modern therapy.

11. Post-mortem examinations were obtained in three cases. Extensive local ulcerations were noted in two cases, and laryngeal edema and septicemia were the important factors in the other case. No lung abscesses were found. No marked gastro-enteric ulcerations were seen.

COMMENT

There has been no study of fusospirochetal angina in the different races. Although no definite figures are available, other than the small series presented here, it is our opinion that the condition is just as common in the urban Negro as in the urban white person. In regard to the severity, the evident factor of neglect of oral sepsis seems strong in this series. In 1917, Heineemann reported an epidemic of fusospirochetal angina with a very large series of fatal cases. This epidemic occurred in Adrianople.

The usual points in a clinical differential diagnosis need not be mentioned.* However, a few facts bear repetition. No diagnosis can ever be made without a positive smear, and in an active untreated case the organism ought to be very numerous, a quantitative difference from the "normal." Furthermore, if streptococci are not found in an acutely involved throat, the condition is either a fusospirochetal angina or diphtheria. It is necessary to get the material from deep in the tissue, as the spirochete is not abundant superficially. This has been shown by the histologic studies of Seguin,¹⁹ Bouchet,²⁰ Logeais, Mangabeira²¹ and Zinserling.²² There is no specific blood picture for this angina, although lymphocytosis and eosinophilia have

been mentioned. The Wassermann test for fusospirochetal angina per se is not positive.

A fact that has not been stressed sufficiently is the frequent "secondary" or associated factors of fusospirochetal angina. This was discussed for the first time by Vincent in 1899. In every case an attempt should be made to find the systemic or local causes making for increased virulence of the organisms. A fusospirochetal angina that has once become extensive will mask effectively any local picture. Especially in the primary blood dyscrasias in which there is marked weakening of the body defenses does this angina assume huge proportions. This is most frequently associated with agranulocytic angina and the leukemias. Daito²³ describes a case associated with leukemia, Beck²⁴ a case with an aleukemic leukemia, Vogl²⁵ a case with an infectious mononucleosis, and Zikowsky²⁶ an angina also with the same type of case. An extensive fusospirochetal angina may mask chronic granulomas or tumors in the mouth. Any type of ulceration in a so-called dirty mouth is potentially liable to infection with fusiform bacilli and spirochetes. Gärtner,²⁷ unlike other authors, believes that a double infection can occur with diphtheria in small children and that therapy should be instituted for each.

As already noted, skin eruptions were observed in four cases. Munkerrem²⁸ describes a case of this type of angina with a pemphigoid skin eruption. Perry²⁹ reports three cases presenting an erythema exudativum multiforme. Gilman³⁰ has reported a case of fusospirochetal infection of the umbilicus with a pemphigus vulgaris, which occurred two months after a "sore throat."

For fusospirochetal angina, the therapeutic principles proposed by Mangabeira³¹ should be followed. These have been based on a study of the pathologic anatomy:

1. The remedy should be absorbed to a greater or lesser extent by the tissue.
2. The remedy should be antiseptically active for an appreciable length of time.
3. The remedy should be neither caustic nor destructive.
4. It should have a dissolvent action on necrotic tissue.
5. Its antiseptic action should be specific on one or the other of the symbiosis.

The simple, mild cases can be made inactive by the usual oral hygiene with mild local applications. When the case does not respond rather quickly and the lesions begin to spread and systemic reactions become manifest, the case should early be considered serious. Almost all known antiseptics have been used in the treatment of this condition. The solutions most commonly used in the local treatment are sodium perborate,

potassium chlorate, hydrogen peroxide, potassium permanganate and solutions of arsphenamine, neoarsphenamine and acetarsone. Laurens³¹ states that bismuth powder is much less irritating locally than the arsenicals. Harrell³² advises a glycerin bismuth solution. The caustics usually advised, chromic acid, trinitrophenol, silver nitrate and trichloroacetic acid of themselves produce ulcerations, which in turn become infected. Since the hopelessness of extensive ulcerations has been seen, general measures should be instituted at once when the case does not respond. The arsenicals arsphenamine, neoarsphenamine and sulpharsphenamine are usually recommended. At present there is no definite information as to their action in fusospirochetal angina. This angina has been only rarely reported as occurring during arsenical therapy for syphilis,³³ and the cases have been very mild and responded to local treatment. When this condition does occur during syphilitic treatment courses, a mercurial stomatitis should be suspected as a predisposing factor. It must be remembered that these measures are recommended only for the fusospirochetal angina, and the "primary condition," if detected, must be treated accordingly.

Fusospirochetal angina, then, can be a very serious disease, not only because of its direct ability in causing the death of the patient, but also because in its so-called chronic form it can give rise to pulmonary abscesses, pulmonary gangrene, putrid otitis media and gangrenous colitis.³⁴ It can also give rise to metastatic lesions almost anywhere on the skin and especially on the genitalia. Schmitt³⁵ observes that the areas of predilection are about the lower incisors, the last molars and, finally, in the tonsils. The prophylaxis, then, rests in the hands of the dentists in the maintenance of good oral hygiene, as well as in the hands of the laryngologist, who should be on the lookout for tonsils chronically infected with these organisms. As evidenced by the cases reported here, the neglected cases come to extensive ulceration and then to death in spite of "adequate" therapy.

SUMMARY

1. Seven patients dying with a fusospirochetal angina were all adult Negroes from among twenty-one patients (52 per cent Negroes) admitted for a fusospirochetal angina to the Cincinnati General Hospital during the period 1929-1932.

2. When extensive ulceration has occurred, the hopelessness of all forms of therapy is evident.

3. The secondary or associated factor of fusospirochetal angina is of frequent occurrence.

4. With a fusospirochetal angina, death can occur from extensive spread in the mouth and adjacent structures, offering a portal of entry for other organisms without extensive ulcerations, causing laryngeal edema, contributing to the toxemia of the primary or associated condition, and indirectly giving rise to metastatic lesions elsewhere in the body.

Clinical Notes, Suggestions and New Instruments

REPORT ON A GROUP OF FIFTY CHILDREN DICK-TESTED EIGHT YEARS AFTER IMMUNIZATION AGAINST SCARLET FEVER

H. G. BULL, M.D., ITHACA, N. Y.

In the spring of 1925, stimulated by the encouraging reports of Drs. George and Gladys Dick, I sounded several parents among my private patients on the subject of immunizing their children against scarlet fever, and finding a most encouraging response from them I sent out to a selected group a form letter, stating how matters stood and expressing my willingness to undertake the work free of charge for those who wished to have it done. Nothing was guaranteed further than that it looked like a hopeful procedure which promised excellent results for the future.

Through the generosity and the helpful cooperation of the department of health of New York City, material was obtained and 122 children between the ages of 3 and 15 years were tested. Of these, 101 gave positive reactions. This large proportion—nearly 83 per cent—seems excessive when compared with other reports, but on consideration of the nature of the group I do not find it so. These were all privileged children, carefully sheltered from infections. For the most part, they belonged to members of the faculty of a large university, and I do not believe it would be extravagant to say that, were a survey to be taken, it would be found that a correspondingly low incidence of other reactions exist, such as the Wassermann and the Pirquet or the Mantoux test. Incidentally, it lends credence to the popular belief that well cared for children are more liable to scarlet fever than others. Witness, in comparison, the recent report from an orphanage in Philadelphia of Dick tests on 551 boys with only 94 (17 per cent) positive reactions.¹

Of the twenty-one children who gave negative reactions, three had a history of scarlet fever; nine had very slight reactions that were called plus-minus and were disregarded; of the remaining nine, none had any history of having had scarlet fever, but in two of the families one each of these children had been thoroughly exposed by another case in the home.

Of the 101 children positive to the Dick test, 83 were given three doses of dilute toxin, in the dosage then advised by the Dicks: 500, 1,000 and 1,500 skin test doses. Within six months, nearly but not quite all were retested, and of those who were still positive twenty-eight were given two or three larger doses, depending on the degree of their positive reaction. At one time or another in the intervening years many of these children have been retested—after some known exposure or in the course of testing younger members of the family before immunization, or, as in the case of my own five children, to satisfy professional curiosity. With one exception they have all tested negative.

And now, with such a decent interval as eight years to fall back on, it is interesting to round up a group of these erstwhile children in an effort to see whether they are still immune to scarlet fever. It seems significant that with the hundreds of cases reported weekly throughout the state in the past two years, not one of these children has picked it up.

Although I had hoped to have the group a little larger, I was glad enough, in a community with such a shifting population, to assemble a total of fifty. These were tested, with material furnished by the New York state laboratories at Albany, in two groups on two consecutive Saturday mornings, the readings being taken the following forenoon. As in the original testing eight years before, the degree of cooperation and the interest shown was pleasant to see.

Of the fifty tested, thirty-two (64 per cent) were definitely negative; eighteen (36 per cent) were slightly positive. By slightly positive I mean the usual reaction so indicated—slightly pink, from 1 to 1.5 cm. in diameter, and without tenderness or swelling. Several patients reported itching. There were no

greater degrees of positive reaction; 0.2 cc. of the dilute toxin had been used for the test, with 0.1 cc. of the prepared control solution on the other forearm.

Five children had reactions at the control, definitely reddened areas from 0.5 to 1 cm. across. It was interesting to note that one of these children had asthma rather badly; another was his smaller brother; a third had had severe serum sickness on two occasions following the use of antitetanic serum, and a fourth was subject to hives. The fifth child, a girl, was a cretin, and from the age of 2 years she has taken 5 grains (0.3 Gm.) of thyroid daily. (She is now 11 and normal in both mental and physical development.)

Of the eighteen children who gave slightly positive reactions there were twelve who, being negative after the original three doses eight years ago, were not given further doses. Only six who had received the larger number of doses had apparently outworn their immunity to become positive again. With this in mind, I do not think it illogical to assume that had all of these eighteen children been given the full number of doses the percentage of immunes would have been noticeably higher. To counterbalance the six who, despite the larger number of doses received, are again positive, I find ten who had only three doses eight years ago who are still negative.

None of these fifty children have received doses as large as are now given, and it would be interesting to compare a similar group over an equal period of time who have received the larger dosage. I believe that the degree of immunity found would be gratifying.

SUMMARY

1. In 1925, 122 children from private general practice, between the ages of 3 and 15 years, were tested for susceptibility to scarlet fever. Eighty-three per cent (101) gave a positive reaction to the Dick test, while 17 per cent (21) were negative. Of the 101 who were Dick positive, 83 were immunized.

2. In 1933, eight years later, fifty of the eighty-three children immunized in 1925 were retested, with the following results:

Of this group of fifty children, 64 per cent (thirty-two) were negative, while 36 per cent (eighteen) were slightly positive.

Of these fifty children, twenty-two had received three doses of dilute toxin, and after eight years ten of these were negative and twelve slightly positive. Twenty-eight had received five or six doses, and after eight years twenty-two were negative (78 per cent) and six were still slightly positive.

3. Dilute toxin, given in adequate dosage, confers an immunity of at least eight years in a high percentage of persons susceptible to scarlet fever.

DERMATOCONJUNCTIVITIS DUE TO LASH-LURE, AN EYELASH AND EYEBROW DYE

SIGMUND S. GREENBAUM, M.D., PHILADELPHIA

This report on a case of dermatconjunctivitis due to Lash-Lure, a new eyelash and eyebrow dye, is offered for record.

The dangerous possibilities of certain types of hair dye has, of course, been known to the medical profession and to dermatologists in particular for many years. The use of such dyes has, however, been restricted to the scalp hair. Extending their use to the eyelash field is new and a reaction as severe as that which occurred in this patient deserves more than the passing comment ordinarily given by dermatologists to the frequent cutaneous reactions to cosmetics observed by them.

Darkening of the eyebrows and eyelashes is accomplished in two ways: one by coating the hairs (Mascara, lamp-black) and the other by actually staining them. Intolerance of the conjunctiva and eyelids to Mascara is well known but rarely produces more than a very mild reaction—commonly only a pruritus or burning if it gets into the eyes. However, actual dyeing of the lashes, as in the case reported, carries with it all the dangers with which dyeing of the scalp hair is attended.

The dye used in this case is advertised as "Lash-Lure"—a new improved eyebrow and eyelash dye. It is manufactured by Lash Lure, Inc., under a copyright from Lash Lure Research Laboratory, Inc., of Los Angeles.

1. Melnick, Theodore: Prevention of Scarlet Fever, Arch. Pediat. 50: 158 (March) 1933.

REPORT OF CASE

A woman, seen, Feb. 15, 1933, had a very itchy, slightly painful redness and a slight swelling of both lids of the left eye. The redness was especially intense and bright at the margins of the lids. She had the day previously been examined and told by the ophthalmologist that there was nothing the matter with her eyes. After four or five days' treatment with wet compresses, during which there was marked improvement, although the eyelid margin remained quite red, the patient was referred back to her ophthalmologist for the treatment of a beginning conjunctivitis. Following the flushing out of the eyes, and metaphen ointment locally, within eight hours an exceedingly severe reaction developed in which there was not only marked swelling of the skin, eyelids and surrounding skin but severe edema of the conjunctiva of the left eye. The patient was hospitalized: wet compresses were reapplied until all the edema and much of the redness had disappeared. After

either metaphen or the chemicals used to flush the eye on her second visit to the ophthalmologist. Entire disappearance of the symptoms and signs was brought about only by removal of the eyelashes.

1714 Pine Street.

[NOTE.—The Bureau of Investigation of the American Medical Association has had a record of Lash-Lure for some time. The product does not contain paraphenylenediamine but does contain an aniline derivative, also large quantities of magnesium. Correspondence indicates at least five other cases in which patients have developed severe symptoms, such as conjunctivitis and dermatitis, following the use of this product.—Ed.]

GANGRENOUS MECKEL'S DIVERTICULUM PERFORATED
BY A TOMATO PEEL

ROBERT I. HILLER, M.D., AND LOUIS A. BERNHARD, M.D., MILWAUKEE

This case is not presented as propaganda against the eating of tomatoes but merely to emphasize a possible surprise that one may encounter in a case diagnosed as acute appendicitis.

History.—J. L., a white man, aged 41, employed as the supervisor of a warehouse, seen by Dr. Bernhard, Aug. 18, 1932, complained of pain in the abdomen to the right of the umbilicus. The pain had started and remained localized in that spot. The patient's appetite was good and his bowel movements were regular. There had been no nausea or vomiting. Tomatoes had been eaten that morning, and pain had begun toward evening.

He had never been in any accidents and had never undergone an operation. He had had mumps and measles in childhood, and a left inguinal hernia had been present for about twenty years.

The patient's mother had died at the age of 50 of pleurisy. His father was living and well at the age of 71. Three brothers and five sisters were living and well.

He was admitted to St. Luke's Hospital, August 19, where physical examination disclosed: temperature, 100.8 F.; pulse, 108; respirations, 26. His face showed an expression of discomfort. His teeth were in fair condition but pyorrhea was marked; his tongue was thickly coated and halitosis was strongly evident. His throat was clean. No significant conditions were noted in the neck and chest. The heart sounds were of good quality and no murmurs were noted. Rhythm was regular. Abdominal examination disclosed tenderness and some muscle spasm over McBurney's point. A left indirect inguinal hernia was present. The extremities and reflexes presented no abnormalities. The white blood count was 17,600; the coagulation time was three minutes. Urinalysis disclosed an acid reaction, a trace of albumin, a few crystals, and many bacteria. Examination of the urine was otherwise negative.

The preoperative diagnosis was acute appendicitis.

Operation.—Under nitrous oxide and ether anesthesia, the abdomen was opened through a Kammerer incision. Free pus and considerable plastic exudate were immediately encountered. The appendix appeared in the wound and was almost completely obliterated. It was obviously not the cause of the acute inflammatory process present in the right lower abdominal quadrant. Further investigation, however, disclosed an acutely inflamed Meckel's diverticulum lying medial and caudad to the cecum. The area was quickly isolated with gauze sponges and the diverticulum was brought into the wound. It was found to be gangrenous, covered with plastic exudate and perforated at one angle of its dome by a white structure which resembled a toothpick but which later proved to be a tightly rolled piece of tomato skin. The diverticulum was located on the anti-mesenteric border of the ileum. It was clamped transversely and amputated, and the ileum was overscwed with a linen suture. Gas passed freely through the oversewed area, and the lumen of the bowel at this point admitted the index finger without difficulty. Because of the marked infiltration of the ileum at the site of its closure, a loop of number 2 plain catgut was passed through its mesentery and brought out through the incision. A Penrose drain was inserted on each side of the closed bowel, and the abdomen was closed in layers. Hemostasis was complete and the sponge count correct. The patient

Eyelash dye dermatitis.

ten days the margins of both eyelids continued to be red and angry. Removal of the eyelashes with a pair of scissors as close to the margins as possible was followed by marked improvement within forty-eight hours and from then on to complete relief.

COMMENT

The condition was recognized when first observed as a dermatitis with an external precipitating factor. Pointed questioning was required before the patient revealed that she had had her lashes dyed some twelve days previously and that this was her third adventure with eyelash dyeing. The dye used this time, however, was of a different nature than the dye used on the previous two occasions. Sensitization to repeated application of the new dye was therefore excluded. The allergic nature of the condition was indicated by the twelve-day incubation period, between application and reaction. Undoubtedly, multiple sensitization was either present or induced, as indicated by the severe relapse following the use of

stood the operation well, the pulse remaining at about 100 during the entire procedure.

Pathologic examination revealed that the specimen was a gangrenous intestinal diverticulum about 1 inch long and 1 inch wide, perforated by a rolled tomato peel.

Postoperative Course.—Recovery was uneventful. The temperature rose to 101.4 F. on the second postoperative day and declined steadily to normal on the seventh day, when the patient left the hospital. He has been seen several times since his operation and has had no complaints except for occasional discomfort from the inguinal hernia, which was not disturbed during his stay at the hospital.

The excised diverticulum and the rolled tomato peel.

He classified the types according to the extent of communication with the umbilicus as follows: (1) A patent tube may connect the ileum with the outside through the umbilicus; (2) the diverticulum may terminate as a fibrous cord attached to the umbilicus, or (3) no communication with the umbilicus may be present, the diverticulum being attached on either the mesenteric or the antimesenteric side.

Misplacements of gastric mucosa or pancreatic tissue associated with ulceration, hemorrhage or perforation have been reported in this type of diverticulum and are cited by Kaufmann² and Aschoff.³ Hudson and Koplik⁴ found gastric mucosa in 52 per cent of twenty-three cases of Meckel's diverticulum examined pathologically. Twenty-seven of thirty-two cases reported by them showed symptoms referable to the diverticulum, and in 63 per cent of these cases hemorrhage was a prominent symptom. They feel that "the association of hemorrhage from the intestine with other acute abdominal symptoms should suggest Meckel's diverticulum." Fronticelli⁵ has contributed a very lucid explanation of the phenomena of hemorrhage and perforation, which are the chief symptoms suggestive of the presence of an ulcer in a Meckel's diverticulum. The ulcers that occur in the diverticulum are not of the peptic type but more of the gastrojejunal type, in which an acid secreting gastric mucous membrane impinges on an alkaline secreting intestinal mucous membrane, producing corrosion and penetration leading to the symptoms of hemorrhage and perforation.

Intestinal obstruction is a common complication of Meckel's diverticulum. The type of diverticulum that terminates as a fibrous cord attached to the umbilicus is prone to this complication. Finny⁶ reported a rather unusual obstruction produced by a diverticulum knotting itself round the bowel. The free

end of the tube had first passed through the mesentery and then through a loop of itself. The knot tied was tight enough not only to obstruct the bowel but to strangulate the distal end of the diverticulum. According to Fronticelli,⁵ Meckel's diverticulum ranks fourth in the nine causes of invagination.

Meckel's diverticulitis produces symptoms simulating appendicitis. It may be a part of an enteritis or it may be produced by local trauma, such as the presence of foreign bodies as in our case or by compression in a hernial sac. If gangrene occurs, peritonitis quickly follows, because the process is located on a freely moving loop of ileum.

208 East Wisconsin Avenue—836 West Mitchell Street.

COMMENT

Meckel's diverticulum is a congenital anomaly that represents a rudiment of the omphalomesenteric duct or yolk stalk. In a review of 5,768 autopsies performed on children at the Babies Hospital in the laboratory of Dr. Martha Wollstein, Christie¹ found sixty-three cases of Meckel's diverticulum, an incidence of 1.1 per cent; of these, 74.6 per cent were in males. The distance from the ileocecal valve varied from 6 to 36 inches; the average was 20½ inches in children under 88 weeks.

WEIGHTED RETRACTORS FOR TRACHEOTOMY

CONRAD WESSELHOEFT, M.D., BOSTON
Chief, Haynes Memorial for Contagious Diseases, Massachusetts
Memorial Hospital

During a tracheotomy it is necessary to have retractors held on either side of the wound while the operator dissects down onto the trachea. If the patient is intubated before the operation, the necessity for speed is not so essential as when intubation has not been previously performed. Nevertheless, anything that allows of greater speed and accuracy is desirable. Ordinary retractors held in place by an assistant are apt to be held unevenly. Spreading retractors are unsatisfactory in very small patients, as they tend to become displaced. Furthermore, the thumb and the middle finger of the left hand of the operator are needed as guides in holding the trachea during the dissection.

The instrument here described consists of a pair of weights hung from a heavy silver wire loop. This loop can be easily bent to form an angle suitable for retracting. As soon as the incision is made, the loops of the retractors are inserted into the two edges, and the weights resting on the sides of the neck hold open the wound with equal traction. If the angle of the loop is made sufficiently sharp, these retractors do not slip. In a baby or small child, one weight on each side is

Weighted retractor with second weight, for tracheotomy.

sufficient. In an adult, second weights can be hung on the first ones, thus increasing the traction.

These self-retaining weight retractors enable the assistant to take a more active part in the operation, and they do not in any way interfere with the field or with the operator's left hand. As the wound is deepened, the retractors can be quickly reset. In short, they simplify the operation by doing the usual work of the assistant and permit of more speed and accuracy.

Each retractor consists of a sterling silver wire loop hung on a flat strip of brass. This brass strip is set into a lead weight, coming out at the bottom, where it is again turned to form a hook for the second weight. The weight, together

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

PAUL NICHOLAS LEECH, Secretary.

SOLUTION COLLOIDAL MERCURY SULPHIDE-HILLE.—Liquor Hydrargyri Sulphidum Colloidal.—Solution Colloidal Mercuric Sulphide.—A colloidal 2 per cent solution of mercuric sulphide in water, stabilized with a hydrolyzed protein substance and preserved with 0.2 per cent of tricresol.

Actions and Uses.—Solution colloidal mercury sulphide-Hille is proposed for intramuscular injection in the treatment of syphilis.

Dosage.—The usual dose is from 2 to 3 cc. administered intramuscularly twice a week for a course of sixteen to twenty injections. With intermittent treatment there should then be a rest period of six or eight weeks. If continuous therapy is being used, of course some other antisyphilitic, for example arsphenamine, might then be employed.

Manufactured by Hille Laboratories, Inc., Chicago. No U. S. patent or trademark.

Solution colloidal mercury sulphide-Hille is black in reflected light and brown in transmitted light. It possesses the odor and taste of tricresol. It has a specific gravity of from 1.0670 to 1.0690.

The solution is neutral to litmus. (Place a drop of the solution over a piece of blue litmus paper and a drop on red litmus paper; after one minute the original color can be detected on the edges of the drop.) To 1 cc. of the original solution add 3 cc. of iodine solution: a clear reddish solution results which within an hour becomes turbid because of the separation of a red precipitate.

To 20 cc. of the solution add 7 Gm. of sodium chloride and boil until the colloid coagulates, filter off the precipitate and cool the solution: the solution remains clear (lead). Transfer about one fourth of the black precipitate to a beaker, add 10 cc. of water, 2 cc. of diluted hydrochloric acid and a small crystal of potassium chlorate, boil until the solution no longer evolves chlorine, filter off the sulphur and add a few drops of stannous chloride: a white precipitate that changes to gray forms. To 5 cc. of the yellowish filtrate add 5 cc. of ammonia water: no color change occurs (copper) and no precipitate forms (bismuth, iron). To 5 cc. of the filtrate add 1 cc. of a 1 per cent solution of tannic acid: a white precipitate forms. To 5 cc. of the filtrate add 2 drops of a 36 per cent solution of acetic acid: a turbidity appears that disappears on the addition of more acetic acid. To 5 cc. of the filtrate add 1 cc. of copper sulphate solution: a slight precipitate forms that is rendered soluble by adding 2 volumes of water; add 1 cc. of normal sodium hydroxide solution: a violet color appears. To 5 cc. of the filtrate add 1 cc. of mercuric chloride solution: no precipitate forms. To 5 cc. of the solution add 5 cc. of diluted hydrochloric acid and a small crystal of potassium chlorate and heat. When the black precipitate has disappeared, filter and boil to a small volume. Add 2 cc. of sulphurous acid and continue the boiling until sulphur dioxide is no longer given off; cool: this solution conforms to the U. S. P. X Gutzeit test for arsenic.

Transfer exactly 5 cc. of the solution to a weighed platinum dish, add sodium sulphide solution (50 Gm. sodium sulphide dissolved to make 100 cc.) until the precipitate just dissolves and then add as much again, electrolyze the solution for six hours using 6 volts, wash with water, alcohol and ether, dry in a desiccator containing sulphuric acid and a beaker containing metallic mercury, weigh: the mercury calculated to mercuric sulphide is not less than 1.94 per cent nor more than 2.06 per cent.

ANTIPNEUMOCOCCUS SERUM (See New and Non-official Remedies, 1933, p. 369).

Parke, Davis & Co., Detroit.

Antipneumococcus Serum (Feltou) Type I.—Prepared by immunizing horses with killed cultures of highly virulent *Diplococcus pneumoniae* isolated from lobar pneumonia. The product is refined and concentrated by the method of precipitation and is tested by three methods: The precipitation test, the Feltou method of standardization by mouse protection test and the National Institute of Health standard test. The finished product contains type II pneumococcus antibodies but not in therapeutically important amounts. It is marketed in packages containing 10,000 and 20,000 units of type I pneumococcus.

Dosage.—From 50,000 to 100,000 units may be given the first twenty-four hours. Following this, the antiserum is given every few hours as indicated by the symptoms.

REPORTS OF THE COMMITTEE

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION, AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

RAYMOND HERTWIG, Secretary.

LARSEN'S GREEN BEANS (STRAINED-UNSEASONED)

Manufacturer.—The Larsen Company, Green Bay, Wis.

Description.—Sieved green beans prepared by efficient methods for retention in high degree of the natural mineral and vitamin values of the raw green beans. No added sugar or salt.

Manufacture.—Freshly harvested succulent refugee variety green beans are snipped, delivered to the factory on the same day, washed, cleaned, sorted by hand to remove any foreign material, again washed, blanched in hot water until soft enough for sieving, and puréed as described for tomatoes (THE JOURNAL, July 1, 1933, p. 35). The puréed beans are admixed with a small amount of water to produce the desired consistency, heated in an enclosed vessel at 82 C. and automatically filled into washed cans, which are sealed and processed for sixty minutes at 116 C.

Analysis (submitted by manufacturer).—

| | per cent |

Calories.—0.2 per gram; 6 per ounce.

Vitamins and Claims of Manufacturer.—See Larsen's Strained Tomatoes Unseasoned—Ready for Use (THE JOURNAL, July 1, 1933, p. 35).

OVENCRAFT FLOUR (BLEACHED)

Manufacturer.—The Robinson Milling Company, Salina, Kan.

Description.—Hard winter wheat "standard patent" flour; bleached.

Manufacture.—Selected hard winter wheat is cleaned, scoured, tempered and milled by essentially the same procedures as described in THE JOURNAL, June 18, 1932, page 2210. Chosen flour streams are blended and bleached with a mixture of nitrogen trichloride (one-seventh ounce per 196 pounds) and with a mixture of benzoyl peroxide and calcium phosphate (one-half ounce per 196 pounds).

Claims of Manufacturer.—For bread baking.

NONE-SUCH BRAND STERILIZED UNSWEETENED EVAPORATED MILK

Manufacturer.—Dean Milk Company, Chicago, or other manufacturers of accepted evaporated milk.

Distributor.—Durand, McNeil, Horner Company, Chicago.

Description.—Canned unsweetened evaporated milk the same as Dean's Quality Evaporated Milk (THE JOURNAL, Aug. 6, 1932, p. 477).

STAUDT'S REDI-SLICED BREAD

Manufacturer.—Staudt's Bakery, Raleigh, N. C.

Description.—A white bread made by the sponge dough method (method described in THE JOURNAL, March 5, 1932, p. 817); prepared from flour, water, sucrose, powdered skim milk, lard, salt, yeast and a yeast food containing calcium sulphate, ammonium chloride, sodium chloride and potassium bromate.

**PIXIE STRAINED PRUNES—FLAVORED
WITH LEMON JUICE**

Manufacturer.—The Fruit Belt Preserving Company, East Williamson, N. Y.

Description.—Sieved prunes flavored with lemon juice. No added sugar or salt.

Manufacture.—Dried prunes are washed, sorted, soaked in cold water for ten to twelve hours, pitted, cooked for twenty minutes, sieved, and brought to a desired consistency in an atmosphere of steam. Sufficient lemon juice is added to produce a citric acid content of 0.6. The mixture is heated to 82 C., automatically canned and processed for forty minutes at 100 C.

| Analysis (submitted by manufacturer).— | | per cent |

| Crude fiber | | 0.4 |
| Carbohydrates other than crude fiber (by difference) | | 23.7 |
| Titrable acidity as citric acid | | 0.6 |

Calories.—1.0 per gram; 28 per ounce.

Claims of Manufacturer.—The sieved prunes require only warming before serving; recommended for infants, children, convalescents and special diets; prepared by methods for retaining in high degree the natural nutritional values.

**CLAPP'S ORIGINAL WHEATHEART
CEREAL**

Manufacturer.—Harold H. Clapp, Inc., Rochester, N. Y.

Description.—Cooked unstrained mixture of durum semolina and wheat germ. The method of preparation is efficient for retention in high degree of the natural vitamins and minerals.

Manufacture.—Semolina, wheat germ and water are cooked under pressure in a closed Pfaudler glass lined cooker for fifteen minutes. The unstrained cooked mass is filled into glass jars, which are sealed and processed in autoclaves.

| Analysis (submitted by manufacturer).— | | per cent |

Vitamins and Claims of Manufacturer.—See Clapp's Original Baby Soup (THE JOURNAL, June 24, 1933, p. 2011).

**HAWAIIAN FINEST QUALITY PINEAPPLE
JUICE (UNSWEETENED)**

- (1) HAPPY HOUR, (2) HOMESPUN, (3) ROUNDY'S SUPREME,
(4) RANNEY'S AND (5) SANITARIUM BRANDS

Packer.—Hawaiian Pineapple Company, San Francisco.

Distributor.—1. Campbell Holton Company, Bloomington, Ill.

2. Phillips-Lewis Company, Inc., Richmond, Va.

3. Roundy Peckham and Dexter Company, Milwaukee.

4. The Ranney-Davis Mercantile Company, Arkansas City, Wichita, Kan.

5. The Battle Creek Food Company, Battle Creek, Mich.

Description.—Canned Hawaiian pineapple juice retaining in high degree the natural vitamin content; the same as Dole Hawaiian Finest Quality Pineapple Juice (Unsweetened) (THE JOURNAL, June 3, 1933, p. 1769).

**JELKE GOOD LUCK EVAPORATED MILK
UNSWEETENED, STERILIZED**

Manufacturer.—John F. Jelke Company, Hillsboro, Wis., a subsidiary of the John F. Jelke Company, Chicago.

Description.—Unsweetened, sterilized evaporated milk.

Manufacture.—The raw milk is obtained from healthy cows from farms meeting the company's requirements for sanitation. The herds and farms are regularly inspected by the company's

inspectors. Milk with a higher acidity than 0.13 per cent as lactic acid is rejected.

The procedure of evaporation and canning is the same as for the usual evaporated milk (THE JOURNAL, April 16, 1932, p. 1367).

| Analysis (submitted by manufacturer).— | | per cent |
|--|-------|----------|
| Moisture | | 73.8 |

| Lactose (by difference) | | 10.0 |

Calories.—1.4 per gram; 40 per ounce.

Claims of Manufacturer.—See announcement of acceptance for Evaporated Milk Association Educational Advertising (THE JOURNAL, Dec. 19, 1931, p. 1890).

**MARY LOU FLOUR (PHOSPHATE ADDED)
(BLEACHED)**

Manufacturer.—The Robinson Milling Company, Salina, Kan.

Description.—A bleached hard winter wheat "straight" flour containing 0.5 per cent added calcium acid phosphate.

Manufacture.—Selected hard winter wheat is cleaned, scoured, tempered and milled by essentially the same procedure as described in THE JOURNAL, June 18, 1932, page 2210. The flour streams are blended, bleached with a mixture of calcium phosphate and benzoyl peroxide (one-half ounce per 196 pounds) and chlorine (three-fourths ounce per 196 pounds); 0.5 per cent calcium acid phosphate is added.

Claim of Manufacturer.—A "phosphated" flour for biscuit baking in the home.

WHITE HOUSE RICENA

Manufacturer.—Standard Rice Company, Inc., Houston, Texas.

Description.—Granulated scoured rice.

Manufacture.—The larger pieces of broken scoured rice grain such as are obtained in the milling of White House Rice (THE JOURNAL, July 22, 1933, p. 283) are crushed between corrugated iron rolls, are passed through wire-covered reels or other grading devices to separate out the granules of desired size, are heated to 70 C. for a short time or electrically treated to destroy insect life and are packed in wax-paper wrapped cartons.

| Analysis (submitted by manufacturer).— | | per cent |
|--|-------|----------|
| Moisture | | 11.9 |

| Protein (N \times 5.95) | | 6.2 |
| Crude fiber | | 0.3 |
| Carbohydrates other than crude fiber (by difference) | | 80.7 |

Calories.—3.5 per gram; 100 per ounce.

Claims of Manufacturer.—Intended for use as a hot breakfast cereal and for cooking and baking; contains no added talcum or "glucose." Rice is especially easily digested.

**SILVERCUP 100% WHOLE WHEAT
BREAD SLICED**

Manufacturer.—Gordon Baking Company, Chicago.

Description.—A whole wheat bread prepared by the sponge dough method (method described in THE JOURNAL, March 5, 1932, p. 817); prepared from whole wheat flour, water, condensed sweetened whole milk, honey, lard, salt, yeast and a yeast food containing calcium acid phosphate, ammonium sulphate, sodium chloride, potassium bromate, potassium iodate and corn starch.

| Analysis (submitted by manufacturer).— | | per cent |
|--|-------|----------|

SATURDAY, JULY 29, 1933

EXPERIMENTAL AGRANULOCYTIC ANGINA

Since the first detailed description¹ of the disease now variously designated as agranulocytic angina, agranulocytosis, malignant neutropenia or granulopenia, more than five hundred acute or chronic cases have been reported. The typical acute attack is usually preceded by two or three days of prodromal symptoms, which generally consist of lassitude, malaise and sore throat. The anginal symptom is occasionally absent. These prodromal symptoms are followed by extreme weakness and almost complete prostration, death usually occurring in from two to three days. The mortality is about 85 per cent. If recovery takes place, a recurrence frequently follows in from one to three months.

The essential diagnostic feature of this disease is neutropenia, often amounting to almost complete absence of granulocytes. The total white cell count may or may not be lowered. The characteristic appearance at necropsy is a "liquefied" condition of the bone marrow. Ulcerative lesions of the mouth, anus or cervix may or may not be present. The other pathologic observations are inconstant, apparently depending on the duration of the disease and the presence or absence of secondary bacterial infections. The whole picture thus suggests a fulminating toxic condition.

Until recently, all attempts to produce a condition resembling this disease in laboratory animals have failed. Arsenicals, benzene and x-rays were found to produce a somewhat similar blood picture, but there is little evidence that these agents play an essential part in most clinical cases. Numerous micro-organisms have been isolated from the blood stream or oral lesions in fulminating cases. Of these, *Bacillus pyocyaneus* and certain saccharomycetes, for example, have been found to produce a generalized leukopenia and destruction of red blood cells in laboratory animals. None of

these organisms, however, would produce a typical agranulocytosis by routine methods of injection. The conclusion has been generally drawn from such data that the causative agent must be a highly specialized bacterial strain, acting only on the granulocytes. A second suggested theory postulates an allergic response of the hypersensitive bone marrow to ordinary infectious agents.

In reviewing the reported experimental and clinical data, Dr. E. W. Dennis² of the Department of Bacteriology, Beirut, Syria, was impressed by the fact that several of the micro-organisms more or less prominently associated with agranulocytosis are capable of producing leukocidins in artificial culture mediums. He was also struck by the fact that previous investigators had studied only the effects of generalized experimental infections with these agents, in spite of the fact that a history of focal infection was elicited from most of the reported cases.

Dr. Dennis, therefore, attempted to study the effects of the suspected micro-organisms when introduced into rabbits under conditions simulating strictly local infections. To do this, parchment capsules were filled with an eighteen hour serum-broth culture of the organisms to be studied, the needle puncture being carefully sealed with celloidin. The sealed capsules were then moistened with 70 per cent alcohol and inserted into the abdominal cavity of rabbits. The symptom complex produced by this method of inoculation simulated agranulocytosis in man.

Of the various micro-organisms thus far studied by him, *Streptococcus viridans* reproduces the fulminating type of the disease, causing acute granulopenia within a few hours, death usually occurring within twenty-four hours. Disintegration of the granulocytes begins in the peripheral blood almost immediately after implantation of the capsule. This action is shown by excessive lobulation and vacuolization of the nuclei, vacuolization and loss of outline of the cytoplasm, and swelling and loss of the pseudo-eosinophilic granules. A less fulminating type of the disease is produced with *Staphylococcus aureus*. In cases in which leakage from the capsules took place or in which there was a secondary infection complicating his test, there was an antagonistic response of the bone marrow, with a transient increase in the circulating granulocytes. Such complications, however, "merely hastened the exhaustion of the bone marrow and shortened the life of the animal."

Dr. Dennis concludes from his studies that "pyogenic bacteria are capable of producing granulocytopenia only when they are restrained from active penetration into the tissues, yet are so situated that their toxic products can be absorbed; otherwise they stimulate the leukopoietic system and produce a leukocytosis. Since [in

2. Dennis, E. W.: *J. Exper. Med.* 57:993 (June) 1933.

the hands of previous experimenters] the injection of filtrates of the same organisms has so consistently failed to induce a depression of the granulocytes, it appears that the constancy of the supply of the toxin is a highly important fact. . . . These conditions are satisfied in a chronic [or encapsulated] focal infection."

HEIGHT-WEIGHT-AGE TABLES FOR CHILDREN

The relationship of weight at given ages and heights to nutrition, and its significance as an index of the general health of the child, have long been of interest to medical investigators. Public health workers have made extensive use of height-weight tables as a screening method to detect at least the most severe grades of undernourishment. The common use of the height-weight tables has so popularized weight that an industry of no mean proportions has developed in the weighing of human beings. It is reported that the largest return on any investment at the Century of Progress Exposition is that of the "guess your weight" scales. The erroneous impression expressed in the current phrase "your weight indicates your health" is evidence of the extent to which this idea has been established with the public. Actually, normal weight does not necessarily mean good health; nor do deviations from the average or mean always indicate poor health.

While much basic work had been done earlier, the first impetus was given to the use of height-weight relationships in 1910 by Wood,¹ who published the tables bearing his name, which with various modifications have been widely used in health teaching and in textbooks and other publications. Four years later, Baldwin² published a review of almost 200 studies of height-weight relationships, and in 1920 appeared Emerson and Manny's³ study of weight and height in relation to malnutrition. Emerson held that the 10 per cent underweight standard commonly employed to distinguish between normal children and those requiring medical attention should be superseded by a 7 per cent underweight criterion, and that a zone rather than a definite line of demarcation should be established. He recognized that, while this zone would exclude on the one hand the definitely undernourished and on the other the manifestly obese, it would include a considerable number who for one reason or another would require individual diagnosis. The use of height and weight tables, however, went on apparently undeterred in numerous school and public health systems.

Also in 1920, Bardeen⁴ published his review of the work of numerous observers with respect not only to height-weight-age relationships, but also to volumetric, surface area, girth, sitting height and other measurements, emphasizing that the height-weight index is altered by physiologic age, by sexual peculiarities of structure, by inherited individual or racial peculiarities and by peculiarities of structure due to habits of living or environment. In 1921, Dublin,⁵ working with children of foreign parentage, warned against the too literal interpretation of an individual child's height-weight-age relationship to group averages. In 1922, Clark, Sydenstricker and Collins⁶ published height-weight tables for children in the southern part of the United States and suggested that such tables would be more useful in that part of the country than the composite tables commonly used in which weights of children representing different racial and environmental backgrounds were all merged in a common average. The same authors⁷ in 1923 pointed out a rough but by no means invariable relationship between underweight and malnutrition and emphasized that underweight might not mean malnutrition nor, on the other hand, overweight always be evidence of good nutrition. Also in 1923 the American Child Health Association published revised tables by Baldwin, Wood and Woodbury.⁸ Clark, Sydenstricker and Collins⁹ found that these new tables classed only 16 per cent of a given group of children as 10 per cent or more underweight, whereas, according to the original Wood tables, 20 per cent would have been so classed.

In 1924, Dublin and Gebhart¹⁰ showed definitely that no great reliance can be placed on a height and weight table as an instrument for identifying the undernourished. In 1929, Franzen¹¹ published a monograph describing the measurements made on groups of children whose height, weight and certain skeletal measurements were taken. He concluded that height and weight comparisons with group averages were not significant and emphasized skeletal measurements and estimates of subcutaneous tissue development. The formulas developed from these studies have been valuable scientific contributions but have not proved

practicable for everyday use. Recently, Curtis¹² has developed a series of curves by which he proposed to predict growth in terms of percentage of maturity, judged in terms of the individual's own growth curves, not of group averages. The Joint Committee on Health Problems in Education of the National Education Association and the American Medical Association¹³ definitely advises teachers weighing and measuring children to interpret heights and weights in terms of growth over a period of time rather than by comparison with an average and has omitted all tables from its report, as has Wood,¹⁴ their original proponent, in a leaflet published by the New York Health Department.

Thus the consideration of height and weight as an index of nutritional health has progressed through a number of interesting phases. Height and weight tables still have definite uses. In the hands of the physician, and associated with a competent physical examination, they are still valuable. They may no longer, however, be accepted as sole measures, or even as satisfactory gross indexes, of the state of nutrition of a given child at a given time. Growth in terms of individual progress, not comparison with averages, is a better index. A good physical examination remains a basic necessity for the diagnosis of malnutrition as of any other disease.

Current Comment

ASPHYXIAL DEATH

In last week's issue of *THE JOURNAL* appeared the first instalment of the published proceedings of the Society for the Prevention of Asphyxial Death. The concluding instalment appears in this issue. This society was organized to focus medical attention more definitely on the importance of asphyxiation as a cause of death, particularly in relationship to carbon monoxide poisoning, drowning, electrical shock, smoke poisoning and acute alcoholism. It is estimated that more than 50,000 lives are lost every year in this way. There has been a tendency in industry and in government to attempt to handle such cases largely by the use of lay teams rendering first aid and practicing muscular and mechanical resuscitation long before any attempt is made to get competent medical advice. Such aid may be of the greatest importance as a measure of first aid, but physicians know that many lives could be saved by medical attention if scientific diagnosis and treatment were made available as promptly as attempts at resuscitation by lay operatives. The first meeting of the Society for the Prevention of Asphyxial Death is of special interest because it calls attention to the numer-

ous aspects of the subject, including not only the statistical and economic points of view but also such highly technical procedures as are concerned in endoscopic examination, treatment with oxygen and carbon dioxide, and the use of such intricate apparatus as the negative pressure cabinet. *THE JOURNAL* has deprecated repeatedly the formation of special societies for every tiny phase of medical investigation and practice; nevertheless, this new organization may serve an especially useful purpose in meeting a trend in medical practice that cannot be met in any other way.

THE STATES' RESPONSIBILITIES IN MEDICAL CARE

In numerous discussions of state medicine which have been published from time to time in various medical periodicals, little cognizance is taken of the extent to which the state has already invaded the field of medical care in various communities. The answer to the question so far as it concerns the state of New York appears in our current issue in the article by Dr. Thomas Parran, Jr.,¹ commissioner of health of New York State. In that state, appropriations for public health now approximate many millions of dollars, including \$20,000,000 annually for mental diseases involving the care of 55,000 patients, and an investment of \$19,000,000 and an annual expenditure of \$3,553,000 for upkeep of tuberculosis sanatoriums, approximately \$2,537,184 for school health services and vast sums for the care of the crippled, the control of venereal diseases, public health, nursing, free dental care, free medical care in the current emergency and similar functions. Fifteen per cent of the population of the state of New York were on the relief rolls in April, 1933. Two thirds of the hospital beds in New York state are owned by the public and supported through taxes. As a result of his survey, Dr. Parran is inclined to the belief that increasingly in the future the state will invade the field of medicine. In the discussion of his paper, two distinguished practitioners deprecated this trend. Dr. W. H. Ross, a former president of the New York State Medical Society, urged a halt on the extent to which intervention by the state is increasing in New York, and Dr. Nathan B. Van Etten indicated the extent to which government interference is tending to demoralize and pauperize both the people and the profession. It is well to have available such a competent statement as that by Dr. Parran concerning the extent of medical practice by the state in New York. The tendency is present and the medical profession will do well to be aware of the trend and to control it when possible. *THE JOURNAL* has emphasized repeatedly the manner in which various bureaus and public officials have been gradually broadening their functions and invading the field of medical practice. It is a natural tendency of bureaus to mushroom out. More functions mean more appropriations. More appropriations mean more employees, more prestige and more power. Such expansion, uncurbed, will inevitably be disastrous not only to medicine but to the state itself.

Association News

MEDICAL BROADCAST FOR THE WEEK

American Medical Association Health Talks

The American Medical Association broadcasts on Tuesday and Thursday from 9:15 to 9:20 a. m., Chicago daylight saving time, which is one hour faster than central standard time, over Station WBBM (770 kilocycles, or 389.4 meters).

The subjects for the week are as follows:

- August 1. Swimming and Common Sense.
- August 3. The Will to Win.

There is also a fifteen minute talk sponsored by the Association on Saturday morning from 9:45 to 10 o'clock over Station WBBM.

The subject for the week is as follows:

- August 5. Head Noises.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ALABAMA

Single Dose of Toxoid Approved.—The use of one dose of precipitated toxoid for diphtheria immunization as a routine procedure to be employed by health officers and physicians of the state was recently approved by the state department of health.

Society News.—The southeastern division of the Alabama State Medical Society was addressed in Enterprise, July 11, among others, by Dr. Walter A. Lewis on "Interrelation of the Cardiac, Arterial and Renal Systems," and Dr. Luther L. Hill, Jr., Montgomery, "Epigastric Hernia."

CALIFORNIA

Motor Vehicle Accidents.—In 1932, accidental deaths in California in which motor vehicles were involved totaled 2,347. Of these, 823 deaths occurred in collisions of motor vehicles with pedestrians; 658 deaths in collisions between motor vehicles; collisions with railroad trains took 77 lives; electric cars, 58; bicycles, 31; horse-drawn vehicles, 3, and with fixed objects, 129. The greatest number of these deaths occurred among persons between the ages of 15 and 24. Most of the persons who lost their lives in collisions of motor vehicles with pedestrians were more than 65 years of age. Next in the causes of accidental deaths were falls in the home; drowning occupied third place.

Promotions at University of California.—The following promotions of physicians have recently been announced at the University of California Medical School, San Francisco:

- Edwin L. Bruck to associate clinical professor of medicine.
- Ernest S. DuBray to associate clinical professor of medicine.
- Mark L. Gerstle, Jr., to assistant clinical professor of neurology.
- Thomas H. McGavack to assistant clinical professor of homeopathic materia medica.
- Howard W. Fleming to associate clinical professor of surgery.
- Alson R. Kilgore to associate clinical professor of surgery.
- Cyril L. Callander to associate clinical professor of surgery and topographical anatomy.
- Frederick S. Foote to assistant clinical professor of surgery.
- Stanley H. Mentzer to assistant clinical professor of surgery.
- Clark M. Johnson to assistant clinical professor of urology.
- Saxton T. Pope to instructor in medicine.
- Francis J. Rochex to instructor in medicine.
- Charles T. Hayden to instructor in obstetrics and gynecology.
- Leon Goldman to instructor in surgery.

Leaves of absence have been granted the following physicians for the academic year 1933-1934:

- John H. Woolsey, associate clinical professor of surgery.
- Sanford V. Larkey, librarian of the medical school library and assistant professor of medical history and bibliography.
- Lewis S. Mace, assistant clinical professor of medicine.

CONNECTICUT

Personal.—Dr. Harry Martin Zimmerman, assistant professor of pathology, Yale University School of Medicine, has been promoted to a professorship.

Society News.—Dr. Howard Fox, New York, addressed the Danbury Medical Society, June 1, on diagnosis and treatment of common skin diseases.—Dr. Samuel M. Baum, New York, gave an illustrated lecture on "Interstitial Implantation of Radium in the Treatment of Malignancies" before the staff of Mount Sinai Hospital, Hartford, June 16.

DISTRICT OF COLUMBIA

Personal.—Dr. Edward Francis of the National Institute of Health, Washington, was given the honorary degree of doctor of science by Ohio State University at its commencement, June 12.—Dr. Hugh S. Cumming, surgeon general, U. S. Public Health Service, recently received the honorary degree of doctor of laws from Yale University.

Portraits Presented.—Portraits of three army medical officers were presented to the Army Medical Center at Walter Reed Hospital, May 30, in a Memorial Day ceremony, newspapers reported. Presentation of a portrait of Major Gen. William C. Gorgas was made by Surg. Gen. Robert U. Patterson in behalf of officers and nurses at the center; one of Brig. Gen. James M. Kennedy by Gen. Carl R. Darnall, retired, in behalf of friends, and one of Col. John Van Rensselaer Hoff by Major Gen. Merritte W. Ireland, in behalf of Mrs. Hoff. Major Gen. Albert E. Truby, commander of the medical center, received the paintings, which are the work of Bernard Godwin.

FLORIDA

Personal.—Dr. and Mrs. Joseph H. Branham, Okahumpka, celebrated their golden wedding anniversary, recently.—New members of the state board of health include Drs. Harry D. Johnson, Daytona Beach, and Leland H. Dame, Inverness.

New Quarantine Station.—Acceptance by the U. S. government of 35 acres of land at Gadsden Point from the Atlantic Coast Line Railroad, for a new quarantine station, was announced in the Tampa *Morning Tribune*, June 8. The greatest asset in moving the station from Mullet Key to Gadsden Point, the report stated, is the probability that a marine hospital may be erected there later.

Society News.—Dr. Gerard Raap, Miami, addressed the Dade County Medical Society, June 2, on "Abnormalities of the Vertebral Bodies."—A symposium on pediatrics was presented before the Duval County Medical Society, June 6, by Drs. Thomas E. Buckman, William E. Ross and Luther W. Holloway, all of Jacksonville.—The Sarasota and Manatee county medical societies held a joint meeting, May 16, in Sarasota, with Drs. Emory W. Bitzer, Tampa, and Jack Halton, Sarasota, as speakers, on "Treatment of Hypertension" and "Treatment of Rectal Strictures," respectively.

ILLINOIS

Society News.—Dr. Archie D. Carr, St. Louis, addressed the Madison County Medical Society, July 7, on diseases of the brain.—Dr. Philip H. Kreuscher, Chicago, conducted a crippled children's clinic at Sterling, July 11, and one at Monmouth, July 12, under the auspices of the Whiteside and Warren county medical societies.—Dr. Paul M. Hardinger, Mattoon, spoke on medical and surgical treatment of cataract before the Coles-Cumberland Medical Society, July 6.—Dr. Ralph A. Goodner, Nashville, has been appointed managing superintendent of the Anna State Hospital; he occupied the same position in 1913.

Epidemic Diseases Present.—Typhoid fever and infantile paralysis are of great concern at present, according to the *Illinois Health Messenger*. Cases during June were widely scattered, one or two in a locality, indicating several sources of infection. Infantile paralysis increased sharply with six cases in the last two weeks against a maximum of five in any full month prior to June. Rabies has been unusually prevalent among dogs. During June about twenty animal heads, mostly of dogs, were examined weekly in the laboratories of the state department of health and positive evidence of rabies was found in more than one third. From ten to thirty cases a week of meningitis have been reported. At the end of the twenty-fifth week of this year, 430 cases had been reported against 176 for that period in 1932. The highest previous record in any whole year was 579 cases in 1929, it was reported.

Chicago

Personal.—Dr. William F. Dickson was honored at a dinner, June 29, and presented with a desk set by the staff of the Woodlawn Hospital, on the occasion of his completion of fifty years in the practice of medicine. Dr. Rollo K. Packard, president of the hospital, presided.

Society News.—Dr. Eben J. Carey, professor of anatomy, Marquette University School of Medicine, Milwaukee, lectured in the Italian Pavilion of the Century of Progress, July 9, on "The Italian Fathers of Basic Medical Science." This lecture was one of a series of cultural lectures on Italian achievements in science, fine arts, literature and politics, being presented under the supervision of Prof. Enrico Bompiani of the University of Rome. Dr. Carey is in charge of medical exhibits for the exposition.

Changes at University of Chicago.—Recent promotions in the Division of Biological Sciences, University of Chicago, include the following:

Dr. Percival Bailey, a concurrent appointment as professor of neurology in the department of medicine.

Dr. William Bloom, associate professor of anatomy.

Dr. Alexander Brunschwig, assistant professor of surgery and also assistant professor of roentgenology.

Dr. Paul C. Bucy, assistant professor of neurosurgery.

Dr. Vernon R. DeYoung, assistant in pediatrics.

Dr. Charles B. Huggins, associate professor of surgery, effective October 1.

Dr. Hülger P. Jenkins, assistant professor of surgery.

Dr. John R. Lindsay, associate professor of otolaryngology.

Dr. Henry B. Perlman, instructor in surgery.

Dr. Gordon H. Scott, assistant professor of otolaryngology.

Dr. John T. Stough, instructor in ophthalmology.

Dr. Theodore E. Walsh, assistant professor of otolaryngology.

Paul Alfred Weiss, Ph.D., has been appointed assistant professor to succeed Benjamin H. Willier in the department of zoology. Dr. Willier has accepted an appointment as head of the department of biology at the University of Rochester, his resignation from the University of Chicago becoming effective October 1. He has been associated with the school since 1920. Dr. Weiss for the last two years has been Sterling research fellow in zoology and anatomy at Yale University.

INDIANA

Society News.—Dr. Pierce MacKenzie, Evansville, talked on "Preventive Measures and Management of Eclampsia" before the Gibson County Medical Society at Princeton, July 10.—The Owen County Medical Society was addressed in Spencer, June 16, by Dr. Frank M. Gastineau, Indianapolis, on "Recent Developments in the Treatment of Skin Diseases."

Personal.—Dr. James H. Crowder has been appointed health officer of Sullivan County, succeeding the late Dr. James H. Neff.—Dr. William B. Hunt, Terre Haute, has resigned as health officer of Vigo County on account of ill health, it is reported, and Dr. Frank G. McCarthy has been appointed to succeed him.—Hanover College conferred the degree of doctor of science on Dr. William N. Wishard, Indianapolis, at its one hundredth commencement, June 6.—Dr. Horace M. Evans, Valparaiso, has been made a member of the new state industrial board, newspapers report.—Dr. L. Doyte Holliday, Fairmount, has been appointed health officer of Grant County, succeeding the late Dr. Otis W. McQuown.

Program for Child Health.—Plans of the state department of child health and maternal welfare, which is now under the supervision of the University of Indiana School of Medicine, Indianapolis, have been announced. Dr. Oscar N. Torian, professor of pediatrics at the university, as chairman of child health on the advisory committee recently appointed (*THE JOURNAL*, July 8, p. 147), has appointed a chairman for each medical district in the state to cooperate in the promotion of child health. Two measures already approved in the program of education are graduate teaching and lectures to child health organizations. Committees under the jurisdiction of Dr. Torian will study, develop plans and make recommendations for the following divisions of work: graduate teaching, immunization, the preschool child, the school child, child health and welfare organizations, and tuberculosis. All plans must be submitted to the university committee for approval. Active programs for the division of maternal welfare, of which Dr. Arthur M. Mendenhall is chairman, and the dental division are in process of formation.

IOWA

Personal.—Dr. Cassius L. Campbell, Atlantic, was recently granted a life membership in the Iowa State Medical Society; he will complete fifty years in the practice of medicine in Cass County this year.—Dr. Harry M. Bradley has been appointed health officer of Independence, succeeding Dr. Delivan M. Fuiks, who resigned and left for Fort Des Moines as a medical officer in the reforestation camps.

Tribute to Veteran Physicians.—Drs. Augustus F. Walter and Herman J. von Lackum, said to be the two oldest practicing physicians in Tama County, were feted at Gladbrook, June 9, by members of the county medical society, their wives

and guests, including officials of the state medical society. Dr. Walter has practiced medicine at Gladbrook for fifty-three years, and Dr. von Lackum in Dysart for forty-seven years. Dr. Arthur A. Pace, Toledo, presented gifts to the physicians on behalf of the society.

KANSAS

Society News.—The Bourbon County Medical Society was addressed in Fort Scott, June 19, by Drs. Lawrence P. Engel and Ferdinand C. Helwig, Kansas City, Mo., on "Diagnosis and Treatment of Tumors of the Breast" and "Pathology of Tumors of the Breast," respectively.—Dr. Clarence B. Francisco, Kansas City, addressed the June meeting of the Johnson County Medical Society on "Fractures of the Pelvis."—A paper on "Blood Platelets" was presented before the Lyon County Medical Society by Dr. Albert Beam, Americus, June 6.—Speakers before the Southeast Kansas Medical Society, in Coffeyville, recently, were Drs. Paul M. Krall and Clifford C. Nesselrode, both of Kansas City, on endocrines and cancer, respectively.

MAINE

State Medical Election.—At the annual meeting of the Maine Medical Association in Poland Spring, June 27, Dr. Warren E. Kershner, Bath, was installed as president, and Dr. Edwin W. Gehring, Portland, was named president-elect. Miss Rebekah Gardner, Portland, was elected secretary.

MASSACHUSETTS

Worcester Campaigns Against Diphtheria.—June 26 marked the opening in Worcester of a campaign against diphtheria, to continue until August 22. Immunization clinics will form a part of the program, which will be carried on in an effort to lower the mortality from the disease.

Personal.—Yale University recently conferred the honorary degree of master of science on Dr. William Bosworth Castle, assistant professor of medicine, Harvard University Medical School, Boston.—Tufts College conferred the degree of doctor of science on Dr. Louis E. Phaneuf, professor of gynecology at the medical school of the college, June 19.

University News.—At the twenty-fifth anniversary of the graduation of the 1908 class of Tufts College Medical School, June 21, Dr. Seth F. Arnold, Belmont, who was toastmaster at the first banquet, again officiated in this capacity. Speakers were Drs. Albert Warren Stearns, dean of the school, and Timothy Leary, medical examiner of Suffolk County and formerly professor of pathology of the institution.

MICHIGAN

Report on Survey of Medical Agencies.—The house of delegates of the Michigan State Medical Society held a special meeting in Lansing, July 11, to consider the report of the special committee which made a survey of medical services and health agencies. The report was received by the house of delegates and a number of the recommendations were approved. The house of delegates did not approve the principle of health insurance but is continuing to direct further study of this problem. The survey committee was discharged, a permanent committee on medical economics was appointed to continue the work of the former, and the appointment of local committees by component societies to work with the state committee was approved. The committee on medical economics was directed to study further the plan of insurance and submit a report at the annual meeting of the society in Grand Rapids, September 11. Health insurance is defined in the report "simply, as a project to equalize the burden of costs arising through illness. It attempts to level this burden by attaching a definite meaning to average costs so that such averages will constitute the exact costs to a family or individual rather than conceal extremes of high or low costs." Health insurance, according to the survey committee, makes possible a wider distribution of medical service and at the same time offers possibilities for the reduction of indigence. Other recommendations of the committee concerned the care of indigents, subsidized medical service, public health administration and the University of Michigan Hospital. In its discussion of the medical care of indigents, the report recommended, among other things, that this problem be undertaken as a joint responsibility by the community and the medical profession, the costs to be met through contribution of funds by the former and a partial contribution of services by the latter. Subsidized medical service was defined in the report as the provision, through national, state or local funds, of reasonably adequate medical care for residents in sparsely settled areas and reasonably adequate incomes and facilities for medical personnel. Intending to place the health department in a position to correlate all medical activities of a public nature in

the county, the committee recommended the establishment of the county as the basic unit of public health administration with financial assistance from national or state funds. A further recommendation relating to the problem of public health was that the committee on medical economics and the state health department should institute a study to determine whether local needs would best be met by single county health departments or by consolidations of two or more counties for the support of a district health unit. The survey committee recommended that the University Hospital adopt a policy which will lead, ultimately, to a restriction of the activities of the hospital to those efforts directed toward medical education. To effect this policy, the appointment of a committee by the university to act with the committee on medical economics of the state society was urged. Recommendations affecting group practice were not made, as the committee felt that it had insufficient data on which to base a judgment and also that at this time it is secondary to the problems already presented. It agrees, however, that while a grouping of certain of the more or less mechanical adjuncts to medical care is reasonable, any arbitrary recommendations for the grouping of personalities can serve no good purpose.

The survey was conducted by a committee appointed following the adoption of a resolution by the house of delegates in Pontiac in September, 1931. Members included Drs. W. H. Marshall, Flint, chairman; F. A. Baker, Pontiac; L. G. Christian, Lansing; B. U. Estabrook, Detroit; C. S. Gorsline, Battle Creek, and F. C. Warnshuis, secretary, ex officio, Grand Rapids. After three months a preliminary report was submitted at a special meeting of the house of delegates, Jan. 27, 1932. As it was realized at that time that the complexity of the subject was too great for such a brief analysis, the committee was made permanent and Nathan Sinai, D.P.H., of the division of hygiene and public health, University of Michigan, was engaged as director of the study. Beginning with the evolution of medical care, the study took up the following problems: geographic features of Michigan; population, income and costs of living; illness: its incidence, care and costs; medical services received and needed; physicians: distribution and practice; physicians: income; the University of Michigan Hospital and public health. In addition, miscellaneous studies were made, among other things, on free and part pay clinics in Detroit, the cancer problem, laboratories, medical care of Negroes and tuberculosis.

MINNESOTA

Personal.—Dr. William J. Mayo, Rochester, and Guy Stanton Ford, LL.D., dean of the graduate school, University of Minnesota, were honored by testimonial awards by the Minnesota chapter of Sigma Xi at the annual dinner, June 7. Samuel C. Lind, Ph.D., Minneapolis, was elected president of the chapter.

MISSISSIPPI

Society News.—At a meeting of the Central Medical Society in Jackson, June 6, speakers included Drs. Leonard Hart, Meridian, on cardiac irregularities and their treatment; Little B. Neal, Jackson, cardiopasm, and Willie H. Watson, Pelahatchie, medical organization. —Dr. Doctor A. Pettit presented roentgenograms demonstrating unique fractures of the upper extremities before the Issaquena-Sharkey-Warren Counties Medical Society in Vicksburg, June 13. Drs. Hiram C. Sheffield, Jackson, and William Pierre Robert, Vicksburg, talked on dementia praecox and prevention of diphtheria in children, respectively. —The Northeast Mississippi Thirteen Counties Medical Society was addressed in Greenwood Springs, June 20, by Drs. Ira P. Burdine, Jr., Jackson, on "Spinal Puncture"; Albert D. Hurt, Corinth, "Chronic Endocervicitis"; James B. McElroy, Memphis, Tenn., "Recent Developments in the Treatment of Malaria," and Thomas F. Wolford, Columbus, "Agranulocytic Angina." —Among speakers before the South Mississippi Medical Society in Hattiesburg, June 8, were Drs. Eugene B. Vickery and Edmund Denegre Martin, both of New Orleans, on "Problem of Vesiculitis" and "Treatment of Fracture of the Femur by New and Simple Devices," respectively.

MISSOURI

Typhoid Outbreaks.—The drinking of polluted water at a church picnic near St. Louis recently caused nine cases of typhoid, with two deaths. Health officials stated that the water used, which was taken from a quarry, was mistaken for spring water, but was in reality a stream formed by surface water which accumulated during the heavy rains of May. Six members of an orphans' home, who attended a later picnic on the same grounds, also contracted the disease. Impure water in the same region recently caused eight cases of the

disease among road workers, with one death. It was also stated that about twelve other members of the crew were ill with similar symptoms. The water taken by the men and the picnickers could not be found by the investigators for the county health department, and it was assumed that it had evaporated before its dangers were known, the report stated.

NEBRASKA

Personal.—Dr. Carl W. Sherfey, Lincoln, has been appointed head of the Nebraska Soldiers' and Sailors' Home, Grand Island, succeeding Dr. John M. Triplett. —Dr. Hiram Winnett Orr, Lincoln, was a speaker at the annual meeting of the British Medical Association in Dublin, Ireland, July 26, on "Treatment of Osteomyelitis and Compound Fractures."

Omaha Clinical Conference.—The first assembly sponsored by the newly organized Omaha Mid-West Clinical Society will be held October 30-November 3, with headquarters at the Hotel Paxton. Guests who will conduct clinics and present papers include Drs. Dean Lewis, Baltimore, President, American Medical Association; Richard H. Jaffe, Kellogg Speed, Julius H. Hess, James T. Case, James B. Herrick, Lewis J. Pollock, all of Chicago; Hugo Ehrenfest, St. Louis; Wells P. Eagleton, Newark, N. J.; Edward H. Skinner, Kansas City, Mo.; Fred D. Weidman and Joseph C. Birdsall, Philadelphia. There will be general assemblies each morning, followed by detailed lectures by Omaha physicians, afternoon clinics in Omaha hospitals and evening programs of scientific addresses. Dr. Adolph Sachs is president of the society and Dr. Joseph D. McCarthy, secretary.

NEW JERSEY

Personal.—Dr. William H. Areson, Upper Montclair, was guest of honor at a dinner given by physicians of Montclair, June 16, at the Montclair Golf Club. Dr. Areson has been associated with the department of health of Montclair for a number of years, and director of the department since 1923. Last year he was president of the Essex County Medical Society and has taken active part in civic affairs in Montclair for many years.

NEW MEXICO

Personal.—Dr. George W. Stephens, Phoenix, Ariz., has been appointed superintendent of the New Mexico Home and Training School for Mental Defectives, Los Lunas, succeeding Dr. Merton O. Blakeslee. —Dr. Robert O. Brown, Santa Fe, has been elected president of the New Mexico Tuberculosis Association.

NEW YORK

Standards for Pathologists Regulated by State.—Regulations establishing qualifications of surgical pathologists similar to those which have been required of bacteriologists for many years have recently been adopted by the Public Health Council. The law now provides that the pathologist shall have an adequate knowledge of pathology and subsequent to graduation at least four years' training and experience in pathologic work, approved by the Public Health Council, of which at least one year shall have been devoted to training and experience in the diagnosis of neoplastic disease. Applicants for approval must demonstrate their efficiency by examining sections of tissue from a series of representative lesions. The tissues used have been selected by a number of eminent pathologists in the state and only those are used on which the division of laboratories and research and the State Institute for Malignant Disease have agreed as suitable for the purpose and as to diagnosis. A certificate is issued only after conference and agreement that the applicant meets minimum standards of efficiency.

New York City

Hospital News.—The medical staff of Bronx Hospital gave a dinner, June 19, in honor of Mr. Alexander Selkin, president of the hospital, in celebration of the first anniversary of the opening of the hospital's new building. More than 8,000 patients have been treated during the year, an average occupancy of 75 per cent.

Personal.—Dr. Haven Emerson, professor of public health practice, DeLamar Institute of Public Health, Columbia University College of Physicians and Surgeons, was recently elected a corresponding member of the Academy of Athens. —Dr. Willis E. Merriman, Jr., assistant physician at Hudson River State Hospital, Poughkeepsie, has been appointed superintendent of Manhattan State Hospital, Ward's Island, to succeed Dr. Isaac J. Furman, who died in May.

Kings County Medical Library.—More readers used the library of the Kings County Medical Society during 1932 than

in any other year, according to the annual report of the librarian. The number of readers was 12,538, an increase of 1,948 over 1931; the number of books consulted was 50,164, an increase of more than 11,000 over the previous year; and the number of books taken out for home use also increased 43 per cent. The society receives regularly 1,509 current serial publications, 890 of which are in English and 619 in twenty-three other languages. The library acquired 745 new books and 911 volumes of periodical publications by subscription or purchase of back files. A special exhibit during the year placed on display the writings of some of the contemporaries of George Washington, including publications by John Jones, John Morgan, Samuel Bard, Benjamin Rush and William Currie, as part of the celebration of the Washington Bicentennial. A set of fluorescent screens for reproduction of printed matter was added to the library's equipment.

NORTH CAROLINA

Personal.—Dr. John P. Hunter has been elected mayor of Cary.—Dr. William P. Richardson, Winston-Salem, has been elected health officer of Richmond County to succeed Dr. Crete N. Sisk, Rockingham.

University News.—Members of the staff of Duke Hospital, Durham, presented a symposium on gastro-intestinal diseases at a meeting of the Durham-Orange County Medical Society at the hospital in May. Dr. Arthur Steindler, Iowa City, Iowa, conducted an orthopedic clinic at the hospital and Dr. Charles R. Stockard, New York, lectured on "Peculiar Form and Type in Man and Animals," recently.

OHIO

Changes at Western Reserve.—The following promotions in the faculty of the Western Reserve University School of Medicine have recently been announced, among others:

Dr. William B. Chamberlin, to clinical professor of otolaryngology.
Dr. William H. Weir, to clinical professor of gynecology.
Dr. Claude S. Beck, to associate professor of surgery.
Dr. Alan R. Moritz, to associate professor of pathology.
Dr. James D. Pilcher, to associate professor of pediatrics.
Dr. John A. Toomey, to associate professor of pediatrics.
Dr. Frederick C. Herrick, to associate clinical professor of surgery.
Dr. William R. Barney, to assistant clinical professor of obstetrics.
Dr. Argyll J. Beans, to assistant clinical professor of medicine.
Dr. John J. Dickenson, to assistant clinical professor of surgery.
Dr. Harold Fell, to assistant clinical professor of medicine.
Dr. Hagop G. Miskjian, to assistant clinical professor of dermatology and syphilology.
Dr. Joseph T. Smith, Jr., to assistant clinical professor of obstetrics.

OKLAHOMA

Personal.—Dr. John B. Smith, superintendent of the University of Oklahoma Hospital, Oklahoma City, since Aug. 15, 1931, retired July 1, because of ill health. Dr. Cecil Bryan of the staff of the state health department has been appointed to succeed him.—Col. Orville D. Wescott has been made superintendent of the Veterans' Administration Hospital at Muskogee, succeeding Col. Louis H. Webb, who has been transferred to the Veterans' Administration Hospital at Legion, Texas.

Society News.—Dr. Peter T. Bohan, Kansas City, Mo., addressed the Garfield County Medical Society, June 15, on "Use of Drugs in Heart Failure."—Dr. Charles P. Bondurant, Oklahoma City, addressed the Canadian County Medical Society, June 4, in El Reno, on "Diseases of the Skin Commonly Seen in General Practice."—Dr. Sylvester N. Mayberry, Enid, among others, presented a paper on subphrenic abscess before the Woods-Alfalfa County Medical Society at its May meeting in Alva.

New Organization of State Board.—Dr. Lewis E. Emanuel, Chickasha, has been elected president of the Board of Medical Examiners of the State of Oklahoma and Dr. James M. Byrum, Shawnee, reelected secretary for four years. New members are Drs. William V. Batson, Marietta; Jesse R. Barry, Picher, and Orion C. Standifer, Elk City. The board now requires candidates for licenses to have a certificate that they have served an internship in an approved hospital before the license is issued.

PENNSYLVANIA

Society News.—Dr. Olin West, Chicago, Secretary and General Manager, American Medical Association, addressed the Third Councilor District of the Medical Society of the State of Pennsylvania in Allentown, June 28, on medical economics.—Dr. Sydney J. Hawley addressed the Montour County Medical Society at a meeting at Danville State Hospital, June 23, on roentgenology.—Dr. George W. Crile, Cleveland, will address the annual meeting of the Lehigh Valley Medical Asso-

ciation at Pocono Manor, July 31, on "The Genesis and Treatment of Cancer." Dr. Jonathan M. Wainwright, Scranton, will speak on "Postgraduate Opportunities in Small Hospitals."

District Society Meeting.—The Seventh Councilor District of the Medical Society of the State of Pennsylvania held its annual meeting in Williamsport, July 14. Dr. Harlow Brooks, New York, addressed the meeting on rheumatic fever; Dr. James D. Stark, Erie, discussed the Erie County plan for care of the indigent and Dr. John P. Harley, Williamsport, the Lycoming County plan. Testimonials were presented to the following members of the district society who have been in practice fifty years or more:

| | |
|--------------------------------|-----------------------------------|
| Joseph W. Albright, Muncy | John A. Klump, Williamsport |
| Elwin H. Ashcraft, Coudersport | William G. Marsh, Watsontown |
| John M. Dumm, Mackeyville | James R. Rankin, Muncy |
| Edward Everett, Dushore | Michael M. Rankin, Ridgway |
| Charles L. Fullmer, Renovo | William J. Shoemaker, Lock Haven |
| Luther M. Holloway, Salona | Charles W. Youngman, Williamsport |
| Ward L. King, Muncy | |

Drs. Charles Falkowsky, Jr., Scranton, president of the state society; Donald Guthrie, Sayre, president-elect, and William H. Mayer, Pittsburgh, chairman of the committee on public relations, also made short addresses.

TENNESSEE

Personal.—Dr. Andrew R. Bliss, Jr., Memphis, has resigned as chief of the division of pharmacology, University of Tennessee School of Medicine, effective August 15. He will take charge of new research laboratories of the William A. Webster Company, manufacturers of drugs. Dr. Bliss has been associated with the university for ten years.

TEXAS

Fifty Years in Practice.—Dr. Edward Randall, emeritus professor of therapeutics at the University of Texas School of Medicine, observed the fiftieth anniversary of his graduation from the University of Pennsylvania School of Medicine in June. For thirty-seven years Dr. Randall occupied the professorship, retiring in 1929 to be succeeded by his son, Dr. Edward Randall, Jr. He has been president of the board of managers of John Sealy Hospital for twenty-five years and in 1929 was appointed a member of the board of regents of the university. Special tributes to Dr. Randall on his anniversary were received from his associates in the university and the city and from medical leaders in other parts of the United States.

Health at El Paso.—Telegraphic reports to the U. S. Department of Commerce from eighty-five cities with a total population of 37 million, for the week ended July 15, indicate that the highest mortality rate (22) appears for El Paso, and the rate for the group of cities as a whole, 9.6. The mortality rate for El Paso for the corresponding week of 1932 was 10.8 and for the group of cities, 10.1. The annual rate for eighty-five cities for the twenty-eight weeks of 1933 was 11.4, as against a rate of 11.8 for the corresponding period of 1932. Caution should be used in the interpretation of weekly figures, as they fluctuate widely. The fact that some cities are hospital centers for large areas outside the city limits or that they have a large Negro population may tend to increase the death rate.

Society News.—The one hundred and fifth semiannual meeting of the North Texas District Medical Society was held in Greenville, June 5-6. The program included the following symposiums:

Acute Surgical Conditions of the Upper Part of the Abdomen, Drs. William Lee Hudson, Dallas, and Rufus C. Whiddon, Gainesville.
Acute Surgical Conditions of the Lower Part of the Abdomen, Drs. Benjamin F. Largent, McKinney, and Charles W. Flynn, Dallas.
Nonsurgical Abdominal Conditions, Drs. Robert B. Giles and Glenn D. Carlson, Dallas; Corwin L. Maxwell, Myra, and Martin L. Wilbanks, Greenville.
Heart Conditions, Drs. Benjamin J. Berger and Merritt B. Whitten, Dallas, and Coble D. Strother, Sherman.

Among other speakers were Drs. William B. Carrell, Dallas, on osteomyelitis; George R. Enloe, Fort Worth, acute infections of the hand, and George V. Brindley, Temple, acute infections of the face.

WASHINGTON

Protective Measures Against Rabies.—Inoculation of all dogs in Pierce County against rabies was ordered by the county authorities, June 27, as a measure of preventing the spread of the disease, which has been prevalent in the county for several months. About thirty persons were reported to have been bitten by dogs and all had received the Pasteur treatment. A ninety day quarantine on dogs was imposed in May and a state quarantine went into effect, June 1.

WEST VIRGINIA

Society News.—A symposium on pediatrics was presented before the Cabell County Medical Society, Huntington, June 8, by Drs. Will D. Hereford, William B. Hunter, George M. Lyon and Ray M. Sloan. The Monongalia County Medical Society was host to the medical societies of Marion and Harrison counties, June 6, in Morgantown. Drs. Roy R. Snowden and Holland H. Donaldson, Pittsburgh, conducted clinics and in the evening presented papers on peptic ulcer. Dr. William V. Wilkerson, Montgomery, presented a paper on duodenal ulcer before the Fayette County Medical Society, Oak Hill, June 13.

WISCONSIN

Personal.—Dr. Hjørleifur T. Kristjanson, Milwaukee, was elected president of the Diplomates of the National Board of Medical Examiners at their annual meeting in Milwaukee, June 16. Physicians and dentists of Waupun recently gave a dinner in honor of Dr. Wallace P. Smith, celebrating his fortieth anniversary of practice in the town and his graduation from medical school. The staff of St. Mary's Hospital, Superior, gave a dinner in honor of Dr. Thomas J. O'Leary, June 26, celebrating his election as president-elect of the State Medical Society of Wisconsin.

Society News.—Speakers at the June meeting of the Barron-Washburn-Sawyer-Burnett Counties Medical Society at Rice Lake were Drs. Walter G. Sexton, on "Resection of the Prostate"; Karl H. Doege, "Purpura Hemorrhagica" and Paul F. Doege, "Cancer of the Cervix." All are from Marshfield. Dr. Forrester Raine, Milwaukee, addressed the Fond du Lac County Medical Society, May 31, on surgery in tuberculosis. Dr. Chester C. Schneider, Milwaukee, made an address on "Modern Management of Fractures" before the Jefferson County Medical Society, Lake Mills, June 8. Dr. Russell A. Oldfield, Eagle River, addressed the Oneida-Vilas County Medical Society, Rhinelander, June 1, on Dupuytren's contraction. Dr. Edward F. Mielke, Appleton, and Mr. B. E. Kuechle, an insurance man of Wausau, discussed silicosis at the last spring meeting of the Outagamie County Medical Society, June 1. The Milwaukee County Medical Society will conduct its fourth annual diphtheria prevention campaign during August. Clinics for those unable to pay will be established in hospitals.

GENERAL

Examinations in Otolaryngology.—Thirty-nine candidates were successful in the examinations conducted by the American Board of Otolaryngology in Milwaukee, June 12. Nine were conditioned or failed. The next examination will be held in Boston, September 16, preceding the meeting of the American Academy of Ophthalmology and Otolaryngology.

Society News.—Dr. Robert M. Howard, Oklahoma City, was installed as president of the American Association for the Study of Goiter at its recent annual meeting; Dr. Allen Graham, Cleveland, was named president-elect, and Dr. Julius R. Yung, Terre Haute, reelected secretary. The next annual session will be held at Cleveland. At the recent annual meeting of the American Dermatological Association, Dr. Harold N. Cole, Cleveland, was made president, and Dr. William H. Guy, Pittsburgh, reelected secretary.

Medical Problems of Prisons.—The medical section of the American Prison Association, which will meet in Atlantic City, October 9-11, has announced the following addresses by physicians:

Dr. Roy K. Flannagan, Richmond, Va., Medical Service in Jails.
Dr. Frederick S. Baldi, Philadelphia, The Neurotic in the Prison Sick Line.
Dr. Walter Freeman, Washington, D. C., Importance of Routine Neurologic Examination.

At the Atlantic City Hospital, Dr. Philip Marvel, Jr., will conduct a clinic on cardiac problems, Dr. Charles H. Shivers, on syphilis, and Dr. David W. Scanlan, hospital service and therapeutics.

Urologic Meeting.—Dr. Miley B. Wesson, San Francisco, was named president-elect of the American Urological Association at its thirtieth annual meeting in Chicago, June 20-22. Dr. Nathaniel P. Rathbun, Brooklyn, became president and Drs. Gilbert J. Thomas, Minneapolis, and James B. Cross, Buffalo, were reelected secretary and treasurer, respectively. Dr. Henry F. Helmholz, Rochester, Minn., gave the Ramon Guiteras Lecture on "Experimental Studies in Urinary Infections." Among other speakers were Drs. Gordon S. Foulds and Hugh Stanley Douglas, Toronto, on "Spinal Anesthesia in Urology"; William E. Lower, Cleveland, "Experimental Study of the Exocrine and Endocrine Functions of the Tes-

ticles" and Anson L. Clark, Rochester, Minn., "Ketogenic Diet in Treatment of Urinary Infections."

Cancer Demonstration.—Dr. Joseph Colt Bloodgood, Baltimore, announces that the next microscopic, oral cavity and bone demonstration will be held in Washington, D. C., September 17-24, instead of Baltimore as previously. The change was made because artificially cooled demonstration rooms have been made available in the Mayflower Hospital without additional cost. The diagnosis and treatment of cancer in all stages, and the local conditions that precede development of the disease will be covered in the demonstration, which is under the supervision of Dr. Bloodgood and Dr. Charles Geschickter, also of Baltimore. The program will include a conference on the problem of preoperative irradiation, Sunday evening; microscopic lantern slide demonstration, Monday; regular bone demonstration, Tuesday, Wednesday and Thursday, and oral cavity demonstration, Friday and Saturday.

Change in Status of Licensure.—The Indiana State Board of Medical Registration and Examination reports the following: License restored to Dr. James M. Sample, Nabb, June 19; the license was revoked, July 14, 1926.

The State Board of Medical Examiners of Florida recently reported the following action:

Dr. Ira Willis Ballard, Miami, license revoked, June 12, because of his conviction of violating narcotic laws; he is now in the federal penitentiary at Leavenworth, Kan.

The Board of Medical Examiners of the State of North Carolina reported the following:

Dr. Michael Roberson, Durham, recently withdrew an appeal from the action of the board in revoking his license, when he entered a plea of nolo contendere to a charge of performing an illegal operation, thus making effective the revocation ordered in 1931. Sentence in the recent case was suspended on condition that Roberson move out of Durham, withdraw his appeal and dispose of all his medical equipment within sixty days.

The Public Health Council of West Virginia has recently taken the following action:

The licenses of Drs. James Carney Hardman, Huntington, and Alvah L. Parsons, Charleston, to practice medicine in West Virginia were restored at a session of the council, July 11-13. The licenses were revoked, March 22, 1932, for violation of the narcotic laws.

Centennial Dental Congress.—The American Dental Association will celebrate its diamond jubilee and the Chicago Dental Society will hold its annual clinics as part of a Centennial Dental Congress in Chicago, August 7-12. Numerous special dental societies will meet during the week, which has been designated "Dental Week" at the Century of Progress. Dr. Hugh S. Cumming, surgeon general of the U. S. Public Health Service, will be a speaker at the opening general meeting, and at another general meeting Drs. Howard W. Haggard, New Haven, Conn., and Eben J. Carey, Milwaukee, will speak on "The Progress of Dentistry" and "A Century of Progress in the Medical Sciences," respectively. In the meetings of the scientific sections the following Chicago physicians will make addresses:

Dr. Wilber E. Post, Recent Developments in Focal Infection.
Dr. Lloyd L. Arnold, Lips and Tongue as Reservoirs for Oral Bacteria.
Dr. Clara M. Davis, Studies in Self-Selection of Diet by Young Children.
Dr. Anton J. Carlson, Some Unknowns in the Physiology of the Teeth.
Dr. Loyal Davis, Trigeminal Neuralgia.
Dr. Edward A. Oliver, Dermatologic Lesions of the Oral Cavity.

Dr. Arthur D. Black, Chicago, is president of the congress; G. Walter Dittmar, D.D.S., Chicago, is president of the American Dental Association, and Howard C. Miller, D.D.S., is president of the Chicago Dental Society.

Automobile Deaths in 1932.—During the calendar year 1932 there were 26,168 deaths from automobile accidents in the death registration area of the United States exclusive of Utah, the Bureau of the Census reports. This compares with 29,885 in 1931. The death rate was 21.9 per hundred thousand of estimated population for 1932 and 25.1 for 1931. Considering states by geographic divisions, the Pacific group had the highest death rate, 33.2. Separate states with the highest rates were Nevada, 63.4; District of Columbia, 38.7; California, 36.9; Arizona, 35.7, and Wyoming, 34.5. States which had the lowest rates were North Dakota, 8.3; Mississippi, 11.4; Arkansas, 13.9; South Dakota, 14.1, and New Hampshire, 15. In ninety-two cities with a population of 100,000 or more, there were 8,573 deaths, a rate of 22.8, as compared with 9,825, or a rate of 26.6 in 1931. Cities with the highest rates were Camden, N. J., 65.4; Nashville, Tenn., 45.9; San Diego, Calif., 41.6; Jacksonville, Fla., and Tacoma, Wash., each 41.5. The total number of deaths within a city cannot be taken as a measure of the automobile hazards, the bureau points out, as the location of the city, its hospital facilities and the volume of traffic all have an influence on the number of deaths. In Camden, for instance, only 27 of the 78 deaths resulted from accidents within the city, giving a rate of 22.7.

Institute for Hospital Administrators.—The American Hospital Association will conduct an institute for hospital administrators in Chicago, September 18-October 6. Subjects to be covered will include topics and principles of hospital planning; construction and reconstruction; different types of hospitals in the United States and Canada; their distribution and organization; hospital occupancy and methods of increasing it; relations of hospitals to the medical profession, public health work and social agencies; outpatient service; costs of hospital care and group hospitalization, and hospital ethics and publicity. Morning sessions will be devoted to discussions and seminars dealing with the organization of hospitals and such departmental problems as admissions, business management, nursing, food service, purchasing and supplies, outpatient departments, records and maintenance of plant. Speakers at the institute are expected to include Drs. Sigismund S. Goldwater, New York; Malcolm T. MacEachern and Bert W. Caldwell, Chicago; Michael M. Davis, Ph.D., and Clarence Rufus Roem, Ph.D., Chicago; the dean and faculty members of the University of Chicago school of business, Dr. Herman N. Bundesen, and members of the Council on Medical Education and Hospitals of the American Medical Association. Students attending the institute will visit Chicago hospitals and will have opportunity to study the particular subjects or departments in which they are interested.

Narcotics Limitation Convention Goes into Effect.—The International Convention for Limiting the Manufacture and Regulating the Distribution of Narcotic Drugs, ratified by thirty-nine nations, went into effect, July 9, by proclamation of the President. The convention, which was drawn up at a conference in Geneva, dated July 13, 1931, was ratified, April 10, when twenty-five countries had sent ratifications or accessions to the secretary general of the League of Nations. The convention is expected to constitute an important step in the suppression of the illicit drug traffic and limitation of the production to amounts needed for medical and scientific purposes. The U. S. Department of State points out that the advantages to the United States lie in the fact that the convention limits the quantities of dangerous drugs manufactured in other countries, tightens restrictions on legitimate traffic, and affords better facilities for suppressing the illicit traffic. The domestic manufacture of drugs in the United States is already closely limited to the medical needs of the country and the illicit traffic is supplied by drugs smuggled in from abroad. It is anticipated that little if any change will be made in this country's handling of the drug situation, as the government already limits the quantities manufactured, prohibits import of the habit-forming derivatives of coca leaf and opium and rigidly controls the legitimate distribution of the products. The government also maintains the special administration for control required by the convention in the Bureau of Narcotics.

FOREIGN

Journal Changes Name.—*Heart*, an English journal for study of the circulation, will henceforth appear under the name *Clinical Science, Incorporating Heart*. Sir Thomas Lewis is editor of *Heart*, which was first issued in 1909.

Statement on Plastic Surgery.—The French Society of Reparative, Plastic and Esthetic Surgery at a recent meeting issued a statement deploring the publication of articles in their specialty by persons without recognized scientific competence. Members of the society were warned against associating themselves in any way with charlatans or sending to unscrupulous persons patients who might be helped by this type of special surgery under proper conditions. "Members of the society can recognize as serious publications only those which are submitted to the sanction of discussion as is the custom in all scientific societies which are entered only after examination of the scientific work required by law," the statement concluded.

Society News.—The German Society for Diseases of Digestion and Metabolism has postponed its meeting which was planned for September in Berlin and will meet in the spring of 1934 at Wiesbaden in conjunction with the German Society for Internal Medicine. The first International Congress of Reparative, Plastic and Esthetic Surgery will be held in Paris at the Oceanographic Institute, October 13-14. Information may be obtained from Dr. Dartigues, 81 Rue de la Pompe, 16, or Dr. Charles Clauoué, 39 Rue Scheffer, 16. The annual meeting of the German Society for Gynecology will be held in Berlin, October 11-14. Information may be obtained from Dr. Frommolt, University Clinic for Women, Artilleriestrasse 18, Berlin N. 24.

Darling Prize Awarded.—The first award of the Darling Foundation Prize will be made, Jan. 1, 1934, to Lieut.-Col. Sydney J. James of the Ministry of Health, London, the Health

Organization of the League of Nations has announced. This award was created by the Health Organization in honor of Dr. Samuel T. Darling, an American physician who was killed in an automobile accident near Beirut, Syria, in 1925 while on a mission for the league. Dr. Darling engaged in public health work in the Panama Canal Zone, accompanied General Gorgas on a sanitary mission to South Africa and, as a member of the staff of the International Health Board, was head of a commission that investigated causes of anemia in Malaya, Java and Fiji. At one time he was professor and director of laboratories in the medical school of São Paulo, Brazil, and later was director of a laboratory of research on malaria in Leesburg, Ga.

Medical Center in Tokyo.—Two units of a new plant for St. Luke's International Hospital and Medical Center in Tokyo, the inpatient department and the college of nursing, were opened, June 4. Funds for the hospital were contributed by popular subscription in the United States. The college of nursing is the gift of the Rockefeller Foundation. Units to be completed are the outpatient department, administration quarters and public health department. The hospital, said to be the finest in Japan, is seven stories high and will accommodate 275 patients. The nursing school has facilities for 200 nurses. According to a statement issued by the hospital authorities, this is the only nursing school in the Orient. St. Luke's was founded thirty years ago by an American physician, Dr. Rudolph Bolling Teusler, who went to Japan as a missionary of the Protestant Episcopal Church. Hon. Joseph C. Grew, American ambassador to Japan, was among the speakers at the dedicatory ceremonies. Interests of the hospital in the United States are represented by a council headed by George W. Wickersham and including among its members Charles A. Lindbergh, Norman H. Davis and Thomas W. Lamont.

Festschrift Honors Dr. Czerny.—The *Journal of Pediatrics*, official organ of the American Academy of Pediatrics, for July was dedicated to Dr. Adalbert Czerny in honor of his seventieth birthday. Dr. Czerny is director of the Children's Clinic, Charity Hospital, Berlin, and professor of children's diseases at the Faculty of Medicine of Friedrich Wilhelm University. The publication of the festschrift was made possible by contributions of the following organizations: the Jacobi Fund of the Section on Pediatrics of the American Medical Association, the American Academy of Pediatrics, the American Pediatric Society and the Central States Pediatric Society. In addition to Drs. Samuel McC. Hamill, Philadelphia, Julius H. Hess, Chicago, Frank C. Neff, Kansas City, Mo., Oscar M. Schloss, New York, and Frederic W. Schlutz, Chicago, as representatives of the foregoing organizations, the committee in charge of the commemorative volume included Drs. Henry F. Helmholz, Rochester, Minn., chairman; Clifford G. Grulee, Chicago, editor of the *American Journal of Diseases of Children*, and Borden S. Veeder, St. Louis, co-editor of the *Journal of Pediatrics*. Dr. Czerny is a graduate of the German University of Prague, 1888, and has been associated with the Children's Clinic since 1913. A picture of the latter institution appears on the cover page of the festschrift.

Government Services

U. S. Public Health Service

Asst. Surg. Kenneth E. Gamm, relieved from duty on Coast Guard Cutter *Mendota*, Stapleton, N. Y., and assigned at Relief Station, Washington, D. C.

Passed Asst. Surgeon Lazelle B. Sturdevant, ordered to Coast Guard Cutter *Tahoe* for duty on Bering Sea patrol.

Medical Reserve Officers' Training

The Army Medical Field Service School at Carlisle, Pa., was ordered reopened, June 14, for a four weeks course of training for medical reserve officers from colleges and universities. The order rescinded a previous one which abolished reserve officers' training this year. Three hundred students received commissions at the commencement exercises, June 19.

CORRECTION

"The Newer Treatment of Strychnine Poisoning."—In the article by Drs. Samuel Stalberg and Harold S. Davidson (*THE JOURNAL*, July 8, p. 102), the dosage of the tribrom-ethanol preparation was stated to be 4 grains (0.26 Gm.) in 6 ounces (175 cc.) of water. The amount administered was 4 Gm. of tribrom-ethanol in 6 ounces of water.

Foreign Letters

LONDON

(From Our Regular Correspondent)

July 8, 1933.

The Treatment of Acute Appendicitis

The controversy over the treatment of acute appendicitis, which began in the spring of 1932, when the veteran surgeon Sir James Berry, at the Medical Society of London, deprecated too frequent operation, has passed into the hands of the younger surgeons and still continues. Berry's paper was followed by a series of letters in the journals from leading surgeons expressing contradictory views on the propriety of immediate operation in every case. The subject was again debated at the Royal Society of Medicine and with the same result (*THE JOURNAL*, Dec. 17, 1932, p. 2124). Then the Fellowship of Medicine arranged a debate by well known surgeons, at which Lord Moynihan presided, with the result that the voting was almost equally divided, there being a small preponderance in favor of immediate operation in all cases. One of the protagonists in that debate, Mr. R. J. McNeill Love, writing in the *Lancet*, divides the cases into four groups: early cases, subsiding cases, those in which the inflammation is still confined to the vicinity of the appendix without evidence that it is subsiding, and those complicated by peritonitis. The controversy centers on the third group, in which the patients are usually seen forty-eight hours or more after the onset. Three quadrants of the abdomen are relatively free from tenderness or rigidity, but these conditions are present in the right iliac fossa or right loin or a tender swelling is felt by rectum. Love points out that immediate appendectomy is often extremely difficult or may have to be abandoned after prolonged searching and considerable trauma. The congestion and turgidity of the bowel and omentum and the friability of the tissues and adhesions are obstacles to a well executed operation. However gentle interference may be or however carefully packing is inserted, the early protective adhesions are easily separated, and local may be converted into general peritonitis. Surgical intervention is particularly dangerous from the third to the fifth day, when natural immunity to infection is exhausted and acquired immunity has not been established (the "negative phase" of Wright). Operative intervention, by exposing fresh planes to infection, accelerates absorption of toxins when the patient is unprotected. The mortality of patients with purely local peritonitis operated on from the third to the fifth day at the London Hospital was 13.7 per cent, while the mortality of patients at the London and St. Thomas's hospitals operated on during all stages of local peritonitis was 5.8 per cent.

Love advocates expectant treatment but insists that the four F's must be rigorously enforced—Fowler's position, fomentations, fluids only and a four hourly chart. As a rule, expectant treatment is not suitable for children or the aged. Children are unlikely to give an accurate history and usually have been given purgatives. The mortality of expectant treatment is only 3 per cent, and 65 per cent of the cases undergo resolution.

Another London surgeon, Mr. R. A. Ramsay, replies to this defense of expectant treatment by saying that experienced surgeons do not attempt removal of the appendix in the presence of the obstacles described and do not separate adhesions. He would "leave severely alone" cases in which congestion and turgidity of the bowel and omentum and friability of the tissues are present. But Love points out that in cases of recent local peritonitis these are the usual conditions found. Surely the obvious way to leave these tissues "severely alone" is not to operate. In many cases the "perityphilitis" is not adherent to the abdominal wall and a tube inserted to "let out the pus" (as advocated by Ramsay) traverses the uninfected peritoneal cavity. More-

over, in 65 per cent of the cases treated expectantly, resolution occurs without suppuration.

An International Standard for the Estrus-Producing Hormone

In July, 1932, a conference was held in London under the auspices of the Permanent Commission on Biological Standardization of the Health Organization of the League of Nations, to discuss international agreement on standards of reference and units of activity for the sex hormones. It was agreed that knowledge of the male sex hormone and of the hormones of the corpus luteum and anterior pituitary body is sufficiently advanced to permit of a standard of reference being established and a unit of activity defined. Important decisions were also reached as to the estrus-producing hormone, which has been prepared from the urine of pregnancy in quantities sufficient for chemical examination. It exists in two forms—a ketohydroxy and a trihydroxy. The former is the more active in producing estrus in animals from which the ovaries have been removed. The conference agreed on the adoption of a standard substance in terms of which the unit could be defined as the only safe basis for international use. The ketohydroxy form of the hormone in pure crystalline condition, preserved at the National Institute for Medical Research, London, was adopted. The unit of activity was defined as that contained in 0.0001 mg. of this substance.

In order to provide an adequate amount of material to serve as an international standard, different countries have sent samples of the pure crystalline ketohydroxy form of the estrus-producing hormone to the National Institute of Medical Research, London, which for this purpose is acting as the central laboratory on behalf of the Health Organization of the League of Nations. At the institute the final preparation of the standard has been completed and arrangements have been made for its storage and dispatch to the laboratories in other countries, which have been nominated by the Health Organization of the League of Nations.

The Experimental Production of Malignant Tumors

At the Royal Society, Dr. J. A. Murray said that investigations of the last thirty years proved that under appropriate conditions the cells of the higher vertebrates were capable of unlimited proliferation. Loose statements were made in the literature that this or that agent conferred on the cells powers of unlimited new growth. This was nonsense, as the cells already possessed such powers. Murray discussed the various suggestions as to the cause of malignant growths. There was first the genetic hypothesis of Boveri, modified by Bauer. The main objection to it was the necessity of assuming a large number of units in each gene, to allow for the great number of slight modifications presented by the new growths of any one tissue, all practically permanent. Gye's conception of a factor derived from the host's cells and carrying all the specific characters of the tumor strain, acting in conjunction with a relatively nonspecific virus, was still without direct experimental proof. Like the enzyme modification, the greatest objection to it was the failure to demonstrate cell-free transmission in the laboratory strains of mouse and rat tumors. Finally there was the special form of the chronic irritation theory of Virchow, which had arisen on the basis of Yamagiwa's work on the experimental production of tar cancer. The experimental confirmation of Virchow's theory had established its validity as a concise description of the emergence of cancer after prolonged localized irritation of the tissues by a variety of agents, and nothing more. Wide differences of opinion still existed as to how this result was brought about. In Dr. Murray's opinion the chemical and physical carcinogenic agents acted directly. The chemical properties of these agents gave no indication how the autonomous and uncontrolled type of proliferation was

induced. Dr. Murray concluded that the experimental production of malignant growths reproduced perfectly the phenomena that occurred in the development of occupational cancer—from exposure to tar or x-rays, for example. The other forms of cancer for which no definite irritant could be identified at present were so similar in their mode of occurrence and the time necessary for their appearance that it was reasonable to accept experimental carcinogenesis as a model for them.

The German Persecution of Jewish Physicians

An appeal was made to the General Medical Council (the official body which controls medical education and registration in this country) from the Jewish Medical Emergency Association, which has been formed to alleviate the sufferings of Jewish physicians whose position has been rendered untenable by the policy of the Hitler government. The association pointed out that numbers of these men, unable to carry on practice in their native land, were being driven abroad, and some of them would be able to settle in this country. The examining bodies here require from those holding a German medical degree and who desire to qualify in this country that they take the anatomy and physiology examination, and then, after two years, the final examination. It was pointed out that those affected by the regulations might include some of the most distinguished names in medical science in Germany. The hardship of strict enforcement of the regulations was obvious, and while the association appreciated that freedom of action was vested in the examining bodies, it felt that those bodies would be only too glad to be guided as to some humane relaxation by any recommendation from the council. The executive committee of the council resolved to inform the association that the granting of qualifications was a matter for the licensing bodies, and, provided the resolutions of the council in regard to the medical curriculum were adhered to, there were no grounds for independent action on the part of the council.

The Chaotic Organization of Hygiene in France

Dr. Hazemann publishes in the *Mouvement sanitaire* the report of an inquiry into the results secured by French hygienic legislation, which he says are not in proportion to the expenditure of money and effort. Countless laws have been passed concerning the various branches of hygiene—from the crusade against infectious diseases down to the care of the child, the mother, the infirm, the aged and the workers. All require the creation of organizations and the appointment of special officers, which is expensive. Many organizations constitute duplication of effort. Others are working at cross purposes. The inadequacy of the results is due less to a lack of good will and clearheadedness than to a veritable administrative chaos. For example, vacation colonies for children have been scattered over France with little thought as to the choice of the most favorable places for their location. All these societies function without any connection with one another, being subject to the whims of local influence. The same conditions are found in other fields. With a better organization superior results might be obtained. The sums expended for the piping of drinking water from a distance, which amounted to a few thousand francs in 1903, amount today to a sum forty times as great. Nevertheless, of 2,000 cities of more than 3,000 inhabitants, 12 per cent have not an adequate supply of pure drinking water. Only two thirds of the communes of France have a reliable water system. The capacity for organization appears to be generally lacking. The bad conditions are not due to a lack of money. In 1914 the appropriations for the department of health amounted to 140,000,000 francs, or nearly \$28,000,000. In 1930 they were nearly double that (gold value), amounting to more than 2 per

cent of the total budget of the republic. In dividing expenditures for public health into the following five classes: one finds in each class a steadily increasing appropriation: (1) hygiene, salubrity, epidemics; (2) maternal and infant protection; (3) crusade against tuberculosis; (4) campaign against venereal disease; (5) crusade against cancer. Likewise the same items in the departmental budgets show a steady increase, with the result that in 1927, out of a total expenditure of nearly 4,000,000,000 francs (\$156,800,000), one fourth was for "assistance-hygiene" and 1.8 per cent of the total for purely hygienic enterprises. The retrenchments effected in 1933, which became necessary as a result of the economic crisis, did not affect the appropriations for hygiene, although, on the whole, the departmental budgets were diminished by more than 10 per cent. In seven years the sales of tuberculosis seals have brought in nearly 100,000,000 francs (\$3,920,000). In 1924 there were eleven departmental inspection services entrusted to full-time physicians. In 1931 there were seventy-one, together with thirty-seven departmental bureaux of hygiene, seven of which confine their attention to tuberculosis. The services looking toward the protection of mothers and children counted, in 1931, nearly 600 centers for prenatal consultations, more than 400 maternities, 133 homes for mothers, more than 4,000 consultation centers for the care of nurslings, nearly 600 day nurseries, nearly 200 nurseries for infants, and more than 100 supervisory centers for the placement of children in families. Thirty-three departments of France have an organized medical inspection schools. There are nearly 900 vacation colonies. Nine departments of France have an organized society that carries on a crusade against tuberculosis. These societies have 80 dispensaries and approximately 40,000 beds available for the tuberculous, or twenty times as many as in 1913. The preventive services have, in addition, 14,000 beds available. The crusade against syphilis is carried on by nearly 1,700 services. There are twenty-five anticancer centers. There are more than 2,700 visiting nurses on duty. The eighty-five training schools have more than 3,000 pupils. These facts show that considerable progress has been made since the war. In the face of the great financial sacrifices made and the great labor involved, the question is in order as to whether important results have been secured. The mortality of young adults in England and Germany is only half that of persons of corresponding age in France. Tuberculosis continues its ravages; they are possibly less severe than formerly but are still very significant. With the available resources, Dr. Hazemann says frankly, one should do more and better. Efforts should be directed toward improving the technique; toward realizing, through coordination, unity of method and action. He cites as an example the region of Nancy, where Dr. Parizot has been able to accomplish better results through the creation of a central committee composed of representatives of all the private and public organizations concerned with the promotion of hygiene, this committee serving each month as a clearing house so as to avoid duplication of effort. A card index, which is kept up to date, aids greatly in this control and makes it possible to compile exact statistics which are lacking in most departments of France.

Yellow Automobile Lights

The use of yellow lenses, recommended since 1906 by Motais and Tscherning, as giving better illumination with less fatigue for the eye, has received an interesting application through Monnier and Mouton in automobile lamps. With yellow cadmium lenses, specimens of which they have presented to the Academy of Sciences, the dazzling effect of automobile lamps encountered during the night is suppressed. This glass, owing to the slight thickness required by the conditions of manufacture of the lenses, transmits poorly radiations of a wavelength below 0.490 millimicron, but this power of transmission increases rapidly as the wavelength approaches 0.510 milli-

micron, then remains practically constant for radiations of greater wavelength. The authors compared the rays emitted by automobile projectors with lamps having yellow lenses and with lamps of the same luminosity with colorless lenses. They noted an increase of visual acuity of 10 per cent; likewise an increase of the visibility due to a slight diffusion of the yellow light, not only in clear but also in foggy weather. This increase in visibility was evaluated by noting the distances at which an observer could distinguish a black object on a dark background. In an experiment carried out in clear weather, they secured the following results: with a white light, 130 meters; with a yellow light, 160 meters. Finally, they observed with the yellow lenses a frank diminution of the readaptation time of the eye to normal vision after prolonged dazzling. To summarize, the application to automobile projectors of yellow light entirely deprived of blue and violet radiations causes a lessening of the dazzling effect and a frank increase of the visibility.

Practicing Medicine Under a Changed Name

French law prohibits the practice of medicine under any other name than the true name of the holder of a diploma as registered at the prefecture of the department. Many foreign physicians seek to change their names on the pretext of making them easier to pronounce, but the main object is to conceal their nationality. These changed forms of names consist sometimes of simple translations, which deceive the public. Klein becomes Petit, Delbrück becomes Dupont, for example. On the other hand, it sometimes happens that a French physician seeks to practice his profession in another part of the country under an assumed name. The minister has urged the authorities to cooperate with him in putting an end to these abusive practices. A Rumanian physician by the name of Fliesmann, having acquired his diploma in the proper manner at the Faculté de Paris, opened an office in Paris, after assuming the French name Florian. He has been sentenced to pay a fine of \$5 and an indemnity of \$50, payable to the syndicate of the physicians of the Seine region, who brought suit against him.

Report of Public Health Service

The report of the public health service of Austria gives a picture of the changes in the population during the year 1932. The number of inhabitants was 6,536,892 (less than that of London or New York). Marriages showed a decrease as compared with the previous year (51,753 > 45,332). The steadily decreasing birth rate is a reflection of unemployment. Only 105,431 births were notified, a decrease of more than 4,000 over the previous year. The number of deaths (93,078) showed a decrease of 1,540. Nevertheless, one can observe here also the effects of the crisis if one considers the mortality according to age groups. Not only in children under 5 years of age but also in the 10-15 age group a distinct increase of mortality amounting to more than 10 per cent was observable. The reduction in the total number of deaths is due to the downward trend in the figures in the older and stronger age groups. This circumstance may be due to the increased resistance of the masses, resulting from improvement in hygienic conditions and the medical care during the past fifteen years. Deaths from tuberculosis have declined further. The economic crisis, which is increasing the incidence of tuberculosis, will show its effects on mortality later. Its influence can already be seen in the increase in the number of deaths due to colds and to infectious diseases resulting from reduced resistance—particularly of the children. The increase concerns chiefly pneumonia (7,934), diphtheria (989), measles (380, as against 120 in 1931), scarlet

fever (148), and, particularly, cholera infantum, which shows an increase of 30 per cent. Not a case of genuine cholera or smallpox was notified in 1932, and no cases of typhus were reported. The deaths from malignant neoplasms numbered 11,549 (an increase of 500); from diseases of the heart and the circulatory organs, 15,844 (an increase of 200); as the result of suicide, 2,972 (an increase of 197); 215 persons were murdered; 2,642 were killed in accidents (an increase of 100). If one takes the figures for Vienna alone, one finds a total mortality of 24,808, or 23 per cent of the total mortality, although Vienna has a population of 1,800,000, or 28 per cent of the total population of Austria. In Vienna there were 2,337 deaths from tuberculosis of the respiratory tracts, 3,998 from neoplasms (of which 4 per cent were in the esophagus), 402 from diabetes mellitus, 248 from leukemia, 5,661 (more than 30 per cent of the total for the republic) from diseases of the heart and the circulatory organs, 2,485 from diseases of the nerves and the sensory organs, 1,971 from pneumonia and pleuritis, 1,504 from gastro-intestinal diseases, 746 from diseases of the urogenital apparatus, 113 as the result of pregnancy or childbed fever (in Austria, as a whole, the number was 209), and 2,100 from cerebral hemorrhage (as compared with 5,937 in Austria). Under 1 year of age, 1,091 children died, as against 10,887 in all of Austria, or only 10 per cent, a proof of the superiority of the hygiene of the capital. The unusually large number of deaths (more than 50 per cent of the total) due to pregnancy and childbirth in Vienna is explained by the circumstance that the majority of the grave cases from the rural districts are brought to the Vienna hospitals. However, the total number of fatal cases (209) is small in comparison with other European countries, with the exception of Germany.

The Removal of a Large Hemangioma

In connection with an operation on an unusually large hemangioma, Dr. Demel experienced a severe hemorrhage, which forced him to interrupt the operation and to postpone the removal of the tumor until later. By the injection of a hypertonic sugar solution into the hemangioma the latter is changed into a solid tumor, the removal of which becomes simple. The bleeding is nil or slight. To get an idea of the size of the hemangioma, 20 cc. of a sodium salt of mono-iodomethanesulphonic acid is injected into the hemangioma before the application of the sugar treatment, and toward the end of the injection a roentgenogram is made. In this manner one obtains information in cases in which a connection of the angioma with important venous areas cannot be assumed or denied without an examination. Dr. Demel, who recently gave a demonstration before the Gesellschaft der Aerzte, suggests that this method be employed in suitable cases.

Permanent Cures of Skin Cancers

Prof. Dr. Arzt, director of the Vienna University Dermatology Clinic, and his assistant, published statistics on the results of treatment of cancer at the radium station of the university clinic. Cases are designated as "permanent cures" only when the malignity was established microscopically beyond doubt and when they remained at least five years without a recurrence. Among 386 controlled cases, a permanent cure was effected in 289, or 75 per cent. These results are equal to those secured in the Radiumhemmet in Stockholm, and in some types of cancer they are superior. The prognosis of pure radium irradiation and of radium irradiation combined with surgical intervention is, according to the experiences of the Vienna clinic, equally favorable, on the average. Pure radium therapy is preferable if it is the purpose to avoid an operation in cases of weakened or aged patients, or when cosmetic reasons are to be considered. In skin cancer a combination of the two methods is generally to be preferred, since the duration of the treatment is thereby considerably shortened, and, consequently, smaller doses of

radium are required. In cancer of the lip, so-called interlarding of the tumor with radium needles, together with cross-fire irradiation with pure gamma rays, has yielded excellent results. This method, as was recently announced in another publication, has given excellent results also at the radium station in the Vienna Municipal Hospital.

Prof. Viktor Mucha's Death

The death of Prof. Dr. Viktor Mucha (who was well known to American physicians who studied in Vienna), at the age of 56, has been announced. As demonstrator for Professor Ludwig in his courses on chemistry, and while serving, in the same capacity, Professor Weichselbaum, under whom he studied pathologic anatomy (1902-1905), Mucha gave evidence of his scientific qualities. He entered later the Dermatologic Clinic of Professor Finger, where he soon became the first assistant. He devoted himself particularly to venereology. He accepted the post of general consultant in venereal diseases for the army of occupation in Russia. When, in 1919, a special institute for women with venereal disease was created, he took over the directorship. He organized there the modern therapy of prostitution, which essayed not merely to heal disease by the use of medicaments but also to combat the psychic factors of prostitution by means of occupational therapy and social aid. To him medicine is indebted for the demonstration of *Spirochaeta pallida* in the dark field.

Poisoning from Arsenic in Wall Covering

Several years ago, Prof. Dr. Oppenheim called attention to the frequent cases of poisoning occurring through the employment of arsenic in wall paints and wall paper. Prof. E. Freund presented recently, before the Vienna Gesellschaft der Aerzte, a woman, aged 56, who, following an attack of articular rheumatism, developed a severe polyneuritis. There were paresthesias, pain in the muscles, weakness, soreness of the muscles, disturbances of sensibility, paresis, and absence of the reflexes of the upper extremities. The blood showed eosinophilia of 14 per cent, although the internal organs were apparently normal. In the urine distinct traces of arsenic were demonstrated, and, in addition, an extensive herpes zoster, arranged in segments, appeared on the side of the thorax. In the green scrapings of the wall paint (which had been applied five years previously) arsenic was found. The diagnosis of polyneuritis due to arsenic intoxication was clearly established. Professor Freund emphasized again the importance of prohibiting the use of any arsenic-containing salt in dyes used in wall paper or in wall paints. The industrial requirements have doubtless been more strictly observed in recent years, so that, at present, poisonous paints are not likely to be used in Austria. But apparently there are still sources of poisoning, which possibly, under the influence of decomposition and crumbling of old wall coverings, cause a chronic though imperceptible absorption of arsenic.

It should be added that sudden unexplainable loss of hair suggests the possibility of arsenic poisoning.

Address of Professor Eppinger

The new director of the first Medicinische Klinik, Professor Eppinger, who was summoned from Cologne as the successor of Professor Wenckebach, assumed today his duties as instructor in internal medicine. In his inaugural address, which was heard by the leaders of the medical societies, he gave a survey of the changes that have taken place in the trends of his specialty during this century. Whereas some investigators have directed their attention to morphology, another group (particularly in Germany) has displayed greater interest in the physiologic side. One group laid emphasis on the functional diagnosis and the conceptions of sufficiency and insufficiency. The others studied the problems of experimental physiology

and their importance for the clinic. In Vienna, the idea has gained ground that pathology is nothing more than a changed form of normal happenings. In connection with experimental pharmacology the new clinical therapeutics has developed. Professor Eppinger emphasized that his method of research (theoretical-experimental) brings him into close connection with therapeutic questions, which he will expound in his lectures. The discovery of new facts and the attainment of new acquisitions will receive full consideration in the management of the Medicinische Klinik. Eppinger, who is a native of Vienna, was welcomed with a storm of applause.

BERLIN

(From Our Regular Correspondent)

June 19, 1933.

The Status of Social Insurance

Recent letters have supplied the latest reports on the financial condition of the health insurance societies. Now the federal bureau of statistics has published the reports for 1932 on the financial situation in all branches of federal social insurance, which show the effects of the numerous emergency decrees for the rehabilitation of social insurance. If unemployment insurance is left out of consideration, the total deficit in the ordinary social insurance system was reduced from 36,200,000 marks (\$8,615,600) in 1931 to about 8,500,000 marks (\$2,023,000) in 1932. The retrenchments in expenditures corresponded to the reduction in receipts in the form of dues, brought about by unemployment and loss of wages. For example, the total receipts in 1932 were 3,300,000 marks (\$785,400), as against 4,100,000 marks (\$975,800) in 1931, and the total expenditures in 1932 were about 3,300,000 marks (\$785,400), as compared with 4,100,000 marks (\$975,800) in 1931. The reduction on both sides of the ledger was about equal, amounting to about 20 per cent. These figures show, to be sure, the application of rigorous measures to the annual budget. The situation in the several branches of the social aid system varies, as is evident in a comparison of receipts and expenditures in 1932 with those of the normal year 1929:

| | Receipts (1929 = 100) | Expenditures (1929 = 100) |
|----------------------------|--------------------------|------------------------------|
| Health Insurance | 57% | 55% |
| Accident Insurance | 60% | 80% |
| Disability Insurance | 63% | 97% |
| Employment Insurance | 90% | 142% |
| Guild Insurance | 74% | 85% |

The retrenchments in health insurance have been the most drastic. The reduction in receipts in this field, for 1932, was, however, less than the reduction in expenditures, which left a surplus of about 30,000,000 marks (\$7,140,000), as compared with a deficit of 56,000,000 marks (\$13,328,000) in 1931. The total receipts for health insurance (including the *ersatzkassen*) amounted to 1,240,000,000 marks (\$295,120,000) as against 1,600,000,000 marks (\$380,800,000) in 1931, whereas the total expenditures dropped from 1,670,000,000 marks (\$397,460,000) to 1,210,000,000 marks (\$287,980,000).

In accident insurance the total expenditures diminished from 420,000,000 marks to 330,000,000 marks (from \$99,960,000 to \$78,540,000), or more than 20 per cent. But the total receipts dropped still more; namely, from 389,000,000 marks (\$92,582,000) to 295,000,000 marks (\$70,210,000), whereby the deficit of 31,000,000 marks (\$7,378,000) was increased to 35,000,000 marks (\$8,330,000). The expenditures for accident benefits fell 20 per cent below those for 1931, which was due to the complete cancellation of all small accident benefits by the emergency decree of December, 1931.

In disability insurance in 1932 the deficit was about 185,000,000 marks (\$44,030,000). The receipts from dues are today barely

sufficient to cover half of the cost. The number of annuitants has been reduced by about 10 per cent.

It is evident from this new report that, in spite of many reforms, a real rehabilitation of the social aid system has not yet occurred. This is confirmed by the fact that the federal subsidies granted the social aid system in 1932 amounted to 478,500,000 marks (\$113,883,000) as compared with 487,700,000 marks (\$116,072,600) in 1931.

Reorganization of the Welfare Aid System

Göring, chairman of the Prussian cabinet, has set up principles according to which all boards are to reorganize public and voluntary welfare aid. The following passage is cited:

The reorganization of Germany's cultural life and form of government necessitates likewise certain modifications of the relation between public and voluntary welfare aid. The well meant endeavors of the past to perform the tasks of the public welfare system by means of public centers have proved a fatal mistake. Following this trend, the public welfare system created its own equipment and machinery likewise in places where the equipment of voluntary welfare organizations was already adequate. As the result of this duplication, full usage of tried existing arrangements of the voluntary welfare organizations became impossible and the administrative costs of welfare aid as a whole were increased. At the same time, political influence became paramount and the whole welfare aid system lost touch with the people. In welfare work the most effective help comes from the contacts of man to man. Welfare work, particularly among juveniles, can never dispense with that offered voluntarily by reason of love of mankind and because of a sense of responsibility for the general welfare. Voluntary welfare aid should therefore be made wide use of.

By "voluntary" in contradistinction to "public" welfare work is meant the social aid that is furnished to one's neighbor as a free service. The voluntary welfare system in Germany is partly in the hands of the churches and in part expresses religious equality, with no distinctions as to church affiliation. It is made up of several large federal leagues. The systematic welfare work performed by these leagues constitutes, in addition to the social performances of the central government, the communes and social insurance, an important factor in the life of the people.

The welfare work carried on by the evangelical church under the general term "home missions" employs, in various institutions and centers, more than 70,000 professional workers, including 45,000 female graduate nurses and 3,800 practical nurses. In its hospitals, retreats and training homes there are about 220,000 beds. The Catholic Charity League employs 78,000 female nurses and more than 3,000 male nurses and has a total of 255,000 beds. These figures do not include the kindergartens, and homes for underprivileged children.

The German Red Cross Society performs its welfare work without distinction as to race or religion. The membership at present is 1,500,000. It has 9,800 female nurses and more than 130,000 sanitary corps men. In the ladies' aid societies there are 800,000 women and girls enrolled. The number of beds in the hospitals, retreats, nursing and training homes is about 20,000.

The Deutscher paritätischer Wohlfahrtsverband comprises a large number of welfare institutions and welfare societies that, owing to their peculiar character, belong neither to the church leagues nor to the Red Cross. With its 48,000 beds and its homes and shelters with more than a million "clients," it constitutes an essential factor in the voluntary welfare system of Germany.

In addition to these leagues, which have existed for years, there is in process of development the welfare service of the national socialists. On the development of this welfare service will depend whether the voluntary welfare system will be

entitled to take over certain fields now administered by the public welfare system.

From the figures cited, one gets some conception of the extent of the voluntary welfare system in Germany in the fields of care of patients, promotion of health culture and domiciliary aid. From conservative estimates, the institutional work of the German voluntary welfare system saves the public welfare administration at least 250 to 300 million marks (from \$59,500,000 to \$71,400,000) annually.

The Consumption of Alcoholic Beverages

In previous letters, attention has been called to the reduction in the consumption of alcoholic beverages in Germany. According to the latest statistics, both beer and brandy show a reduced consumption. In the fiscal year 1929-1930, the consumption of beer amounted to 90 liters per person for the whole population, whereas in 1931-1932 it was 56.8 liters per person; in the last nine months of 1932 a further reduction in the consumption of beer amounting nearly to 12 per cent is reported. The consumption of beverage brandy (figured on the basis of 100 parts alcohol) was reduced from 0.75 liter per person to 0.61 liter.

Statistics on Suicide

Recently Chancellor Hitler announced in the Reichstag that, since the day of the signing of the Versailles treaty, 224,900 persons in Germany have committed suicide. The figures for the German reich are as follows:

| Year | Total Number of Suicides | Number of Women Suicides |
|-----------|--------------------------|--------------------------|
| 1919..... | 5,800* | |
| 1920..... | 13,319 | |
| 1921..... | 12,700 | |
| 1922..... | 13,402 | |
| 1923..... | 13,288 | 2,563 |
| 1924..... | 14,338 | 3,020 |
| 1925..... | 15,273 | 4,201 |
| 1926..... | 16,480 | 4,634 |
| 1927..... | 15,974 | 4,647 |
| 1928..... | 16,036 | 4,797 |
| 1929..... | 16,665 | 4,829 |
| 1930..... | 17,880 | 5,208 |

* Estimate for the second half of the year.

A comparison with the prewar figure reveals that the percentage of suicides has steadily increased. Before the war, one figured about 23 suicides to 100,000 of population, whereas now the proportion is in excess of 31. The percentage of women, and especially unmarried women, has greatly increased, whereas most of the male suicides have been married men.

University Teachers Serving as Consultants

The Prussian minister of public instruction has sent a bulletin to all the university teachers under his jurisdiction, in which he discusses the question of teachers serving as consultants. The rendering of expert opinions brings about a closer union of the university with the problems of practical life. In many cases the expert opinions are desired by eminent persons. Such activity, if carried to extremes, may distract the attention of university teachers from their essential tasks and expose them to attacks, which, in the interest of the authority and reputation of the higher schools of learning, is far from desirable and may impair the work of the liberal professions. The teachers in schools of higher learning should therefore be conservative and accept only such outside tasks as involve scientifically important questions and are in keeping with their position as teachers and investigators.

Undulant Fever in Germany

When, four years ago, an order was issued requiring cases of undulant fever to be notified throughout the German reich, an increase in the number of cases was expected. In spite of the fact that the examining centers in the past three years have

tested all blood specimens sent to them, for *Alcaligenes abortus* agglutination, the expected increase has not been observed. The number of notified cases has, in fact, decreased from 626 in 1929-1930 to 498 in 1931-1932. Of the patients notified, only one died (a man aged 63, whose heart apparently was previously seriously damaged by arteriosclerosis). No miscarriages in women or transmission from man to man were observed. The principal sources of the infection, as in the past, were doubtless contact with infected cattle or the use of raw milk.

The Munich Medical Foundation

Professor Friedrich von Müller, internist of Munich, has founded the Münchener Mediziner-Stiftung. The object of the foundation is to furnish aid to members of the faculty of medicine at Munich, when in distress; also to members of their families. The foundation will likewise promote scientific research.

Prof. Erich Leschke's Death

The death of Prof. Erich Leschke, June 10, at the age of 45, has been announced. After studying physiology under Pflüger in Bonn, Leschke served as assistant to F. Kraus at the second clinic of internal medicine at the Berlin Charité Hospital. In his research, he devoted himself chiefly to disorders of the vegetative nervous system, and to problems pertaining to internal secretion and diseases of metabolism.

ITALY

(From Our Regular Correspondent)

May 30, 1933.

Meeting of Pediatricians

The Società italiana di pediatria, chapter of Venezia Euganea, met at Padua under the chairmanship of Professor Allaria, on the fiftieth anniversary of the creation of the chair of pediatrics in Padua, which was the first to be established in Italy.

Baccichetti of Treviso analyzed the 506 cases of laryngeal diphtheria admitted to the hospital from 1927 to 1932. In the 446 cases of intubation, not one was dismissed with chronic laryngeal stenosis secondary to intubation. The tube remained in the larynx in some cases more than a month; nevertheless, in no case was a cicatrix observable. Short tubes that were easy to remove were employed. No recourse was had to secondary tracheotomy, the operator preferring, if necessary, to increase gradually the caliber of the tube. Of the 446 patients in whom intubation was performed (thirty-six of whom were under 1 year of age), twenty-eight died.

Professor Brunetti brought out that otorhinolaryngologists, on the whole, look with disfavor on intubation. Professor Frontali stated that the number of children subjected to intubation who become invalids is very small, although the laryngologists raise that objection. He recommended early intubation in all cases of laryngeal stenosis, even though of moderate type.

Orefice of Vicenza reported on an epidemic of acute anterior poliomyelitis in the province of Vicenza. The twelve children attacked were nearly all under 2 years of age. In three cases the disease was rapidly fatal, following the development of the Landry type of acute ascending paralysis. The milder cases improve either through natural retrogression or with the aid of medullary roentgenotherapy—especially if applied early. Professor Frontali said that the disease is endemic in the province of Padua. He had the impression that the course of the disease is not much influenced by the use of the Pettit serum, which, as purchased on the market, is derived from horses. Professor Allaria admitted that he also had not secured encouraging results with the commercial Pettit serum.

Careddu of Padua reported 158 cases of acute pulmonary disorders in children admitted during the past two years to the Clinica pediatrica of Padua, of which 116 cases were bronchopulmonary and forty-two were lobar pneumonia. In

the bronchopulmonary types, convulsions or meningeal disorders occurred in 2.5 per cent of the cases. Among the cases of lobar pneumonia, however, 21.5 per cent showed marked nervous phenomena, as revealed by hyperexcitation, meningeal signs and convulsions.

Professor Frontali discussed congenital stenosis of the pylorus. He said that the disorder occurs more frequently in Italy than the statistics indicate. A precise diagnosis is necessary in children who habitually vomit to discover those in which vomiting is due to an anatomic obstacle rather than to a spastic disorder. In such cases, the Werner-Ramstedt intervention is indicated.

Delitala of Venice explained the early surgical treatment of such deformities as spina bifida, stenosis of the pylorus, anal imperfections and megacolon. There is much discussion as to the best time for intervention in other deformities—whether during or after the period of lactation or years later. During the first twenty-four hours after birth, the resistance of the new-born is greatest, and all plastic operations give better results, the sooner they are performed after birth.

A discussion arose on infantile scurvy, in which Bombassei, Orefice and Frontali participated. Infantile scurvy may occur also in breast-fed children if the mother has a defective diet; for instance, if she lives chiefly on maize pudding. The cases are numerous if, in addition to the frank cases, those are included which show the changes in capillary fragility that precede the true scorbutic lesions.

Trachoma

Dr. Parisotti, who presented a paper on trachoma before the Academy of Medicine in Rome, observed years ago an epidemic of acute conjunctivitis in children. At the end of the acute stage, in seven persons who had been free from the disease, trachoma developed. The author conceived the idea that a trachomatous person does not transmit trachoma but conjunctivitis, which is its substratum, and that trachoma is the result of conjunctivitis with a constitutional base. Trachoma, in other words, develops in persons of weak organic structure, often with manifestations of adenoidism. The histopathology of trachoma serves to strengthen the conception of the author, whereas the bacteriologic researches, begun in 1880, have today only reached a point of which Nicolle could say, in 1930, that the research on trachoma has scarcely started.

BELGIUM

(From Our Regular Correspondent)

June 20, 1933.

Bronchiectasis

The Société belge d'études scientifiques sur la tuberculose took up recently the subject of the pathology and treatment of bronchiectasis. Drs. Derscheid and Toussaint attempted a classification of these disorders. To class 1 they assign acute bronchiectasis, involving often a whole lobe, more commonly the left inferior lobe. In addition to medical treatment, including the thirst treatment, the postural treatment, the use of spirillicides, emetine, methenamine, colloidal metals, colloidal sulphur, balsamics and injections of alcohol, they recommend early bronchoscopy, artificial pneumothorax and surgical methods of exeresis. Class 2 includes chronic infected bronchiectasis with infectious paroxysms, amenable to active bronchoscopic cleansing with antiseptics to reduce the bronchorrhea; then phrenectomy or pneumothorax, combined, during the first months, with instillations by means of a sound at increasingly prolonged intervals, and possibly exeresis. Class 3 comprises noninfected dry bronchiectasis, in which, aside from a possible specific therapeutics, the treatment is to prevent infection. Class 4 groups the types of clinically benign bronchiectasis, dry or secreting (persons affected by war gases or tuberculous

persons). In addition to the etiologic treatment of the causal disorder (gout, diabetes, renal or hepatic deficiency), the authors recommend climatotherapy, arsenical and sulphurous crenotherapy, balsamics and colloidal sulphur.

Report on Ancylostomiasis

The mission organized for the study of ancylostomiasis has published a report. The feces were examined by a modification of the Stoll technic. Ancylostoma was found in 71 per cent of the 2,653 stools examined. The blood in the feces was examined by means of the amidopyrine test. Blood is always present when there are more than 3,000 ova per gram of fecal matter. An antigen can be secured by drying and pulverizing the worms. Fixation of complement is obtained in 78 per cent of the cases in subjects who present 1,000 ova per gram and in about 90 per cent of the cases in those who present more than 1,000 ova.

The chief physician of the colony made an investigation at Mayumbe, in the western part of the Belgian Congo region, to determine whether helminthiasis, and particularly ancylostomiasis, increased the mortality among the inhabitants. The infection is more prevalent in the plains than in the mountain regions, and the effects are more pernicious.

Medical Aid for African Natives

The report on the first activities of the Queen Elizabeth Fund for the promotion of medical aid for the natives of the Belgian Congo has appeared. This report covers a period of fourteen months, and already the results of this benevolent organization are manifest. On several occasions—notably at the colonial congresses of 1920 and 1926—the king declared that it was necessary to give health matters first place in planning work in the colonies. In 1928 the journey of the king through the colony strengthened this opinion and induced the government to intensify its work against diseases that threatened the existence of the native black population. Two years later, parliament voted an appropriation of 50,000,000 francs, to which was added 100,000,000 francs to complete the extraordinary budget of the colony for the year 1930. It was then possible to consider the creation of a special fund for medical aid to the natives and to grant the administrator of the fund power to enable him to adapt his activities to the circumstances and to use his financial resources without being hampered by restrictions affecting the budget as a whole. The plan of the administration included work to reduce the mortality and morbidity in children and in adults, and the protection of pregnant women. The physicians serving the Queen Elizabeth Fund centered their efforts more on social and prophylactic medicine for combating epidemics than on curative medicine. Philanthropic and social societies, special villages for leprosy patients, dispensaries, maternities, prenatal consultation centers, and consultation centers for nursing mothers were some of the fields the development of which devolved on the personnel. Of 384,799 natives in the villages, 327,679 were visited by the physicians. It is especially pleasing to note the efforts made to protect the race, from the onset of maternity to the birth of the child. In the Lower Congo, the consultation centers for nursing mothers are making constant progress. Furthermore, the native women are presenting themselves more and more at the prenatal consultation centers. In the rural regions about Kangu, a maternity has been annexed to the hospital. Nurseries have been created to care for young orphan children.

The fund assists in the hygiene of the villages, for their relocation and regrouping, for the renewal of trails, for the upkeep of the main caravan roads, for fishing places, and for the construction of camping places. It provides also free medicaments in regions where economic conditions are bad.

The rôle of a sanitary unit of the Queen Elizabeth Fund consists in raising the standards of health among the natives

and in aiding the native communities. Its medical aid is based on a rapid organization, and after the introduction of general health measures in a given district the maintenance of the acquired agencies is left to the regular health service in the colony.

RIO DE JANEIRO

(From Our Regular Correspondent)

June 15, 1933.

Lymphogranulomatosis

Dr. Clovis Corrêa reports in the *Revista de gynecologia e de obstetricia*, May, 1932, observations on twenty-five cases of chronic hypertrophic ulcer of the vulva, which was usually found on the labia. The anorectal region was frequently affected, always resulting in stricture of the rectum. The ulcers had punched-out, undermined borders and an irregular bottom. Often there were long fistulous tracts, edema and infiltration of the labia majora resembling elephantiasis. The anal sphincter may be destroyed. The etiology is much discussed. Race does not seem to be important. Among thirty-three patients Corrêa has found sixteen white, eleven mulatto and six Negro women. He questions whether his cases were not a form of lymphogranulomatosis. Histopathologic examination has revealed elements similar to those of the primary lesion of Nicolas-Favre disease. Frei's reaction by intradermic injection of diluted pus of the bubo of lymphogranulomatosis was positive. The initial venereal chancre must have passed unnoticed. It may be admitted that lymphogranulomatosis is connected with the appearance of chronic anorectovulvar ulcer.

With sodium iodide intravenously Corrêa obtained at least a great improvement. He recommends this medication, associated with the use of the thermocautery.

Alcoholism and the Endocrine Glands

In its April, 1932, issue, the *Jornal dos clinicos* of Rio de Janeiro publishes a paper by Dr. J. Moreira Fonseca in which the author reviews the literature on the action of alcohol on the endocrine glands and his own research on the suprarenals in the cirrhosis of Laënnec. Acute alcoholism stimulates the thyroid to the point of producing exophthalmic goiter, and chronic alcoholism diminishes hypothyroidism (Pende). It produces hypofunction of the hypophysis (Schmiergeld) and deficiency of the suprarenals during grave infections (Giovinì) as well as in cirrhosis. Steatosis of alcoholic origin plays a part in the reaction of the endocrine glands, the histology of which is much disturbed, particularly the testes. The descendants of alcoholic individuals, on account of the diminished functional activity of the glands of internal secretion, suffer from infantilism, myxedema, and so on. Alcoholism is consequently a real cause of endocrine disturbances.

Hypervitaminosis D

Dr. Helion Povoá published a study of hypervitaminosis D in the April, 1932, issue of the *Archivos de medicina* of Rio de Janeiro. The toxic action of vitamin D used in large doses causes a loss of appetite, drop of temperature and weight and progressive diarrhea, followed by cachexia. The animal does not take food or drink and goes into coma; the respiratory movements and the pulse become imperceptible and later stop. Nearly all animals are sensitive to large doses of viosterol, but the macacus is very resistant. The intoxication is characterized by (1) disturbances of the metabolism of fats, especially pronounced in the kidneys; (2) disturbances of the calcium metabolism characterized by calcareous deposits; calcification frequently attacks the middle tunic of the blood vessels, creating an aspect similar to human arteriosclerosis. The pathogenesis of these disturbances has given rise to many discussions. It would, indeed, be strange if a substance as active as vitamin D, which is active in a dose of a fraction of a milligram, did not produce toxic symptoms with high doses.

Marriages

SAMUEL J. McDONALD, JR., Sumter, S. C., to Miss Natalie C. Frederick of Columbia, at Lexington, June 12.

KENNETH NEWTON GOULD, Pine Mountain, Ky., to Miss Elizabeth Barrett of Berea, June 8.

HAMILTON SOUTHWORTH to Miss Katharine Robertson Jones, both of New York, June 30.

LOUIS JOSEPH HALPERN, Chicago, to Miss Gertrude Jenne Epstein of Danville, Ill., June 10.

WALTER H. GILSDORF, New England, N. D., to Miss Esther Anderson of Dickinson, recently.

FRANK CHARLES MORGENROTH to Miss Katherine Rogers, both of Milwaukee, June 17.

JOHN B. JAMES, Page, N. D., to Miss Gena Johnson of Fargo, recently.

VITO J. MEROLA to Miss Madeleine Galardi, both of New York, June 29.

CHARLES S. NOONAN, Cincinnati, to Miss Frances T. Wise, June 20.

LLOYD FRICK KAISER, St. Louis, to Miss Hattie May Jury, June 19.

Deaths

Frederick Henry Baetjer, a pioneer investigator in the therapeutic use of the roentgen ray, and a martyr to research in this field, died, July 17, at his home in Baltimore. In his work, Dr. Baetjer suffered injuries of his hands and eyes which necessitated many operations. He was born in Baltimore, Aug. 7, 1874, studied in the public schools in Winchester, Va., in the Shenandoah Valley Academy, and received his A.B. degree in 1897 and his M.D. in 1901 from Johns Hopkins University, serving his internship at the Johns Hopkins Hospital. The following year he took postgraduate work at the University of Berlin and later became successively assistant and associate in surgery in charge of actinography, associate professor of clinical roentgenology and professor of roentgenology, Johns Hopkins University School of Medicine. He was a member of the Medical and Chirurgical Faculty of Maryland and the American College of Radiology; in 1908, was a delegate to the International Roentgen Ray Congress at Amsterdam, and was a member and, in 1911, president of the American Roentgen Ray Society. Dr. Baetjer was a major in the M. C., U. S. Army, 1917-1919. He was roentgenologist to the Johns Hopkins Hospital and consulting roentgenologist to the Union Memorial and Sinai hospitals, Church Home and Infirmary, Children's Hospital School, and Hospital for Women of Maryland, and was the author of "Injuries and Diseases of Bones and Joints" and co-editor of the "United States Army X-Ray Manual."

Edwin McGinnis * Chicago; Northwestern University Medical School, Chicago, 1904; assistant clinical professor of laryngology and otology, Rush Medical College; secretary of the American Bronchoscopic Society; member of the American Academy of Ophthalmology and Oto-Laryngology, the American Laryngological Association and the American Laryngological, Rhinological and Otological Society; fellow of the American College of Surgeons; on the staffs of the Chicago Municipal Tuberculosis Sanitarium, Presbyterian Hospital and the Children's Memorial Hospital, the Veterans' Administration Hospital, Hines, and St. Francis' Hospital, Blue Island, Ill.; aged 55; died, July 1, of angina pectoris, in Muskegon, Mich.

Harry Walter Mitchell * Warren, Pa.; University of Vermont College of Medicine, Burlington, 1896; member of the Massachusetts Medical Society, the American Neurological Association, the New England Society of Psychiatry, the Association for Research in Nervous and Mental Diseases and the American Psychopathological Association; member, past president, vice president and secretary-treasurer of the American Psychiatric Association; aged 65; superintendent of the Eastern Maine Insane Hospital, Bangor, 1907-1910, the Danvers (Mass.) State Hospital, 1910-1912, and the Warren State Hospital, 1912-1933, where he died, June 13, of chronic interstitial nephritis.

Willis Fred Harvey, Rushville, Ill.; College of Physicians and Surgeons, Keokuk, Iowa, 1897; member of the Illinois State Medical Society; past president and secretary of the Schuyler County Medical Society; served during the World

War; formerly county coroner; aged 63; died, June 18, of chronic myocarditis.

Carl G. Swenson, Chicago; Rush Medical College, Chicago, 1891; an affiliate Fellow of the American Medical Association; associate professor of (extramural) surgery, Northwestern University Medical School; fellow of the American College of Surgeons; veteran of the Spanish-American War; on the staff of the Passavant Memorial Hospital; aged 77; died, July 8, of pneumonia.

Emil Regard, Mansura, La.; Tulane University of Louisiana Medical Department, New Orleans, 1894; member of the Louisiana State Medical Society; formerly bank president; aged 61; died, June 3, at the Baptist Hospital, Alexandria, of acute dilatation of the heart following an operation on the gallbladder.

Clyde Ray Stingily Meridian, Miss.; Vanderbilt University School of Medicine, Nashville, Tenn., 1901; member of the Mississippi State Medical Association; at one time bacteriologist to the state board of health; formerly on the staff of the Jackson (Miss.) Infirmary; aged 53; died, June 24, of heart disease.

Andrew Joseph Keenan, Philadelphia; Jefferson Medical College of Philadelphia, 1912; member of the Medical Society of the State of Pennsylvania; instructor in laryngology at his alma mater; served during the World War; aged 46, died, June 15, of carcinoma of the lung with metastasis to the brain.

Edward Le Motte Eustice, Kewanee, Ill.; Chicago College of Medicine and Surgery, 1916; member of the Illinois State Medical Society; aged 51; on the staffs of the Kewanee Public Hospital and St. Francis' Hospital, where he died, June 25, of peritonitis, following an operation for appendicitis.

Eugene Patrick Sullivan, Morrison, Ill.; Rush Medical College, Chicago, 1899; member of the Illinois State Medical Society; served during the World War; aged 59; died, June 28, in the Jackson Park Hospital, Chicago, of pneumonia, as the result of injuries received in a fall.

Thomas Murphy Jordan, Raleigh, N. C.; College of Physicians and Surgeons, Baltimore, 1881; member of the Medical Society of the State of North Carolina; formerly on the staff of the State Hospital; aged 76; died, June 29, of heart disease, at Fayetteville.

Pierre Leonce Thibaut * New Orleans; Tulane University of Louisiana Medical Department, New Orleans, 1900; veteran of the Spanish-American War; president of the medical staff of the Hotel Dieu Hospital; aged 57; died, June 14, of heart disease.

James McKeon, St. Paul; Bellevue Hospital Medical College, New York, 1889; Minneapolis College of Physicians and Surgeons, 1890; member of the Minnesota State Medical Association; aged 71; died, June 28, of heart disease, at Montgomery, Minn.

Burton Peter Thom * New York; Baltimore Medical College, 1897; consulting physician to hospitals of the department of correction in New York; author of "Syphilis," "Hygeia, or Disease and Evolution" and "Dust to Life"; aged 58; died, May 3.

George Alexander Graham, Kansas City, Mo.; McGill University Faculty of Medicine, Montreal, Que., Canada, 1884; member of the Missouri State Medical Association; aged 73; died, March 23, of diabetes mellitus and arteriosclerosis.

Irby B. May * Columbia, La.; University of the South Medical Department, Sewanee, Tenn., 1906; health officer of Caldwell Parish; died, June 21, in St. Francis Sanitarium, Monroe, of injuries received in an automobile accident.

Lloyd Russell Carson, Bradford, Pa.; Kansas City (Mo.) Medical College, 1905; member of the Medical Society of the State of Pennsylvania; aged 54; was found dead, July 5, in a hotel room at Hiawatha, Ont., of heart disease.

Francis H. Brobst, Reading, Pa.; Jefferson Medical College of Philadelphia, 1888; Hahnemann Medical College and Hospital of Philadelphia, 1889; aged 67; died, June 16, of arteriosclerosis and cerebral hemorrhage.

Louis Rollin Head, Madison, Wis.; Rush Medical College, Chicago, 1885; member of the State Medical Society of Wisconsin; medical director of the Morningside Sanatorium; aged 73; died, June 27, of arteriosclerosis.

Henry L. Wenner * Tiffin, Ohio; Western Reserve University Medical Department, Cleveland, 1882; aged 71; on the staff of the Mercy Hospital, where he died, June 26, as the result of an automobile accident.

William Anderson Lyman, Burlington, Vt.; University of Vermont College of Medicine, Burlington, 1894; member of the Vermont State Medical Society; aged 73; died, April 10, of carcinoma of the gallbladder.

Frederick Augustus Davis, Denver; Harvard University Medical School, Boston, 1891; aged 60; died, March 27, in the Presbyterian Hospital, of obstruction of the bowel, pneumonia and myocarditis.

Alfred Roncovieri, Jr. ☉ San Francisco; University of Pennsylvania School of Medicine, Philadelphia, 1911; aged 46; died, May 16, of coronary sclerosis with infarction and myocarditis.

John Storer, Los Angeles; Hahnemann Medical College and Hospital, Chicago, 1889; aged 64; died, May 9, in the Los Angeles County General Hospital, of acute appendicitis and peritonitis.

William Guthrie Wendell ☉ Marmarth, N. D.; University of Pennsylvania School of Medicine, Philadelphia, 1894; aged 73; died, June 1, in Miles City, Mont., of carcinoma of the liver.

William Oscar Lubken, Johnstown, Pa.; Medico-Chirurgical College of Philadelphia, 1901; member of the Medical Society of the State of Pennsylvania; aged 58; died, July 8.

J. Herbert Patten, Bar Harbor, Maine; New York University Medical College, 1886; member of the Maine Medical Association; aged 70; died, May 7, of cerebral hemorrhage.

Stephen Archibald Wilkinson, Chappleau, Ont., Canada; Queen's University Faculty of Medicine, Kingston, 1920; served during the World War; aged 46; died suddenly, May 15.

Emmanuel M. Jennings ☉ Menlo, Ga.; Chattanooga (Tenn.) Medical College, 1900; past president of the Chattooga County Medical Society; aged 64; died, June 17, of heart disease.

Corwin G. Warden, Berea, Ohio; University of Wooster Medical Department, Cleveland, 1878; formerly postmaster of Berea; aged 75; died, May 26, of cerebral hemorrhage.

Carl Keller, San Francisco; National University of Arts and Sciences Medical Department, St. Louis, 1912; aged 67; died, May 12, of arteriosclerosis and chronic myocarditis.

David Albert Beard, Tulsa, Okla.; Memphis (Tenn.) Hospital Medical College, 1901; formerly superintendent of public health; aged 56; died suddenly, June 27, of heart disease.

Clayton E. Fawcett, Aurora, Ill.; Hahnemann Medical College and Hospital, Chicago, 1905; aged 55; died, June 22, in the Copley Hospital, of acute myelogenous leukemia.

Fred Elmer Webster, Amherst, Wis.; Rush Medical College, Chicago, 1891; member of the State Medical Society of Wisconsin; aged 70; died, June 3, of diabetes mellitus.

John Cleveland Phillips, Portsmouth, Va.; Maryland Medical College, Baltimore, 1912; aged 48; died, June 9, in the King's Daughters' Hospital, of pneumonia.

William Wilberforce Claybaugh, Grand Junction, Colo.; Rush Medical College, Chicago, 1883; aged 76; died in June, of auricular fibrillation and Raynaud's disease.

William P. Alexander, Cleburne, Texas; Louisville (Ky.) Medical College, 1876; aged 80; died, June 20, of hypostatic pneumonia and carcinoma of the larynx.

William Leander Zuill, Pasadena, Calif.; University of Pennsylvania School of Medicine, Philadelphia, 1884; aged 78; died, May 31, of diabetes mellitus.

Elijah Jackson Thornberry, Columbus, N. M.; University of Louisville (Ky.) School of Medicine, 1898; aged 59; died, June 10, of septicaemia.

Emmette Edward Walker ☉ Pamplin, Va.; University College of Medicine, Richmond, 1900; aged 62; died, June 9, of diabetes mellitus.

Hearn M. Adkins, Bowen, W. Va.; American Eclectic Medical College, Cincinnati, 1892; aged 61; died in June, of cerebral hemorrhage.

Harry Converse, Carrollton, Ill.; Missouri Medical College, St. Louis, 1886; aged 68; died suddenly, June 23, of cerebral hemorrhage.

William Wallace Burckhalter, Tunica, La.; Southern Medical College, Atlanta, Ga., 1888; aged 70; died, June 14, of erysipelas.

Coatney R. Walters, Flat Rock, Ind.; Medical College of Indiana, Indianapolis, 1902; aged 54; died, June 20, of myocarditis.

William Edwin Kneale, Akron, Ohio; Cleveland Homeopathic Medical College, 1902; aged 57; died, June 21, of heart disease.

William E. Truesdell, Alexander, Ky.; Medical College of Ohio, Cincinnati, 1895; aged 64; died, May 26, of carcinoma.

Bureau of Investigation

THE NICOTINE CONTENT OF TOBACCO

A Re-Publication of Some Interesting Figures

During the past few months the Bureau of Investigation has received an increasingly large number of inquiries from physicians regarding the nicotine content of various tobacco products, with particular reference to some of those on the market that are sold under the claim that they have had most of the nicotine removed. The American Medical Association's Chemical Laboratory has done no work on this problem, but this department of THE JOURNAL did publish in the issues of August 25, 1928, and September 21, 1929, respectively, rather full abstracts of some work done by the Connecticut Agricultural Experiment Station on the subject. This material appeared originally in *Bulletin 295* and *Bulletin 307*, respectively, issued by the Connecticut Agricultural Experiment Station. The following figures were given in the later (1929) report of the Connecticut chemists. Most of the various brands examined, both processed and ordinary, are arranged in the order of the total nicotine percentage (air-dry basis) given in the report:

PIPE TOBACCO

| (Ordinary) | | (So-Called Denicotinized) | |
|------------------------------|------|---------------------------|------|
| Blue Boar | 1.45 | O-Nie-O | 0.97 |
| Lucky Strike Plug | 1.76 | Carl Henry | 0.98 |
| Prince Albert | 1.82 | Sackett | 0.98 |
| Old English Curve Cut | 1.94 | Dormy (Cestrada) | 2.26 |
| Hudson's Bay Imp. Mixt. | 1.95 | | |
| Gilbert's Mixture | 2.09 | | |
| Tuxedo | 2.22 | | |
| Craven Mixture | 2.84 | | |

CIGARS

| (Ordinary) | | (So-Called Denicotinized) | |
|------------------------------|------|---------------------------|------|
| King Perfectos | 0.91 | Sackett | 0.67 |
| Reyes de Espana | 1.16 | Carl Henry | 0.74 |
| Partagas, Habana | 1.38 | Sano | 0.87 |
| Knickerbocker (Osterweis) .. | 1.76 | Girard | 1.54 |
| Judges Cave | 1.80 | | |

CIGARET'S

| (Ordinary) | | (So-Called Denicotinized) | |
|------------------------------|------|------------------------------|------|
| Condax | 1.06 | Sano | 0.79 |
| Makaroff | 1.21 | Lord Nestor | 0.92 |

Whether these figures represent the total nicotine percentage of the same brands today is not apparent. The probabilities are, however, that there is no wide difference. In this connection, it is to be remembered that there are various factors to be taken into consideration when discussing tobacco and tobacco products as a health problem. One of the most exhaustive and thorough investigations of the subject was that made by the late Dr. W. E. Dixon of the Pharmacological Laboratory at Cambridge, England. It was published in the *British Medical Journal*, October 22, 1927. There were many interesting facts brought out by Dr. Dixon in his article. One was that nicotine, which is usually looked upon as the *bête noire* of the smoker, is by no means the only constituent of the tobacco that is harmful, although it is probably the most important; but

there are, for instance, ammonia gas, pyridine or pyridine derivatives, and carbon monoxide.

Another thing that was brought out in the article was that the amount of nicotine in tobacco is not necessarily any criterion of the amount of nicotine the smoker will get. When tobacco is smoked, part of the nicotine is burnt and a part passes in smoke as free nicotine. The drier the tobacco, the greater the destruction of the nicotine. Dr. Dixon was strongly of the opinion that moist tobacco produces much more serious effects than dry tobacco, the water content of the tobacco, in his opinion, being more harmful to the smoker than the original nicotine.

The amount of nicotine and other volatile substances that reach the smoker also depend on the form in which the tobacco is smoked. A cigaret or slender cigar which is well cooled will yield less nicotine and other volatile substances than a thick cigar. Dr. Dixon pointed out that while Virginia tobacco leaf, from which cigarets are made, often contains twice the amount of nicotine that is present in a Manila cigar, yet when equal weights of cigarets and cigars are smoked, the total cigar smoke contains double the amount of nicotine present in the cigaret smoke. It was also emphasized that in pipe smoking the amount of volatile products, including nicotine, that reached the smoker depends to no small extent on the construction of the pipe. In the long clay pipes of the old "church-warden" type, there is great opportunity for the nicotine to condense, so that the smoke, when it reaches the smoker, may be almost free from that substance.

OYLOFF DRY SHAMPOO

The Commercial Possibilities of Salt Water

Inquiries have been received asking for information on the composition of a preparation known as "Oyloff Dry Shampoo," put out by the Godefroy Manufacturing Company of St. Louis. In an advertisement published in the *Woman's Home Companion* for January, 1933, these claims are made for Oyloff:

"Amazing new liquid makes shampooing quick, easy, right at your dressing table."

"Here is what you have always wanted—a thrilling new way to shampoo your hair in 15 minutes without washing out your wave."

"It's amazing how Oyloff Dry Shampoo removes all oil and dirt, cleans the scalp and reveals the silky luster, beauty and romance of your hair."

"Just apply Oyloff, let it dry, then brush thoroughly. You can see the oil and dirt come tumbling out."

"Try it once and you'll thrill over it, too."

A bottle of Oyloff was purchased on the open market and \$1.05 had to be paid for it. It came in a most modernistic container, characteristic of the present high-hat tendency in the cosmetic trade. The bottle was turned over to the A. M. A. Chemical Laboratory with the request that it be analyzed. The chemists' report follows:

LABORATORY REPORT

"One original bottle of Oyloff (Godefroy's Manufacturing Company, St. Louis, U. S. A.) was submitted to the A. M. A. Chemical Laboratory for examination. The bottle contained 168 cc. (5 fluid ounces) of a light amber-colored liquid, possessing a slight aromatic odor, suggestive of a perfume. The reaction of the mixture to litmus was slightly alkaline.

"Qualitative tests indicated the presence of sodium and chloride. No heavy metals, carbonates, sulphates, alkaloids and soap were found. The specific gravity at 25 C. was found to be 1.148. The residue on evaporation was 20.16 per cent, consisting essentially of a slightly colored crystalline solid with a distinct odor of burnt sugar (caramel).

"From the foregoing tests, it was concluded that Oyloff is essentially a colored aqueous solution of dairy salt (commercial table salt), with a dash of perfume."

From the chemists' report we learn that this "amazing" product that reveals the "romance of your hair" and that will "thrill" you is, essentially, a pinch of salt in five ounces of water—incidentally, the bottle states "net contents, 6 ounces." Paying \$1.05 for five ounces of salt water would seem, under present economic conditions, to furnish a text for a discussion on certain phases of modern business.

Correspondence

RUSSIAN EXPERIENCES WITH LEGALIZED ABORTION

To the Editor:—My attention has been drawn to an editorial in *THE JOURNAL*, February 4, regarding "Russian experiences with legalized abortion as reflected in the first All-Ukrainian Congress of Gynecologists and Obstetricians, meeting in Kiev in May, 1927. May I draw your attention to an article contributed by Dr. J. Leunbach of Copenhagen to the *Saertryk af Ugeskrift for Læger*, 1933, number 13, page 391. He states that only 25 per cent of 6,000 cases of abortion in Kiev were really legal, while 75 per cent were induced outside the hospitals. The material dates from the first five or six years after the legalization of abortion in Russia. The number of women who desired to have their pregnancy interrupted was much greater than the number of beds available in the hospitals. It was therefore necessary to refuse admittance to the majority of the women who applied for a bed. The women who were so refused, as well as those who shrank from presenting themselves to the "commissioners of abortion," had the operation undertaken at home or by a quack and were brought to the hospitals bleeding and suffering from the consequences of infection. As in Russia the women themselves cannot be punished for abortion, they are not afraid of entering a hospital and need not try to conceal the fact that the abortion was provoked artificially.

As Kiev is a city which is comparatively well supplied with hospitals, it is probable that the proportion of interruptions of pregnancy outside hospitals is far higher in the country districts than in Kiev itself. Therefore the great majority of the 423,000 cases that were presented to the congress in May, 1927, were not regular legal abortions but abortions of the same kind as those that are so well known to the hospitals in all other countries. Thus the unfavorable results brought forward throw no light on the danger or absence of danger of legalized abortion carried out by competent surgeons in proper hospitals.

The following information is given by Dr. Madjuginsky, the director of one of the largest abortion clinics in the Soviet Union, who carried out about 30,000 abortions during the year 1930: In the abortion clinics in Moscow, 90,000 abortions were undertaken in 1930, and 140,000 in the two years preceding. There was one casualty for each 20,000 cases. Perforation of the uterus occurred in 0.04 per cent of the cases, but practically never with a fatal issue. Elevation of temperature, mostly slight and transitory, occurred in about 2.3 per cent of the cases. Madjuginsky maintains that psychic disturbances and sterility in consequence of legalized abortion are extremely rare.

The number of abortions was growing continually until 1930-1931, but it is now stationary and only 10 per cent of the treatments are entirely gratuitous. Thus the Russians appear to have abandoned the original principle according to which legal abortion was undertaken only in free beds in hospitals. The right to have an abortion undertaken is now limited only by the conditions that at least six months must have passed since the last abortion and that a thorough medical examination fails to reveal any circumstances that make an abortion inadvisable.

Illegal abortion is now practically nonexistent in the larger cities, where physicians and clinics are sufficiently numerous. But conditions are still far less satisfactory in the country and in out-of-the-way parts of the Soviet Union where there is a shortage of physicians.

Legal abortion is made available in order to suppress illegal abortion. But even legal abortion is not favored, and endeavors are made to prevent its necessity by propagation of contracep-

tive knowledge. On the wall of the waiting room in Dr. Madjuginsky's clinic there are placards with such inscriptions as the following:

"This abortion ought to be the last."

"An undesired pregnancy should be prevented rather than interrupted."

"When you know how to prevent pregnancy, abortion will be unnecessary."

At the congress in Kiev it was emphasized that contraception is the best prophylactic against abortion.

Finally, the well known book of Dr. Krassilnikian is largely based on the data of the congress in Kiev, but this author is a Russian emigrant who has not visited Russia since abortion was made legal.

I think you will agree that the foregoing facts, as presented by Dr. Leunbach, definitely challenge the views put forward by those who have used the reports of the Kiev congress to condemn the legalization of abortion.

NORMAN HAIRE, CH.M., M.B., London, England.

Co-President, World League for Sexual Reform.

"CALCIUM NEED AND CALCIUM UTILIZATION"

To the Editor:—In THE JOURNAL, April 1, Bernheim makes out a rather sad case for the average American diet with respect to calcium. Without trying to detract from proved clinical uses of calcium, I would say that conclusions based on the realms of probability are questionable. Thus, specifically quoting Sherman, she states that "probably a larger proportion of the ordinary dietaries, both of adults and of children, can be improved by enrichment in calcium than in any other one chemical element" and, further, "he believes that a number of weaknesses and increased susceptibilities to infection may be the results of calcium deficiency," although in his original article Sherman says "probably plays a part in a number of weaknesses and increased susceptibilities to infection without being exclusively responsible for any one of them."

The size of the rôle calcium plays in the difficultly appraised human equations of "passable" and "buoyant" health is considerably weakened when it is stated that "a sustaining diet enriched by the addition of calcium and vitamins makes for the difference between 'passable' and 'buoyant' health."

Regarding longevity, Sherman (THE JOURNAL, Nov. 14, 1931, p. 1426) divides the responsibility again: "Vitamin G also appears to contribute to the betterment of longevity induced by Sherman and Campbell through improvement of an already adequate diet." Yet Bernheim gives a rather strong implication that calcium is the chief factor.

An inadequate calcium diet in the histories of 3,998 patients out of 4,000 questioned seems to be at a marked variance with the observations of Sherman and his co-workers in 1910 and 1918. They found the mean of American diets to contain 0.85 Gm. of calcium oxide (quoted from Sollmann's Manual Pharmacology, ed. 3, who in addition states that ordinary diets contain from 0.3 to 4.2 Gm.). Peters and Van Slyke, Sajous and Hundley, and the New and Nonofficial Remedies of 1933 support the contention that "under ordinary conditions the food supplies the body with enough of the salts of calcium to satisfy the needs of the tissues."

Keeping in mind that this discussion deals only with the adult, may it not be a fair question to ask, With a proper childhood diet, has there not been built up enough reserve of calcium to take care of the ordinary vacillating diets which at times may contain little calcium?

The many conditions that have to do with the adequate and proper metabolism of calcium in the body speak more for a well rounded perspective of the American diet. Advertising today has swung the pendulum of calcium therapy to an arc that is

bewildering to a rationalization of its proper uses. Advocating uses of methods that are still in the realms of probabilities is too expensive for the public, especially when dealing with the difficult status quo of health.

CHARLES BARON, M.D., Covington, Ky.

[NOTE.—The letter of Dr. Baron was sent to Dr. Bernheim, who replies:]

To the Editor:—My purpose was to stress the fact that "the existence of optimum conditions in regard to calcium cannot be taken for granted, but that special effort is necessary to assure adequate supply and utilization of this element." There was no intention, as implied by the correspondent, to ascribe to calcium the chief rôle in the maintenance of health or in the prolongation of life.

Calcium, of course, is necessary to life, but so admittedly are numerous other elements and substances. Not one of these plays its rôle alone. True evaluation of function, so far as it is possible, comes only after study of the various factors, both separately and in their interrelationships. It is never a simple problem.

Dr. Baron's observation that "conclusions based on the realms of probability are questionable" is undeniably true. The conclusions in question, however, are based on acceptable evidence, despite the word "probably," twice used by Sherman in his comments on the rôle of calcium in the diet. These conclusions are that:

1. The average American dietary is poor in calcium content.
2. The calcium requirement is 1 Gm. of calcium oxide a day.
3. General health is improved and recovery from disease aided when the optimum calcium supply and utilization are assured.
4. Without milk or cheese in the diet, it is difficult to obtain the needed calcium through food alone.
5. Utilization of calcium is ineffectual, even with a sufficient calcium intake, unless the factors that control the absorption of calcium are also adequate.

Your correspondent is of the opinion that the average American dietary is not calcium poor. He cites Sherman's figure, from Sollmann's Manual of Pharmacology, which gives 0.85 Gm. of calcium oxide as the mean of American diets, but this is incorrect. Sherman himself states it to be 0.45 Gm. of calcium, or 0.63 Gm. of calcium oxide. The further statement that ordinary diets contain as much as 4.2 Gm. is surely erroneous, for even the highest calcium diet known, that of the Finns, contains no more than 2.5 Gm. a day. It is simple for any one to calculate the calcium content of the ordinary diet. In most instances it will be found to be not only deficient but markedly so, if 1 Gm. of calcium oxide is accepted as the desired amount. Sherman says "Both the published and the unpublished observations of my own laboratory . . . and McCollum's experiments seem to lead to an even higher estimate of the optimal calcium intake. While fully recognizing that the experimental evidence is in some respects conflicting and that there is still some divergence of opinion among investigators, one should, I think, conclude that after much study of vitamin D the importance of liberal calcium intake is more fully established than it has appeared to be at any previous time."

To the question of "the size of the rôle" played by calcium "in the difficultly appraised human equations of 'passable' and 'buoyant' health," my answer is that on the addition of calcium to diets adequate in everything but that element there is to be noted an improvement, often dramatic in character, and warranting the statement that a condition of passable health has been transformed into one of buoyancy. This, however, does not imply that calcium would be thus effectual without the other factors essential to an optimum state of health.

Comment is made that there is "marked variance" between the calcium-deficient diets of more than 4,000 patients in the New York Hospital and Sherman's standard for the ordinary

diet (incorrectly quoted as 0.85 Gm.). This comparison, irrespective of the figures, has scant validity, since Sherman's observations apply to the general population, and mine to sick people in the hospital.

The question is asked whether "with a proper childhood diet there has not been built up enough reserve of calcium to take care of the ordinary vacillating diets which at times may contain little calcium." Apparently with "a proper diet" there is built up a reserve of calcium (mostly in the bones), which seemingly well supplies the needed amount of calcium lacking, not merely "at times," but most of the time, in the "ordinary vacillating diets." This reserve may be drawn on for considerable periods of time—even for two to three decades in many cases—without obvious ill effects, but there is suggestive evidence that this reserve calcium is in reality a substitute form and different from that absorbed from the food. Actual proof that this is so awaits the development of a method for measuring the three forms of calcium in the blood. At any rate, in view of what holds elsewhere in the body economy, it is reasonable to assume that undesirable and even unsafe conditions may be created when there is too steady a call on reserve supplies or forces.

It is not quite clear what the correspondent means by his concluding contention: "advocating uses of methods that are still in the realms of probabilities is too expensive for the public, especially when dealing with the difficult status quo of health." Surely it cannot reasonably be claimed that a diet sufficient in milk and vitamins is an expensive recommendation to the public.

Finally, when the correspondent states that "advertising today has swung the pendulum of calcium therapy to an arc that is bewildering to a proper rationalization of its proper uses" he seems to imply that I have added fuel to the fire. I think, on the contrary, that my statement "scant attention, however, has been given to calcium therapy by means of diet, a method that yields surprisingly satisfactory results" lends no support to advertising.

ALICE R. BERNHEIM, M.D., New York.

DIAGNOSIS AND TREATMENT OF ADDISON'S DISEASE

To the Editor:—The recent article by myself and my co-workers on the "Diagnosis and Treatment of Addison's Disease," which appeared in THE JOURNAL, June 10, should have described in detail, and not merely by citation, the work of Dr. R. F. Loeb and his co-workers in New York, on the general influence of the suprarenal glands on sodium metabolism. The low concentration of sodium in the blood serum of patients during the crisis of Addison's disease was reported last year by Loeb in *Science* (76:420 [Nov. 4] 1932). Dr. Loeb subsequently observed a patient with Addison's disease who recovered rapidly from an acute crisis with sodium chloride therapy alone. The subsequent appearance of edema caused this patient to be given a salt-poor diet. She promptly showed symptoms of insufficiency, from which she was again relieved by the use of salt alone. A description of this case, together with studies of the characteristic changes in the plasma electrolyte structure, particularly sodium, appeared in Loeb's article in the *Proceedings of the Society for Experimental Biology and Medicine* (30:808 [March] 1933). That increased urinary loss of sodium occurs during the addisonian crisis is rendered highly probable from the demonstration by Loeb and his co-workers that such urinary losses follow suprarenalectomy in dogs (*J. Exper. Med.* 57:775 [May] 1933). Credit for the conception of sodium deficit in suprarenal insufficiency and in Addison's disease belongs solely to Dr. Loeb, who bases on it a theory that regulation of sodium metabolism is one important function of the suprarenal glands. Our studies on the

effect of salt withdrawal from patients, which were designed to test the value of this procedure as a diagnostic method, were made during the months of February and March 1933 and constitute a confirmation of Loeb's clinical study. No analyses for sodium were made by us either for diagnostic or for therapeutic reasons until after Dr. Loeb's studies were completed. I greatly regret that our paper failed to give proper distinction to this work, which I regard as one of the most important contributions to the solution of the problem of suprarenal cortical function that has yet been made.

GEORGE A. HARROP, M.D.

Johns Hopkins Hospital, Baltimore.

POLLEN TESTS IN MILWAUKEE AREA— DESENSITIZATION

To the Editor:—What pollens should be suspected as causative factors in hay fever occurring from August to frost in the region of Milwaukee? If sensitivity to one or several pollens is determined by dermal tests: (a) When is it best to desensitize? (b) How is desensitization done? (c) Does the patient remain desensitized or must desensitization be repeated every year?

BERNARD OVERHILL, M.D., Milwaukee.

ANSWER.—During the time mentioned, the pollen content of the air in Milwaukee, as revealed by pollen slides exposed by the United States Weather Bureau, is 98 per cent ragweed. Short ragweed is most common in Milwaukee, but along creeks and about the lakes west of the city there is plenty of giant ragweed. Possible but unlikely offenders during August and September in Milwaukee are pigweed (*Amaranthus retroflexus*), cocklebur (*Xanthium commune*), lamb's quarter (*Chenopodium album*), Russian thistle (*Salsola pestifer*) and annual sage (*Artemisia annua*). To be affected by these pollens, one would necessarily have to live immediately adjacent to large acreages of the plants or engage in some unusual occupation that would expose him to the pollens, as they are not found in toxic quantities in the upper air in the city.

(a) Desensitization may be begun at any time during June or July, preferably about July 1. This gives time to raise the tolerance to a safe level before the ragweed season.

(b) Tolerance to pollen is obtained by a graduated series of doses of extract of the pollen or pollens to which the patient is sensitive—in this case, short ragweed and giant ragweed. The initial doses must be very small, 10 pollen units or less. The rate of increase of the actual size of each subsequent dose depends on the reaction of the patient to the injections. The following is a typical schedule:

| | | | |
|-------------|-----------|--------------|-------------|
| Dose 1..... | 10 units | Dose 9..... | 1,000 units |
| Dose 2..... | 20 units | Dose 10..... | 1,500 units |
| Dose 3..... | 40 units | Dose 11..... | 2,000 units |
| Dose 4..... | 70 units | Dose 12..... | 3,000 units |
| Dose 5..... | 100 units | Dose 13..... | 4,000 units |
| Dose 6..... | 200 units | Dose 14..... | 5,000 units |
| Dose 7..... | 400 units | Dose 15..... | 5,000 units |
| Dose 8..... | 700 units | | |

The maximum dose is really the protective dose and it is most important that this should be administered just prior to the time of heaviest local atmospheric pollen contamination. Ragweed pollen incidence is usually heaviest in Milwaukee about September 1. The exact date varies according to weather conditions. Maximum pollen dosage should be given in your vicinity about August 25. Most allergists supplement this graduated series of doses with several doses during the season, in an effort to retain the tolerance. The coseasonal doses are sometimes as large as the maximum dose; at other times considerably less, depending on the reaction of the patient. Books to consult are:

Duke, W. W.: Allergy, Asthma, Hay Fever, Urticaria and Allied Manifestations of Reactions, St. Louis, C. V. Mosby Company, 1926.
Balyeat, R. M.: Allergic Diseases—Their Diagnosis and Treatment, Philadelphia, F. A. Davis Company, 1931.
Rackemann, F. M.: Clinical Allergy, New York, Macmillan Company, 1931.
Asthma and Hay Fever in Theory and Practice: Part 1, Hypersensitivity, Anaphylaxis, Allergy, by A. F. Coca; Part 2, Asthma, by Matthew Walzer; Part 3, Hay Fever, by A. A. Thommen; Springfield, Ill., Charles C. Thomas, 1931.

(c) Tolerance to pollen usually remains at a high level for only a short time. It is necessary to repeat the treatment each year unless it is thought best to sustain the tolerance throughout the year with doses conveniently spaced. The so-called perennial method of treatment is described by Vaughan (*THE JOURNAL*, July 11, 1931, p. 90).

EFFECTS OF CAMPHORATED OIL BY MOUTH

To the Editor:—What would be the effect of 2 ounces (60 cc.) of camphorated oil taken internally? Kindly omit name.

M.D., West Virginia.

ANSWER.—The probabilities are that emesis would occur, which might rid the patient of a considerable portion of the otherwise possibly fatal dose. Severe abdominal pain, flushing of the face, and a feeling of warmth all over the body, headache, dizziness, disturbance of vision, mental excitement, impulsive movements and anuria might be followed by delirium, epileptiform convulsions, coma, collapse with pallor of the surface, and death from paralysis of the respiratory center. If the patient recovers, strangury and albuminuria as well as persistent gastric disturbance might delay recovery for days or weeks.

"DIABESAN" ALIAS "FERMOGEN"

To the Editor:—Will you kindly send me whatever information you have available concerning the product "Fermogen" (literature enclosed), which is alleged to be an oral preparation for the relief of diabetes. Please omit name or initials.

M.D., New Jersey.

ANSWER.—As long ago as 1925 the Council published a report on "Diabesan," a preparation stated to contain "the trypsin of dead yeast cells" and claimed to be "indicated in all cases of diabetes and glycosuria." The evidence for the value of this dried yeast preparation appeared to consist solely of a paper written by one A. H. Werner, the president of the Solosan Company, which exploited "Diabesan." Werner has a long record in the files of the Bureau of Investigation of the American Medical Association as a "medical authority" of highly dubious antecedents and equipment. The Council found the claims for Diabesan to be unsupported by acceptable evidence and not in harmony with accepted facts and pointed out that there is no evidence that trypsin—or a preparation such as Diabesan, said to contain it—has any value in the treatment of diabetes.

In the advertising circular sent by our correspondent, the "directions" and many of the testimonial letters for "Fermogen" are word for word the same as those contained in an advertising circular for Diabesan, except that the name "Diabesan" is replaced by "Fermogen." Further, it is brought out that the president of the Sano Laboratories, Inc., which markets Fermogen, is none other than one A. H. Werner. The conclusion that "Fermogen" is only "Diabesan" under another name appears so obvious as to need no further comment.

BUERGER'S AND RAYNAUD'S DISEASES

To the Editor:—Please explain briefly the most important points in the differential diagnosis of Buerger's and Raynaud's disease. The works on surgery available to me are of but little help in the matter. What is considered now the best form of treatment for a mild case of Raynaud's disease? An operative procedure has been discussed with the patient by a surgeon to whom he was referred, but the patient, a mechanic, aged 33, does not look favorably toward any operative procedure. Is physical therapy of value in a mild or moderately advanced case of Raynaud's disease? Please omit name and address.

M.D., Virginia.

ANSWER.—Little difficulty is encountered in differentiating Raynaud's and Buerger's disease in their advanced stages. Only in the beginning should there be any difficulty. In the differential diagnosis of these two diseases the sex of the patient is of paramount importance, Raynaud's disease occurring almost exclusively in the female and Buerger's disease occurring almost exclusively in the male. The onset of Raynaud's disease occurs most frequently in the winter months and is characterized by pain or abnormal fatigue in the perineal anterior tibial muscles or the arch of the foot. The symptoms are usually first ascribed to either flatfoot or rheumatism. Somewhat later, intermittent claudication or muscular cramp is brought on by uninterrupted exercise. It is readily relieved by rest. Still later, pain may be present even at rest. Superficial phlebitis commonly precedes or accompanies the early stage of the disease. Rubor appears well on in the course of the disease, sloughing or gangrene in the end stage. Although red, the feet are cold and on elevation develop undue pallor.

The obliteration in thrombo-angiitis is organic in character, leading to decreased pulsation in the peripheral vessels, par-

ticularly the dorsalis pedis. Vasospasm or angiospasm of a functional nature is sometimes superimposed on this organic occlusion. It is frequent in Jews and in excessive smokers in a large proportion of cases. From the standpoint of treatment the condition is benefited by vascular postural exercises, control of walking, and the use of vaccines and of warmth. The success of surgical procedures depends on the extent of the functional element superimposed on organic occlusion, sympathetic ganglionectomy being the operation of choice.

Raynaud's disease is much more frequent in the hands than in the feet and is characterized by a peripheral cyanosis coming on with exposure to cold. Continued or extreme exposure leads to blanching or to rubor, the parts exhibiting the two or three color phase changes. Pulsation in the vessel is usually readily felt. Involvement tends to be symmetrical. The patient is usually well in warm weather. Attacks of severe pain are precipitated by cold. Gangrene is lacking except in the end stages.

In Raynaud's disease the angiospasm is chiefly functional in character, true organic occlusion being absent. Raynaud's disease gives little trouble in warm weather and when cold is avoided. Physical therapy, especially in the form of contrast baths, may prove helpful. Contrast baths consist of immersion of the part, hands or feet, in warm water, from 100 to 110 F., for thirty seconds; cold water, from 40 to 50 F., for fifteen seconds; hot water for fifteen seconds; cold water for fifteen seconds; hot water for thirty seconds. Raynaud's disease of the lower extremities can usually be cured by appropriate surgery, bilateral sympathetic ganglionectomy of the second, third and fourth lumbar sympathetics; and that of the upper extremities helped in the majority of cases by sympathetic ganglionectomy of the upper thoracic ganglions.

As the patient in question is a man, the odds are strongly in favor of thrombo-angiitis as the cause of his symptoms, particularly if the involvement is the most marked in the lower extremities.

TREATMENT OF SYPHILIS

To the Editor:—Four and one-half years ago, at the age of 28, a patient contracted a syphilitic infection which was not diagnosed until two months after joint pains and lymphadenitis began. The Wassermann reaction was four plus; there was no visible chancre. He began treatment at once but developed a severe neuritis of the extremities after the ninth dose of neoarsphenamine (0.9 Gm. each at five day intervals). One month later the Wassermann reaction was two plus. Fifteen doses of bismuth potassium tartrate (0.2 Gm.) were given intramuscularly and after a month's rest the blood and spinal fluid Wassermann reactions were negative. Since that time and mostly within the first two years he has received the following (total for all treatment received): neoarsphenamine, nine doses, 0.9 Gm. before the neuritis; mercuric cyanide, twenty-four doses intravenously; bismuth compounds, fifty-nine doses. The blood Wassermann reaction has been observed every six months and has always been reported negative. He has had no symptoms of syphilis since shortly after treatment was begun. The peripheral neuritis has cleared up, except for an occasional tingling of the toes. The knee jerks, which were lost with the onset of the neuritis, were sluggish until six or eight months ago, when they became normally active. Please advise me on the following points: 1. Is it safe, in the presence of a negative physical examination, negative blood Wassermann reactions and no symptoms, to wait for some indication before giving further treatment? 2. Do you think it safe to give this patient preparations containing arsenic? 3. Can he marry with a reasonable assurance that he will not become a burden to his family as a result of the infection? 4. If further treatment is indicated, please outline the course. Please omit name and address.

M.D., Texas.

ANSWER.—1. Considering the total amount and duration of the treatment which the patient has so far had, it is probably safe to wait for some indication before giving him further treatment. Before entering on a long rest period, however, the spinal fluid should be retested. If it is negative, treatment may be discontinued. The patient should be told that his future safety depends on his cooperation in periodic reexaminations. The blood Wassermann test should be made every six months and he should have a complete physical examination yearly, with particular emphasis on the cardiovascular and central nervous system. Treatment need not be resumed unless the patient develops lesions or a positive blood Wassermann reaction.

2. The use of further trivalent preparations of the arsphenamine group had better be avoided in view of the previous peripheral neuritis.

3. The question of marriage hinges on the patient's potential infectiousness for his marital partner, on the possibility of the birth of a syphilitic child, and on the possibility that he may become incapacitated or die as a result of his syphilitic infection at an earlier age than would otherwise be the case. The result

of potential infection to his marital partner is probably negligible in view of the duration of the patient's illness and the amount of his previous treatment. However, his fiancée should be told of the fact that he has had syphilis and instructed that, if she becomes pregnant, a blood Wassermann test should be made several times during the course of her pregnancy. There is an increased liability that any syphilitic patient, no matter how well treated, may become a burden to his family. The actual, as compared to the expected, mortality rate among well treated syphilitic patients, as compared with normal individuals, is as 150 to 100. This added liability should be explained to the fiancée, and the decision as to whether or not she cares to accept the risk should be left to her.

4. No further treatment is indicated unless there is evidence of relapse or progression. Its character cannot be outlined in advance of the potential relapse.

FLAT FEET

To the Editor:—As school physician I am anxious to examine the children entering school, for flat feet. Can you tell me whether there is an instrument that is used for this purpose which does not stain the child's feet and if so where it can be obtained? Some schools use a preparation of bluing or mercurochrome but both of these stain the feet and are messy to use.

P. RALPH McFEELY, M.D., Bogota, N. J.

ANSWER.—A method that is satisfactory is the use of a box with a glass top and a mirror inside, set at an angle so that, when the child stands on the glass and the examiner stands in front of the box, the imprint of the foot is reflected from the mirror to the examiner's eye.

Many years ago, Dr. A. H. Freiberg of Cincinnati recommended the use of ferric chloride painted on the foot and tannic acid painted on the recording paper. When the two chemicals meet, prussian blue is formed and a good record obtained.

More recently Miss Helen King of Detroit (*Am. J. Dis. Child.* 43:89 [Jan.] 1932) outlined a simple method consisting of a platform to stand on, after india ink had been painted on the child's foot. King devised a method of recording children's footprints in both the walking and the standing position. It consists in the use of Flak Finger Print ink and a board walk equipped with wrapping paper. All details of the sole of the foot and toes in the weight-bearing position are shown. Photographs of the strips measuring $3\frac{1}{2}$ by $4\frac{1}{2}$ inches are kept in a file as part of the record of the child's physical growth. Prints recorded in this manner at intervals of about six months show the growth and development of the foot, changes in gait, position, and the results of corrective exercises in cases of weak or pronated feet.

Inspection is not the only means of obtaining information but it is an important one. Direct inspection of the weight-bearing foot from the front, back and side affords much information.

FORMULA FOR CROWE'S MEDIUM

To the Editor:—Will you please send me the formula for Crowe's medium for growing streptococci in its treatment of chronic rheumatic diseases as found in his book "Bacteriology and Surgery of Chronic Arthritis and Rheumatism."

M.D., Chicago.

ANSWER.—The reference is Crowe, H. W.: Bacteriology and Surgery of Chronic Arthritis and Rheumatism, Oxford Medical Publications, 1927.

Bullock's blood must be obtained in as sterile a fashion as possible by being caught direct in a large sterile vessel. The blood is whipped until coagulation is complete, and 750 cc. is strained through fine muslin into a 2 liter flask. The flask is placed in a water bath and raised to a temperature of 50 C. Then 250 cc. of melted trypsin agar, 1.5 per cent, together with 10 Gm. of dextrose, is cooled to 50 C. and thoroughly mixed with the blood. The whole is then poured into sterile plates through a sterilized funnel and tubing. The plates are filled to a depth of at least a quarter of an inch. The lids of the plates contain a layer of blotting paper so that the moisture which collects from steaming may be absorbed. Since even when cooled the medium is not solid, the plates must be moved with extreme care. They are placed on shelves in an iron stand (incubator shelves will do). The stand can be bodily lifted in and out of a large steamer. The steamer has a conical lid of the Koch type, so that the water of condensation runs down the sides of the vessel instead of falling on to the plates. The preliminary heating must be done with great care. At the first, the temperature is raised to 60 C. and kept there for at least two hours in order that any air dissolved in the medium may be discharged. Otherwise bubbles will result. After two hours, the temperature is raised to 80 C. for another half hour. Then the next two or three days the temperature is raised again to between 80 and 90 C. for half an hour. It is important that the boiling point should not be reached or the medium will be ruined by bubbles. When sterilizing is complete, the plates are dried off in the incubator, wrapped in paper, and stored away in an air-tight box. The appearance of the finished medium must be dark chocolate color and very glossy.

VARIATIONS IN BLOOD PRESSURE OF ARMS AND LEGS

To the Editor:—I recently examined a man, aged 51, with a history of rheumatic fever at 9 years and knowledge of a heart lesion for the past fifteen years, a physician telling him of the condition. Physical examination revealed evidence of an aortic regurgitation. The blood pressure was: left arm, 132/70; left thigh, 168/74; right arm, 128/64; right thigh, 172/80. The point I am especially interested in is the cause for the difference in the pressure in the upper and lower extremities. I understand that the systolic pressure in aortic regurgitation is usually higher in the lower extremities, varying from 50 to 80 mm. (Hill and Holtzman). I do not have access to literature on this subject. Please omit name.

M.D., North Dakota.

ANSWER.—Hill, Flack and Holtzman (*Heart* 1:73, 1909) stated that normally there is an increase of several millimeters in systolic pressure in the legs over that in the arms, as the result of differences in hydrostatic pressure, and that in subjects suffering from aortic insufficiency the pressure taken in the recumbent position is from 20 to 95 mm. higher in the arteries of the leg than in the brachial artery. In febrile conditions or when the legs are immersed in hot water this difference is much less. Hill and Rowlands (*Heart* 3:218 [Feb. 8] 1912) and Rolleston (*Heart* 4:83 [Nov. 2] 1912) have verified this statement.

Mention of this fact is made by Vaquez (*Diseases of the Heart*, 1924, translated by George Lardlow) by George Hermann (*Oxford System of Medicine* 2, No. 2, p. 492 [52]) and by T. F. Reilly (*Tice: System of Medicine* 6:106). No real explanation is given for this except that the difference in pressure is due to differences in hydrostatic pressure.

FURUNCULOSIS OF AUDITORY CANAL

To the Editor:—A woman, aged 24, five weeks ago had pain in the left ear, so severe that she had been kept awake for four nights. On examination, I found the external meatal canal extremely tender on manipulation, reddened, and bulged in various portions. After twenty-four hours of expectant treatment, a competent aural specialist examined the ear and concurred in the diagnosis of furunculosis. The canal was incised under ethyl chloride general anesthesia, after which the patient experienced relief and was able to get some rest. Since then, she has been treated with almost daily packings of one of the following: creasatin solution, diluted Burrow's solution, or 10 per cent sulphated bitumen in glycerin. Only the first named seems to give her relief. Occasionally there is a small amount of pus on the removed packing. In addition, she has been given four injections of combined staphylococcus and streptococcus vaccine, and following this, several injections of a foreign protein (Activin). Several urinalyses, a blood Wassermann test and a blood sugar and nonprotein nitrogen test all give normal results. I have been unable, with the foregoing methods, to clear up the infection, the canal still appearing inflamed and the patient having occasional bouts of pain. Kindly inform me as to the outlook for early cure, and any further suggestions on the treatment. Please omit name and address.

M.D., New York.

ANSWER.—While diabetes is often a cause of furunculosis, the finding of a normal blood sugar would probably exclude this factor. The patient should be watched, however, and repeated examinations should be made. It is sometimes better not to incise the furuncles but to insert in the canal a gauze packing saturated in 1 per cent trinitrophenol or 1 per cent silver nitrate, leaving the packing in place from twenty-four to forty-eight hours, and then replacing. The application of ultraviolet radiation or x-rays to the external auditory meatus is often of considerable value.

ANTITYPHOID VACCINATION

To the Editor:—I have a patient with typhoid, and it has been almost five years since I have taken any typhoid vaccine; so I began the immunizing dose, March 20, using H. K. Mulford's vaccine. Only slight reaction followed the first dose. One week later I took the second dose and this was followed by a severe reaction. It was given subcutaneously over the left deltoid. Two hours later I had a severe chill, which lasted from thirty to forty-five minutes, hyperpyrexia, severe pains, nausea and vomiting. On the second day the severe headache and fever continued. Today, the third day, there is no fever but I feel quite sick. I am not familiar with such reactions from typhoid vaccine. I have taken it many times and have given it considerably but have never seen a reaction so severe as the one described, except when given intravenously as foreign protein. I once gave a patient a second dose on the same day and he had a similar experience. Should I take the third dose? I want to immunize myself but don't want to undergo the recent experience again. Possibly another product would be more satisfactory. What dose should be used in immunizing a child, aged 5 years, against typhoid? Please omit name.

M.D., Mississippi.

ANSWER.—Since the correspondent has had typhoid vaccine "many times," the last time less than five years ago, it appears reasonably safe to conclude that adequate immunity is present. The sharpness of the reaction to the second dose supports this idea, and accordingly the third injection had better be omitted. In case a third injection is ventured, special care must be

taken to avoid injecting any vaccine into the muscle or veins. For a child, weighing say 60 pounds (27 Kg.), not more than one-half the adult doses of typhoid vaccine may be given. If the child weighs less than 60 pounds, the dose should be adjusted to the weight as compared with the average adult weight.

CHEMOTHERAPEUTIC INDEX—NEOARSPHENAMINE CLAIMS

To the Editor:—Various manufacturers of neoarsphenamine claim advantages for their particular brand on the basis of what is termed a chemotherapeutic index. Would you kindly explain the meaning of this index? Also would you give the best opinions of pharmacologists and syphilologists as to whether a brand with a high chemotherapeutic index really possesses any advantage of therapeutic efficiency in the treatment of syphilis?

LUCAS W. EMPEY, M.D., Roseville, Calif.

ANSWER.—Chemotherapeutic index is a term proposed by Ehrlich to express the ratio between toxicity for the host and toxicity for the infecting parasites, viz.:

$$\frac{\text{Minimal Tolerated Dose per Kilogram}}{\text{Minimal Curative Dose per Kilogram}} = \text{Chemotherapeutic Index}$$

The chemotherapeutic index must of necessity be established on laboratory animals and with strains of micro-organisms to which the particular animals used are susceptible (usually rats infected with trypanosomes). The toxicity of arsphenamine compounds varies greatly for different species of animals and for different strains of organisms; other complicating factors also modify the result. Consequently, the chemotherapeutic index is not an adequate indicator of efficacy in clinical syphilis. The Council maintains that no single accepted brand of arsphenamine or neoarsphenamine is superior to other accepted brands when considered from the point of view of clinical evidence.

REMOVAL OF SUPERFLUOUS HAIR

To the Editor:—Would you kindly give me your opinion as to the best procedure in removing superfluous hair from the face? The patient is a woman, aged 22, and has quite a heavy growth of hair on the chin and both sides of the face. Six months ago she took a number of treatments (electric needle) which, instead of removing the hair, merely aggravated the condition. Last November a course of roentgen treatments was begun, and, according to the suggestion of a good authority on the subject, one-fourth skin unit at intervals of three days was given five consecutive times. From five to eight one-fourth units was the dosage suggested but at the same time caution was advised against a possible telangiectasia. For this reason, only five treatments were given, with the result that there was no visible effect on the growth. Kindly outline a technic that is both effective and safe. Please omit name.

M.D., North Dakota.

ANSWER.—Electrolysis, when properly done, is the only safe method of removing superfluous hair. Roentgen therapy has been abandoned by all reputable roentgenologists and dermatologists. There is no technic that is both effective and safe. Atrophy and telangiectasia are the usual sequel to an amount of x-rays necessary to produce permanent depilation. The physician who undertakes the treatment of hypertrichosis with x-rays should have a clear understanding of the risk involved and the medicolegal possibilities.

USE OF SODIUM AMYTAL BY RECTUM IN LABOR

To the Editor:—I have recently lost a baby following delivery with 9 grains (0.6 Gm.) of sodium amytal given rectally about two hours before delivery. This is my first death with sodium amytal in obstetrics and I am wondering whether this might be attributed to the quinine that was given by mouth at the same time as the amytal. The mother had quite a severe respiratory reaction immediately following delivery and the baby could not be resuscitated. I would appreciate any information you may have on this. Please omit name.

M.D., Missouri.

ANSWER.—In spite of the fact that two drugs were given during labor, the fetal death may, of course, have had little or nothing to do with either of these drugs. Sodium amytal is being used considerably and, while it produces excitement in a large proportion of women and apnea in many babies, 0.6 Gm. given by rectum would hardly produce fetal death. Many patients have received from 15 to 30 grains (1 to 2 Gm.) of sodium amytal without apparent harm to the baby. Quinine, on the other hand, has been held responsible for a few fetal deaths. Dilling and Gemmell (*J. Obst. & Gynec. Brit. Emp.* 36:352, 1929) say: "In a series of 765 patients in whom quinine was used for induction of labor, the drug may have been responsible for eight stillbirths (1.04 per cent)." De Lee (*The Year Book of Obstetrics and Gynecology*, by J. B. De Lee and J. P. Greenhill, 1930, p. 313) says: "Quinine should not be used in large doses during or before labor. We have had several fetal deaths and two maternal deaths from even moderate dosages."

TOXICITY OF ETHYL VALERATE

To the Editor:—How toxic is ethyl valerate? I have had several cases of exposure in which the only complaint was impotence. These occurred in young vigorous males, after very little contact. I understand that ethyl valerate is a by-product formed in the manufacture of ethyl acetate and similar ethyl compounds.

F. F. BOYS, M.D., East Chicago, Ind.

ANSWER.—Little is known about the industrial toxicity of ethyl valerate. The National Dispensary describes ethyl valerate and its therapeutic use. The fact that the dose is limited to one or two drops a few times daily implies that the substance possesses potent properties. Its medical use is limited to spasmodic conditions, including some forms of asthma. A lesser use is as a sedative. The substance finds use in small quantities in beverages and confectionery as a flavoring extract simulating apple.

It is anticipated that industrial exposure will lead to lowered tonicity of various muscular tissues and lessened activity of various body functions.

The suggestion has been made that digestive disturbances may be expected to arise after the taking of ethyl valerate. It is believed that this chemical is eliminated through the kidneys unchanged.

SUSCEPTIBILITY TO TOXIN-ANTITOXIN

To the Editor:—A boy, 8 years old and in good health, received the Schick test, which was positive. He then was given diphtheria toxin-antitoxin with only mild local reaction, but about a week later complained of malaise and had a temperature of 101 F. daily for several days. No more toxin-antitoxin was given and he then felt able to go to school for several days but again ten days from the first immunizing dose began to complain of nausea, weakness, dizziness and again had a temperature of from 100 to 102, with a pulse rate between 110 and 120. He fainted while on the street, the second day of this illness. Physical examination was essentially negative except for the symptoms mentioned. He has had no previous serious illness. Could the one dose of diphtheria toxin-antitoxin have caused the symptoms so long after, with no heart signs other than rapid pulse this late? Please omit name and address.

M.D., Ohio.

ANSWER.—It is possible that the symptoms may have been caused by the toxin-antitoxin. In especially susceptible persons, minute amounts of various proteins are toxic. The toxin-antitoxin mixture contains, besides the blood serum, also other protein of the broth in which the diphtheria bacilli are grown in producing toxin. Injections of serums and other protein substances are sometimes followed by slight, transient disturbances, such as fever, joint pains and general malaise, and while not corresponding to typical serum reactions are still probably due to the toxic reactions produced by the injected materials and not explained in any other manner.

USE OF ETHER AND ETHYLENE IN ANESTHESIA

To the Editor:—1. What percentage of the leading surgeons and hospitals in the United States are using ethylene and oxygen anesthesia? 2. How is ethylene and oxygen rated as to safety? 3. What percentage of anesthetists are able to keep the patient sufficiently relaxed to permit the surgeon to work without the aid of ether? 4. Why does a patient become blue on ethylene and oxygen and yet not be sufficiently relaxed for the surgeon to work? All these questions apply to surgeons doing major abdominal operations lasting from twenty minutes to two or more hours. Please omit name.

M.D., West Virginia.

ANSWER.—1. It is impossible to state definitely the number of surgeons and hospitals using ethylene, but a recent survey would place the number at about 40 per cent.

2. Anesthetists who have had the largest experience unhesitatingly claim that when ethylene is properly administered it is the safest of all anesthetic agents.

3. It is difficult or impossible to produce good relaxation in abdominal operations with ethylene alone. With liberal premedication and local anesthesia, relaxation will be secured without the addition of ether.

4. Cyanosis will not produce relaxation and, if extreme, may endanger or destroy the life of the patient.

DERMATITIS DUE TO ROTOGRAVURE INKS

To the Editor:—What suggestions have you to offer for the treatment of an acute dermatitis definitely caused by rotogravure inks such as are found in comic sections, rotogravure sections of Sunday papers and certain types of rotogravure found on books and toilet preparation coverings?

R. L. RUTLEDGE, M.D., Alliance, Ohio.

ANSWER.—An acute dermatitis due to rotogravure ink should be treated as an ordinary dermatitis venenata. If the eruption is a moist one, wet dressings of aluminum subacetate solution should first be used, the official 8 per cent solution being diluted with 1 ounce to the pint of water. If the acute eruption has

Council on Medical Education and Hospitals

COMING EXAMINATIONS

ALASKA: Juneau, Sept. 5. Sec., Dr. Harry C. DeVigne, Juneau.
AMERICAN BOARD FOR OPHTHALMIC EXAMINATIONS: Boston, Sept. 19. Application should be filed before August 1. Sec., Dr. William H. Wilder, 122 S. Michigan Ave., Chicago.
AMERICAN BOARD OF DERMATOLOGY AND SYPHILOLOGY: Written. Boston, Chicago, Cleveland, New York, Philadelphia, St. Louis and San Francisco, Oct. 28. Oral. New York, Dec. 15-16. Application must be filed before Sept. 1. Sec., Dr. C. Guy Lane, 416 Marlboro St., Boston.
AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY: The examinations will be held in various cities of the United States and Canada, Dec. 9. Sec., Dr. Paul Titus, 1015 Highland Bldg., Pittsburgh.
AMERICAN BOARD OF OTOLARYNGOLOGY: Boston, Sept. 16. Sec., Dr. W. P. Wherry, 1500 Medical Arts Bldg., Omaha.
NATIONAL BOARD OF MEDICAL EXAMINERS: Parts I and II. The examinations will be held at centers where there are five or more candidates, Sept. 13-15. Ex. Sec., Mr. Everett S. Elwood, 225 S. 15th St., Philadelphia.
NEW HAMPSHIRE: Concord, Sept. 14-15. Sec., Dr. Charles Duncan, State House, Concord.
OKLAHOMA: Oklahoma City, Sept. 12-13. Sec., Dr. J. M. Byrum, Mammoth Bldg., Shawnee.
PUERTO RICO: San Juan, Sept. 5. Sec., Dr. O. Costa Mandry, Box 536, San Juan.

Colorado Endorsement Report

Dr. William Whitridge Williams, secretary, Colorado State Board of Medical Examiners, reports 3 physicians licensed by endorsement, April 4, 1933. The following colleges were represented:

| College | LICENSED BY ENDORSEMENT | Year of Grad. | Endorsement |
|---|-------------------------|---------------|-------------|
| College of Medical Evangelists | | (1921) | California |
| College of Iowa College of Medicine | | (1931) | Iowa |
| State University of Iowa College of Medicine and College of Physicians and Surgeons | | (1931) | Maryland |

Illinois April Examination

Mr. Paul B. Johnson, superintendent of registration, Department of Registration and Education, reports the oral, written and practical examination held in Chicago, April 11-13, 1933. The examination covered 10 subjects and included 100 questions. An average of 75 per cent was required to pass. Forty-one candidates were examined, 36 of whom passed, and 5 failed. The following colleges were represented:

Rhode Island April Examination

Dr. Lester A. Round, director, Rhode Island Public Health Commission, reports the written and practical examination held in Providence, April 6-7, 1933. Eleven candidates were examined, 10 of whom passed and one failed. Two physicians were licensed by endorsement. The following colleges were represented:

| College | PASSED | Year Grad. | Per Cent |
|--|--------|------------|----------|
| Georgetown University School of Medicine | | (1931) | 82.1 |
| Boston University School of Medicine | | (1932) | 86.5 |
| Boston University Medical School | | (1932) | 88.3 |
| Harvard University Medical School | | (1932) | 87.5 |
| Tufts College Medical School | | (1929) | 90.2 |

subsidized, a soothing ointment such as ointment of zinc oxide, or equal parts of Lassar's paste and petrolatum, or 10 per cent naftalan with 2 per cent sulphonated bitumen in Lassar's paste can be used. The patient, of course, should avoid all contact with roto-gravure ink. These cases are not common nowadays, because most of the newspaper publishers have discontinued the strong powder containing paranitro-aniline, which was used in the manufacture of these inks.

TOXICITY OF TETRA-ETHYL LEAD

To the Editor:—Recently an automobile accident occurred close to town. One child was burned to death and two women were brought into the hospital. One woman died in twenty-four hours and the other in forty-eight hours. These deaths were apparently not toxic, because the burns were only of the first degree and one especially was not very extensive. The only thing that I could figure out was that it could have been from the fumes of ethyl gasoline. I checked the automobile but there was no gasoline left anywhere in it. I would appreciate any information on this subject.

ANSWER.—It is improbable that the lead in the gasoline was a factor in these deaths. At least the report gives no details that would so indicate. Although tetra-ethyl lead in concentrated form is extremely poisonous, up to the present time no fatalities have been proved to have resulted from the use of ethyl gasoline.

VESTIBULAR AND CALORIC TESTS IN DIAGNOSIS

To the Editor:—Kindly advise whether the Bárány test is of value in making diagnoses in disease of the semicircular canal, and also if useful in differential diagnosis between intracranial lesions and labyrinthine disease.

N. H. COLTON, M.D., Norristown, Pa.

ANSWER.—Bárány's name is often used to include all the vestibular tests, such as the turning, caloric and galvanic. At other times his name is associated merely with the caloric reaction. These tests are of great value in the study of pathologic changes involving the vestibular apparatus, especially the semicircular canals. They are also of great aid in making the differential diagnosis between labyrinthine and intracranial lesions.

PROPHYLAXIS FOR RENAL CALCULI

To the Editor:—I have a patient who has had two operations for renal calculi that consisted of calcium magnesium phosphate. What prophylactic measures would you suggest to try to prevent any recurrence? Please omit name.

M.D., Philadelphia.

ANSWER.—1. Any disturbance of the normal drainage from the renal pelvis should be corrected.
2. The renal pelvis should be lavaged with 1 per cent solution of phosphoric acid.
3. The patient's intake of fluid should be kept quite high.
4. The reaction of the urine should be determined from time to time and, if alkaline, should be changed by the administration of sodium benzoate or acid sodium phosphate.
5. All possible foci of infection should be studied (teeth, throat, sinuses) and if found infected they should be cleaned up.

HARDNESS OF WATER AND ETIOLOGY OF PYURIA

To the Editor:—Since moving to this city to practice medicine in July, 1932, I have noticed that a high percentage of my patients show a persistent pyuria, at least 75 per cent of all cases showing infection of the urinary tract. Inquiry from other physicians reveals that they too are seeing too many cases of pyuria. Several hundred men have moved here while doing road construction work, and their history almost invariably is that they were in perfect health until they began drinking the water, a chemical analysis of which shows: depth of wells, 164 feet; total solids, 1,380; hardness, 565; sodium chloride, 594; calcium bicarbonate, 205; calcium sulphate, 218; sodium sulphate, 194; magnesium sulphate, 120; magnesium chloride, a trace; iron and aluminum, traces (International Filter Company, Analyst, 1926). From the data available is it probable that this water has any effect on the incidence of urinary infections in this city? M. E. BARRETT, M.D., Fort Stockton, Texas.

ANSWER.—The hardness of the water has no connection with the incidence of urinary infections. Pyuria can occur in many conditions other than infections of the bladder, ureters and kidneys. Admixture of pus from the foreskin can give a marked pyuria. In gonorrhea, and from below the foreskin can give a marked pyuria. In marked dehydration in infants a sterile pyuria may occur, but, with this exception, pus coming from the bladder and upper urinary passages is always due to an infecting organism.

If it is true that at least 75 per cent of all cases show infection of the urinary tract, it certainly would be worth while taking cultures to determine what the infecting organism is. The water is extremely hard but there is no evidence at hand that hard water predisposes to infection.

Book Notices

Practical Hematological Diagnosis. By O. H. Perry Pepper, M.D., Professor of Clinical Medicine, University of Pennsylvania, and David L. Farley, M.D., Physician to the Pennsylvania Hospital, Philadelphia. Cloth. Price, \$6. Pp. 562, with illustrations. Philadelphia & London: W. B. Saunders Company, 1933.

The authors present the practical aspects of hematology in concise and simple terms. They point out that much of the information in clinical hematology is not readily available to the practitioner of medicine because of a confusion of terms and methods.

The book is divided into three parts. The first part deals with components of the blood that are of hematologic interest. Each discussion on the cellular elements of the blood is well balanced and includes the most recent information. The first chapter, on the origin and development of the formed elements of the blood, is concise but comprehensive. It contains only such information as is necessary for a practical consideration of the facts that are developed later. Chapters on the erythrocyte, hemoglobin, white blood cells and blood platelets are practical and instructive. The material is selected with discrimination and presented in a well organized manner. The authors' selection of the methods for platelet counting are, with the exception of Fonio's methods, those recently described in current literature. It is questionable whether the technic cited has any special advantage over the ones commonly given in standard books on laboratory methods. The statement that the bleeding time is in direct proportion to the number of platelets is also open to question. The disparity between the two observations is well known and is one of the reasons why the absolute relationship of platelet reduction and purpura has been recently questioned.

The chapter on blood coagulation is well presented. The theoretical aspect is concisely reviewed and several methods are given for the practical determination of the clotting time. Blood grouping and the hematologic aspects of blood transfusion is a well written chapter. The large amount of material on this subject is well summarized and its practical application has been utilized to the fullest extent. The data in the chapter on blood parasites are well selected and concise. Illustration of the parasites would have aided the descriptive methods of identification, as many physicians do not have the opportunity of seeing many of the forms described.

The second part of the book deals with the diagnosis of disorders of the hematopoietic system and the hematologic observations. This is a particularly well organized section of the book. The hematology of the anemias comprises the most recent studies and data available. The leukemias and leukemoid conditions are discussed with adequate completeness for

a work of this kind. It is difficult, however, to give this subject proper consideration without more detailed information on the pathology of the blood-forming organs. The chapter on purpura and hemorrhagic diseases should have been considered more critically. It is difficult to conceive of a practical classification of purpura on the basis of quantitative platelet counts with our present information. More space could have been profitably devoted to the pathogenesis of the various types of purpura. Under hemophilia the work on the stability of the platelets as demonstrated by Howell and Cedaka and later by Birch is not mentioned.

A chapter is devoted to the hematology of infancy. The authors take issue with the term "von Jaksch anemia" and the newer terms "erythroblastic" anemia and "Cooley's anemia." While their criticisms are valid, their substitute for "hyperplastic anemia" is also open to the same objections. No one who has observed many cases of so-called von Jaksch or erythroblastic anemia could agree to many of the statements in the text. The blood examination in icterus gravis and edema of the new-born, recently described in current literature under "erythroblastosis fetalis," was not covered in this section. It would have made an excellent addition to the point of view expressed by the authors, namely, an unusual blood picture of infantile anemia.

Part II is concluded by an interesting and instructive chapter on effects of irradiation, splenectomy and certain chemicals on the normal and pathologic blood picture.

Part III deals with hematologic conditions of diseases not primarily of the blood. In this section the authors list alphabetically diseases that have an effect on the blood-forming organs and discuss the changes reflected in the blood picture. The colored plates that appear in the text do not bring out sufficient nuclear detail in the younger cells to facilitate recognition.

The book, taken as a whole, is an exceptionally well organized and practical presentation of hematologic diagnosis. The authors have made a sincere attempt to present the data in a simple and rational manner and the book should be well received by practitioners of medicine.

Chemische Grundlagen der Lebensvorgänge: Eine Einführung in biologische Lehrbücher. Von Professor Carl Oppenheimer, Dr. phil. et med., Berlin. Paper. Price, 22.50 marks. Pp. 298, with 1 illustration. Leipzig: Georg Thieme, 1933.

The author presents something different from the ordinary textbook of biologic chemistry. In fact, it is an introduction to such works. The author appreciates the difficulties and modestly asks consideration for any shortcoming in the attainment of his ideals. These ideals are a philosophical unification and simplification of the chemical and physical processes of living matter. He prefers the term "living matter" to the term "cell." In the introduction he discusses protoplasm and closely related matter, building material and "heat material," electrolysis, energy, material of the cell nucleus, and the bioelements. The inorganic elements are classified as the essential and the accidental or relatively nonessential. Under the latter term many metals heretofore considered nonessential are deemed worthy of perhaps more consideration than some writers have accorded to them. Such metals include aluminum, copper, arsenic, lead, bromine, cobalt, manganese, silicon and others. The author gives full references to the original work for his statements, and these references are mainly from recent research. It would seem that the biologic importance of many metals has not been fully appreciated. The second chapter deals with colloids, fats, waxes, lipoids, carbohydrates, respiration and proteins. The interrelationship of these bodies and their relationship to other elements of protoplasm, including vitamins and hormones, is considered. The chapter is impressive because of its comprehensiveness and compactness, yet it puts the reader in contact with the latest and most important literature. The third chapter deals with circulation and the processes of anabolism and catabolism and is distinctly modern. The greater part of the literature citations are from 1925 to 1933. The fourth chapter deals with the chemical mechanism of cell processes, catalysis and ferment action, "desmolyse" (enzymotic processes), assimilation, ion action, oxidation and reduction, cell respiration and surface action. While many of these processes are not well understood, the work given shows that research in the mechanism of cell chemistry during the last

few years has made great strides. The last chapter deals with the energetics of living matter and with living matter as a chemodynamic machine. This is a highly specialized branch of biology in which relatively few are engaged. The pages devoted to it show its importance and are sufficient to give the reader a good general knowledge of the methods used, and an acquaintance with the investigators working in this important and fundamental branch of biochemistry. As the name would indicate and the discussions confirm, this is not a book for the uninitiated. It is the product of a scholarly investigator and is recommended to those with scholarly inclinations who desire information on the chemistry of life.

Clinical Endocrinology of the Female. By Charles Mazer, M.D., F.A.C.S., Assistant Professor of Gynecology and Obstetrics, Graduate School of Medicine, University of Pennsylvania, and Leopold Goldstein, M.D., Demonstrator of Obstetrics, Jefferson Medical College. Cloth. Price, \$6. Pp. 519, with 137 illustrations. Philadelphia & London: W. B. Saunders Company, 1932.

Well nigh a year has passed since the publication of this volume. Its title is in itself an indication of the extremes of specialization that have occurred in medical science; this monograph concerns not endocrinology as such but endocrinology as it affects the female. No doubt, the special point of view is warranted since probably more work has been done in the past few years on the estrus hormones and the relationship of other glands of internal secretion to the gonad than on almost any other subject. Authorities are in general agreed that a derangement of the pituitary anterior lobe affects the body as a whole more seriously than a primary derangement of any other endocrine gland. A few years ago it was conceivable that the pituitary might contain one or two hormones. Today there are authorities who postulate as many as eighteen different substances. Most of the discussion of the pituitary gland in the present book is devoted to the growth promoting principles and the gonad stimulating substance, which are well recognized. Conceivably either of these two major effects may have side effects not specifically pituitary in character. The posterior pituitary has a well recognized antidiuretic effect and an oxytocic action. It is, of course, also associated with the carbohydrate and fat metabolism. The presentation by Mazer and Goldstein is concerned primarily with menstruation and menstrual disorders. They cite numerous cases not only from their own practice but also from medical literature. A chapter is devoted to sterility, and there are also chapters dealing with lactation, tests for pregnancy, and obesity. A well selected bibliography completes the book.

Electricity: What It Is and How It Acts. Volume II. By Andrew W. Kramer. Cloth. Price, \$2. Pp. 290, with 112 illustrations. Chicago: Technical Publishing Company, 1931.

With the minimum amount of simple mathematics, the author has compiled in this small volume a splendid series of articles on the fundamental nature of electricity. A physician having an elementary knowledge of college physics should enjoy reading about some of the recently advanced theories concerning electricity. Electromagnetic radiation, roentgen rays, light, photo-electrical effects and the electron are dealt with in simple, readable language. The scientific aspects of the problems have not been unduly strained for simplicity's sake. A physician specializing in roentgen therapy or ultraviolet radiation therapy will probably find this volume a worth while addition to his library.

Le terrain cancéreux et cancérisable; Physiologie pathologique du cancer. Action biologique des radiations. Par R. Reding, directeur de la Fondation Yvonne Boël. Paper. Price, 50 francs. Pp. 389, with 17 illustrations. Paris: Masson & Cie, 1932.

In this treatise, Reding has accumulated the available evidence in support of the theory that cancer is primarily a constitutional disease. To the evidence gathered in the literature the author has added his own investigations, the results of which support this view. The susceptibility of some animals to tar and the immunity of others are indicated as an example of an underlying constitutional predisposition. Variations in racial susceptibility in animal and man are interpreted in a similar manner, as is also hereditary predisposition and resistance. The author maintains that physicochemical changes in the cancerous organism are found in the precancerous state and persist after surgical extirpation of the lesion. These facts

are interpreted as indicating that these changes are an integral part of the general predisposition. In almost all cancer patients the author discovered a more or less serious disturbance of sugar metabolism. Alkalosis of the plasma, a diminution in the concentration of ionized calcium, and a disturbance in the sugar regulating mechanism are said to be already present in the precancerous state and are therefore not secondary to the appearance of the tumor. X-rays and radium are reported to exercise a profound and lasting effect on the reaction of the blood in cancer patients. A reduction in the degree of alkalosis, an increase in calcium and a reestablishment of the normal sugar regulating mechanism were noted to follow effective irradiation. The author believes that a determination of the pH of the blood constitutes a practical and important diagnostic procedure, especially in the detection of the internal cancers. The prevention of cancer by regulating the alkalosis is suggested. Recurrences developed in patients in whom the pH of the blood was only slightly modified by irradiation. Those in whom the pH of the blood recovered showed a better prognosis. This elaborate treatise is of interest and constitutes a useful though uncritical summary of the evidence dealing with this subject. The array of evidence that the author has succeeded in lining up to support his thesis is truly formidable, but the review is not sufficiently critical and all contradictory evidence is either omitted or minimized. This attitude is obviously a dangerous one in medical research, as it is likely to lead to fallacious conclusions. In spite of their alluring appeal, the facts scarcely justify the conclusions which the author has drawn. The suggestions that diagnosis and treatment of cancer can be based on the evidence presented, though most attractive, cannot be accepted without further study and confirmation of these results. The treatise nevertheless presents a highly interesting point of view, which should be subjected to further study. This research has stimulated considerable interest in this field of investigation, the results of which should help to clarify this highly interesting and controversial problem.

Bibliographical Survey of Vitamins, 1650-1930. Compiled by Ella M. Salmonsens, Medical Reference Librarian, The John Crerar Library, Chicago. With a Section on Patents. By Mark H. Wodlinger. Cloth. Price, \$10. Pp. 334. Chicago: M. H. Wodlinger, 1932.

This is a useful compilation of references on vitamins, listed chronologically from the year 1650 up to and including 1930. After 1916 the references for each year are subdivided by the type of vitamin, and a section is included on general vitamin references. The bibliography is unusually complete, containing approximately 12,000 references. Those available in the John Crerar Library, as well as additional rare material secured from other American and European libraries, are included in the survey. In addition, 240 patents pertaining to vitamins are listed with numbers, names of patentee and title. The book will be welcomed by any one who is interested in vitamin research and related fields. The material is well organized and discriminatingly inclusive.

Annual Report for the Year 1932 of the Egyptian Government, Central Narcotics Intelligence Bureau. Paper. Pp. 170, with illustrations. Cairo: Government Press, 1933.

This report reveals some astounding facts relative to the difficulty of controlling narcotic addiction in Egypt. Apparently that country is now suffering with a flood of hashish introduced from Syria. Great benefit has accrued from the closing of opium factories in Turkey. The Egyptian authorities insist that the European center for the manufacture of heroin destined entirely for illicit trade has shifted from Istanbul to Sofia in Bulgaria. Driven from Turkey, it is now elsewhere, and the director of the intelligence bureau considers that, driven from Sofia, it will turn up in some other city. Mr. Russell says that only complete international understanding and agreement can control the drug traffic. The report is a highly interesting document showing that drugs are shipped in every possible way and that the tricks of the trade are amazingly intricate and devious. The report gives names, dates and places, one statement being to the effect that an attaché of the Peruvian government, traveling with a diplomatic passport, brought a ton and a half of heroin into the United States in six different trips. It shows, furthermore, that the notorious "Legs" Diamond of New York was intimately in contact with the narcotic trade and that several

murders in New York were directly related to the stealing and manipulation of narcotics. For those who wish something in the way of an intimate and exact insight into this deplorable traffic, this official document is a revelation.

The Book of Delight. By Joseph Ben Meir Zabara. Records of Civilization, Sources and Studies. Volume XVI. Translated by Moses Hadas. With an introduction by Merriam Sherwood. Cloth. Price, \$3.25. Pp. 198. New York: Columbia University Press, 1932.

This volume is a document from the eleventh and twelfth centuries which affords an excellent illustration of the wit, science and literary resources of Spanish Jewish society of that period. For the physician it is especially of interest because of certain medical discussions. In chapter 8 there is the usual good advice relative to the avoidance of excesses in eating. Chapter 9 is devoted wholly to a knowledge of medicine of the period. There are thirty-two questions in a medical catechism showing how simple was the actual knowledge of the period. For instance, the questioner asks "How many are the canals of the bowels?" The answer is "Three; one lengthwise to receive the food, and one diagonal to retain it until it be digested, and the third crosswise to force the food on and expel it when it hath been digested." On the other hand there is much of wisdom in the following question: "Wherefore doth a little lad eat more than a grown man?" To which the answer is given "Because the lad requireth his food for two purposes, to carry on life and for growth, whereas the man requireth his food only to carry on life."

Die Erkrankungen der Harnorgane im Röntgenbild. Von Dr. Hans Boemlinghaus, a. o. Professor für Chirurgie an der Universität Marburg, und Dr. Ludwig Zeiss, Facharzt für Urologie, Chefarzt des Sanatoriums Helenenquelle Bad Wildungen. Cloth. Price, 45 marks. Pp. 232, with 379 illustrations. Leipzig: Johann Ambrosius Barth, 1933.

This atlas is an important addition to the literature of roentgenology. The illustrations are excellent and the subject matter is presented in a clear and concise manner. The detail in the urographic pictures is brought out distinctly, since extraneous matter, such as gas, has been removed. The arrangement is good and includes many of the important urologic subjects. After a short historical review of the development of the x-rays, instruments and urography, the methods and preparation are considered. This is followed by a condensed account of instrumental pyelography, excretion urography and the urologic roentgen examination of children. Then in succession are presented abridged descriptions and urograms of malformations and anomalies, urinary lithiasis, inflammations, tuberculosis, tumors, injuries, fistulas and disturbances of function. Pyeloscopy is given but little space and importance. Pneumoradiography is cautiously described, with proper warnings. This volume is an excellent work and should be of value to both the urologist and the roentgenologist.

Text-Book of Massage and Remedial Gymnastics. By L. L. Despard. With two chapters contributed by Hester S. Angover, Sister-in-Charge of the Massage Department, Guy's Hospital, London. Third edition. Cloth. Price, \$6. Pp. 474, with 222 illustrations. New York: Oxford University Press, 1932.

The first part is devoted to the principles of elementary anatomy and physiology necessary to students of the technic of physical therapy. The theory and practice of massage are thoroughly considered in the second part. Swedish remedial gymnastics, the reeducation of muscles and other exercises are given in detail. The book is well illustrated throughout. It is an excellent textbook for physical therapy technicians.

The Professions. By A. M. Carr-Saunders and P. A. Wilson. Cloth. Price, \$6.75. Pp. 536. New York & London: Oxford University Press, 1933.

This volume is a study of the organization of the professions in Great Britain. The sections of special interest to the physician concern doctors, dentists, nurses, midwives, pharmacists, opticians and masseurs. The second part of the book covers the evolution of the professions following the industrial revolution, state interference in practice, economic problems and relationships of the profession to the public and the relationships of the professions to the future. Two of the six appendixes deal with professional codes and the conditions of service of doctors under the national health insurance scheme.

Most American physicians know that the British medical profession is organized and licensed on a different basis from

our own. The nature of organization and licensure in Great Britain is fully explained. In Great Britain there are 55,000 names on the medical register, and the membership of the British Medical Association amounts to about 35,000. There is also a medical practitioners' union with approximately 3,000 members. The success of the British Medical Association is credited by the writers to the fact that it has had persistently skilful leadership over a long period through a long succession of unusually able permanent officials and of medical men willing to sacrifice time to the affairs of the association. The British Medical Association is organized on a democratic basis similar to the organization of the American Medical Association. High praise for the constitution of the British Medical Association is offered by the authors; indeed, they credit the British Medical Association with an important effort in the passing of the national health insurance bill providing for free choice of doctor by patients and for representation of physicians on all committees controlling the workings of the act. There is now general agreement that the British Medical Association was right in 1911 in insisting on the conditions under which insurance should be introduced. In the opinion of the authors, however, the British Medical Association went beyond what it hoped to do at that time and was used "as a stick with which to beat the government of the day." The method employed during the insurance bill fight was collective bargaining, a method that is still used by the British Medical Association in dealing with the government. The British Medical Association spent more than £30,000 in the controversy on the national health insurance bill in addition to money raised by special funds. It is pointed out that, through refusal to publish in its journal advertisements of positions which do not come up to the requirements of the association, the association exerts a powerful influence.

Chapters on dentists, midwives, veterinary surgeons, opticians, pharmacists and masseurs consider in detail the history of these professions in Great Britain, their organization and their relationship to other professions and to the public. It is pointed out that a medical education in Great Britain costs approximately £1,500. The book contains a vast amount of useful information for those who are participating in current widespread discussions of the future of American medical practitioners.

Lehrbuch der klinischen Untersuchungsmethoden für Studierende und praktische Ärzte. Band II, Hälfte 1. Von Prof. Dr. H. Sahli. Seventh edition. Paper. Price, 22 marks. Pp. 368, with 92 illustrations. Leipzig: Franz Deuticke, 1930.

The first section of volume II is completely revised. The author has not only brought the various laboratory methods down to date but he has reevaluated their significance in clinical medicine. The first half of volume II deals, for the most part, with urine analysis and its clinical significance. Every phase of the subject has been completely revised. Long and tedious methods have been replaced by procedures that are easier to carry out without sacrifice of accuracy. The author has added a comprehensive discussion on urinary pigments and carefully revised the quantitative analytic methods. The microscopic examination of urinary sediment is unusually complete. Kidney and liver function tests and gallbladder visualization are discussed with reference to technic and clinical significance. The chapter on examination of sputum is concise but comprehensive. Special attention has been given to the bacteriologic examination of sputum; the detection and study of the tubercle bacillus is stressed particularly. The remaining part of this section of volume II is devoted to physicochemical methods of blood examination that are of clinical interest. The author has enlarged considerably the section on examinations of blood in hemorrhagic diathesis. The latest methods of evaluating the clotting mechanism of the blood are discussed and the changes in various diseases are emphasized. The methods of corpuscular volume determinations are critically discussed and the sources of error are noted. Sahli suggests a new method of his own to meet the errors inherent in the ones in use previously. Those who are familiar with the wealth of data and charming manner of presentation of the previous editions of Sahli's book will welcome the seventh edition. It has been thoroughly revised not only from the point of view of laboratory methods but also from their clinical

indications. The author makes a plea to the clinician to use laboratory work only to develop more completely his clinical observation. He criticizes routine laboratory work, particularly as carried on in some American hospitals, in that so much time is taken up in routine collection of data that not enough time is left for careful study of the patient and the work that is specifically indicated. This book will be enthusiastically received by clinicians who have a scholarly interest in disease and are critical in their clinical investigation.

Exploration fonctionnelle des voies biliaires et chirurgie. Par L. Bérard, professeur de clinique chirurgicale à la Faculté de médecine de Lyon, et P. Mallet-Guy, chef de clinique chirurgicale à l'Hôtel-Dieu. Paper. Price, 68 francs. Pp. 362, with 86 illustrations. Paris: Masson & Cie, 1932.

This is a new monograph by two prominent French surgeons, who for the past six years have made a clinical study of Meltzer-Lyon duodenal drainage and cholecystography in an effort to determine their clinical applicability in surgery of bile tract disease. Both of these methods give information regarding the physiology of the bile tract. Every surgeon of experience is familiar with that group of cases in which disease of the bile tract unquestionably exists but in which at operation the gallbladder shows no gross pathologic anatomic change. The authors believe that the surgery of the bile tract should be developed not only to correct any pathologic anatomy but, what is more fundamental, to remedy any pathologic physiology that exists. The aim of this volume is to show the clinical value of these functional tests as guides in the treatment of surgery of the bile tract. The authors have carefully studied 135 cases of bile tract disease, using these two methods of testing the function before operation, immediately after operation, and a long time after operation. Their experience forces them to agree with Mathieu, with Santy and with Cotte in avoiding cholecystectomy as a routine operation in gallbladder disease. They have found duodenal drainage of value in improving the condition, without risk, in those patients in whom cholecystectomy has been followed by failure. They admit that treatment of biliary tract disease by duodenal drainage alone is not permanent and that its therapeutic efficacy does not compare with cholecystectomy. But they do feel that its use as a preoperative test yields valuable information in guidance as to what operative intervention is indicated. A large amount of space is devoted to studies by these methods postoperatively: the physiologic observations after cholecystectomy, after cholecystogastrotomy, and still more after cholecystostomy. The authors believe that cholecystostomy offers incomparable possibilities for the study of the normal and pathologic physiology of the bile tract in man. This chapter is perhaps the most original in the entire volume. They have recorded the variations in the types of bile excreted and have studied the passage of bile following the injection of lipiodine. The volume will be of interest to both surgeons and internists.

William Shakespeare, M.D. By Harry B. Epstein, M.D. Boards. Price, \$1. Pp. 24. Newark: Lasky Company, Inc., 1932.

This is a brief essay on the medical aspects of some of Shakespeare's writings. The universality of interest in Shakespeare needs no comment. This well arranged and studious essay is a welcome contribution.

Manuel d'urétroscopie postérieure. Par Gaston Busson et Robert Henry. Préface du Dr. Marion. Paper. Price, 55 francs. Pp. 80, with 50 illustrations. Paris: Masson & Cie, 1931.

This manual of posterior urethroscopy is like several others on the same subject, especially those emanating from France, being rather an atlas in which the more common pathologic processes are well illustrated. The subject of posterior endoscopy has been stimulated recently in the United States by the various endo-urethral methods of prostatic resection, and there is no doubt that an increased familiarity with the anatomy and pathology of the posterior urethra as observed through the endoscope would have a salutary influence on American urology. The present volume is satisfactory as far as the text is concerned, but the color values in some of the plates are markedly exaggerated. The book can be heartily recommended, and the information that it contains should be a part of the knowledge of every surgeon treating genito-urinary diseases.

Medicolegal

Medical Practice Acts: Drugless Healers May Not Practice Surgery; Mechanotherapy Does Not Include Surgery.—Lydon, a sanipractor, was licensed to practice drugless healing in the state of Washington. A patient suffering from an advanced cancer of the breast consulted him, Aug. 12, 1930. He told her that he could effect a cure in three months, and she thereupon placed herself under his care. Lydon's treatment consisted principally in keeping his patient on a liquid diet, with frequent hot baths. According to his theory, the general condition of the patient was to be improved by aiding the eliminative processes, and the cancer would be brought to a head. Then it could be treated by lancing, as boils are commonly treated. On December 1, with his patient in a desperate condition, Lydon made an incision into her breast, from which blood and pus exuded. Later, on the same day, the patient was taken to a hospital. Lydon examined her there the next morning, but because of his limited license and sectarian practice he was not allowed to treat her. She died, Jan. 12, 1931. Lydon was convicted of practicing medicine and surgery without a license. He appealed to the Supreme Court of Washington.

The legislature of the state of Washington, the Supreme Court pointed out, in 1919, enacted a law to regulate the practice of osteopathy and of osteopathy and surgery; a law to regulate the practice of chiropractic; a law to regulate the practice of drugless healing, which includes sanipractic, although it is not specifically named; and a law to regulate the practice of medicine and surgery in all branches. A study of these laws, said the court, leads to the inevitable conclusion that the legislature intended to provide and did provide that licentiates authorized to practice medicine and surgery may use drugs or medicinal preparations, practice surgery, and employ any and all other methods in the treatment of human ailments, but that licentiates of other classes should restrict themselves each to the particular method of healing professed by him and designated in his license. The law regulating the practice of drugless healing makes no provision for an examination in surgery or for the issue of certificates authorizing practitioners of drugless healing to practice surgery.

In *Wilcox v. Carroll*, 127 Wash. 1, 219 P. 34, the Supreme Court of Washington said:

Appellant is what is called a sanipractor physician, not licensed as a full sanipractor, but licensed to use the methods of treating disease known as hydrotherapy, dietetics, electrotherapy, and psychotherapy. Such practitioners are not permitted to use drugs such as physicians of the regular schools use, nor to perform operations.

In *State ex rel. Walker v. Dean*, 155 Wash. 383, 284 P. 756, the court said:

It was the manifest intention of the Legislature to prohibit the holders of restricted licenses from practicing branches of the art of healing not embraced within the subjects upon which the licensee had been examined, and which by his certificate he was authorized to practice.

In harmony with these decisions and others cited, the Supreme Court concluded that drugless healers, including sanipractors, may not practice surgery unless specifically authorized by proper certificates.

The defendant-sanipractor contended that because the examination which drugless healers are required to take includes an examination in obstetrics, and because obstetrics may involve a form of surgery, he was entitled to use surgery to the extent to which he used it in the present case. Whether the defendant is limited in an obstetric case to the severing of the umbilical cord or to the removal of the after-birth or may go to the full length of performing a cesarean operation, said the Supreme Court, it is not necessary here to determine; the present case is not an obstetric case, but one involving an operation on a cancer. The defendant-sanipractor further undertook to justify the treatment of his patient by contending that the statute does not condemn individual and sporadic acts but condemns only the general holding out of oneself as being regularly engaged in the practice of surgery. His act in the present case, he claimed, was merely incidental, casual, an emergency act of a "Good Samaritan," under the stress of immediate circumstances. With these contentions the Supreme Court did not agree. The law censures and forbids not only the holding out of oneself as being engaged in the practice of surgery generally, but also the practice

or attempted practice of surgery specifically. The act of the defendant was not an incidental, causal or emergency act, said the court, but was deliberate, designed and prearranged. The defendant claimed finally the right to practice surgery by virtue of his right to practice mechanotherapy and mechanical manipulation. The terms mechanotherapy and mechanical manipulation, said the court, imply simply a remedial treatment consisting of the manipulation of a part or of the whole of the body, with the hand or by mechanical means. In plain English, they mean massage manually or mechanically performed. They certainly do not include the practice of surgery in any form.

The conviction of the defendant was affirmed.—*State v. Lydon (Wash.)*, 16 P. (2d) 848.

Hernia and Lymphatic Leukemia Attributed to Trauma.—Jan. 12, 1931, a wagon driven by Stanley Witkowski was struck by an automobile operated by the defendant. Witkowski received lacerations about the head, face, mouth, lower lip and tongue and was severely injured over a large area of the abdomen and right thigh. He remained in bed from the date of the accident until Feb. 1, 1931. No physician saw him during that period, except a physician sent by the defendant to examine him, who, according to the record, seems to have found merely that the patient's lip was infected. February 1, a physician found the patient acutely ill, with considerable swelling and infection of his mouth and tongue, very extensive contusions of the abdominal wall, marked ecchymosis on the right side, and a hernia in the right inguinal region. Witkowski was taken to a hospital, February 2. February 9, an operation for hernia was performed, and on that day symptoms of anemia appeared. June 20, he was readmitted to the hospital, his physician having determined that he was suffering from lymphatic leukemia. He died, Jan. 6, 1932, his death being attributed to that disease. Witkowski's executrix prosecuted the suit he had begun, and the jury gave a verdict in her favor. The defendant appealed to the Supreme Court of Errors of Connecticut.

The defendant claimed that the evidence did not show that the hernia was caused by the accident. In addition to the testimony as to the decedent's good health before the accident and his physical condition and pain in the region of the lower abdomen immediately after it and up to the time of the operation, said the Supreme Court of Errors, the physician who operated expressed the opinion that the hernia was caused by the accident. The lymphatic leukemia from which Witkowski died was attributed by the witnesses for the defendant to causes other than the accident, but physicians for the plaintiff were of the opinion that the accident caused it, through the resultant infection of the wounds of the lips and mouth. They testified not that the disease might have resulted or was likely to have resulted from the injury but in substance that in their opinions, taking into consideration all the facts presented and considering every other hypothesis suggested, it was reasonably probable that the disease did result from it and that the injury was its direct cause. Such testimony is sufficient, said the court, to remove the case from the realm of speculation and to present a question of fact to be determined by the jury, and the trial court did not err in refusing to set aside the verdict.—*Witkowski v. Goldberg (Conn.)*, 163 A. 413.

Sheriff's Liability for Hospital Services for Prisoners.—McNabb and Peterson, while committing a crime in Hamlin county, were seriously injured in an automobile accident. Bystanders took them to the plaintiff's hospital in an adjoining county. The sheriff of Hamlin county apprehended the injured men at the hospital and placed guards in the hospital and kept them there until his prisoners could be removed. The hospital sued the sheriff and Hamlin county for services rendered, including the cost of housing and feeding the guards. The trial court gave judgment in favor of both the sheriff and the county, and the plaintiff hospital appealed to the Supreme Court of South Dakota. Under the statutes of South Dakota, said the Supreme Court, it is the duty of the sheriff to confine prisoners in the county jail and to provide for their necessities, including medical attention and nursing. If he cannot furnish adequate attention in the county jail, he may place his prisoners under proper safeguards where they can have that attention. Regardless of how the prisoners in the present case came into the hos-

pital, from the time that the sheriff apprehended them their continuance there was the act of the sheriff. When he permitted his prisoners to remain in the hospital he announced by his conduct that he was adopting that method of furnishing the care that it was his statutory duty to provide. He was therefore held to be liable for the expenses thus incurred. The county, the court thought, may be liable to the sheriff for any money he reasonably expended in caring for his prisoners, but the hospital had no direct claim against the county. The judgment of the trial court in favor of the county was therefore affirmed, but the judgment in favor of the sheriff was reversed.—*Bartron Clinic v. Kallemeyn, Sheriff (S. D.)*, 245 N. W. 393.

COMING MEETINGS

- American Academy of Ophthalmology and Otolaryngology, Boston, September 18-22. Dr. William P. Wherry, 1500 Medical Arts Building, Omaha, Executive Secretary.
- American Association of Physicians, Gynecologists and Abdominal Surgeons, Philadelphia, September 11-14. Dr. Magnus A. Tate, 1 W. 4th St., Cincinnati, Secretary.
- American Association of Railway Surgeons, Chicago, August 10-12. Dr. Louis J. Mitchell, 29 East Madison Street, Chicago, Secretary.
- American Congress of Physical Therapy, Chicago, September 11-15. Dr. F. B. Balmer, 185 North Wabash Avenue, Chicago, Secretary.
- American Roentgen Ray Society, Chicago, September 25-30. Dr. Eugene P. Pendergrass, 3400 Spruce Street, Philadelphia, Secretary.
- Association of Military Surgeons of the United States, Chicago, September 25-27. Dr. J. R. Kean, Army Medical Museum, Washington, D. C., Secretary.
- Colorado State Medical Society, Colorado Springs, September 14-16. Mr. Harvey T. Sethman, 537 Republic Building, Denver, Executive Secretary.
- Idaho State Medical Association, Twin Falls, September 18-19. Dr. Harold W. Stone, 105 North Eighth Street, Boise, Secretary.
- Indiana State Medical Association, French Lick, September 25-27. Mr. T. A. Hendricks, 23 East Ohio Street, Indianapolis, Executive Secretary.
- Kentucky State Medical Association, Murray, September 11-14. Dr. A. T. McCormack, 532 West Main Street, Louisville, Secretary.
- Michigan State Medical Society, Grand Rapids, September 12-14. Dr. F. C. Warnshuis, 148 Monroe Avenue, Grand Rapids, Secretary.
- Ohio State Medical Association, Akron, September 7-8. Mr. Don K. Martin, 131 East State Street, Columbus, Executive Secretary.
- Utah State Medical Association, Salt Lake City, September 14-16. Dr. L. R. Cowan, 305 Medical Arts Building, Salt Lake City, Secretary.
- Washington State Medical Association, Seattle, August 28-30. Dr. Curtis H. Thomson, 1305 Fourth Avenue, Seattle, Secretary.
- Western Branch Society, American Urological Association, Vancouver, B. C., August 3-5. Dr. George W. Hartman, 999 Sutter Street, San Francisco, Secretary.

SOCIETY FOR THE PREVENTION OF ASPHYXIAL DEATH

New York State Conference on Problems Relating to Death from Asphyxiation, held in New York, May 24, 1933

(Concluded from page 314)

The Practical Application of Laryngoscopy and Gas Therapy in the Treatment of the Asphyxiated

DR. EDMUND B. PIPER, Philadelphia: The subject of asphyxia is one of the gravest importance. We of the medical profession are naturally more liable to concentrate our studies on asphyxia neonatorum; but as we must deal with asphyxia resulting from anesthesia in the surgery of women, we must necessarily have some knowledge of the treatment of adults. Unfortunately, the teaching of some subjects in medicine has come down to us as a sort of bankrupt inheritance. Some of these teachings have been utterly fallacious and modern thought should have supplanted them many years ago. There is no place in medicine where this is more true than in certain recognized, accepted methods of resuscitating the new-born.

Let us consider some methods taught me as a student and which I taught some years ago myself. The most annoying is the method of spanking the baby. I can conceive that no harm can come from spanking a child where it should be spanked, but this method has grown to the extent of spanking the baby in the back, which occasionally may be over the kidney region or in the lumbar region, instead of possibly in the back over the lung. I doubt whether any spanking is of particular benefit. However, I make it a rule to spank my grandchildren when they arrive in the world, but it is always

in that locality in which the Almighty intended it should be done. Recalling the inexcusable methods of resuscitation, there comes to mind the method of having in the delivery room a tub of hot water and a tub of cold water. When the infant failed to breathe it was often placed into the hot and then immersed in the cold tub; then back into the hot tub, and so on. The cold tub has been eliminated from the delivery rooms of hospitals with which I am connected.

Possibly the application of electricity in the form of the faradic current may be of some benefit, but I question it. The various types of artificial respiration used in adults are also of questionable efficiency in the new-born. Mouth to mouth insufflation may, in some instances, aid in the resuscitation, but I believe we sometimes blow up the stomach instead of the lungs. Schultze's method of waving the baby around in the air which, incidentally, used to be one of my favorite methods, is, in my opinion, of very doubtful value. Of those aids in resuscitation which have been instituted in the last twenty years, probably the oldest and at one time considered the best was the infant lung motor. I have seen this work with a considerable degree of success, but it is not comparable to some methods brought out in the last four or five years.

What may be considered the actual causes of asphyxia neonatorum? The causes may be divided into three groups:

1. Asphyxia proper, occurring during delivery from such complications as prolapse and compression of the cord, abruptio placentae, or any condition cutting off the blood supply through the cord. A plug of mucus or other obstruction in the air passages, making it impossible for the baby to breathe following birth would, of course, give the same picture. This type of asphyxia is perhaps least often encountered in my services. Our breech presentations, when section is not considered, are extracted almost as a routine as soon as the cervix is fully dilated and effaced. In this manner one is more likely to obviate prolapse of the cord.

2. Injury and shock, particularly intracranial injury from prolonged pressure and trauma in protracted labors. I am convinced that in cases of intracranial injury following forceps delivery the injury may have occurred from protracted labor before the forceps were even sterilized. Unfortunately, for statistical reasons, delivery by forceps is almost invariably charged with the incidence of intracranial hemorrhage. In this type of asphyxia, one is dealing with an injured central respiratory control apparatus, and the prompt application of the general principles underlying the resuscitation of asphyxiated babies is of great importance.

3. Narcosis, or the effect of drugs given the mother before delivery which may have a narcotic action on the infant. In this group must be considered the babies narcotized or anesthetized by the anesthetic given the mother before operative delivery is attempted. One is bound to deliver a baby which is slow to cry when a deep ether anesthesia follows too closely on morphine used in any analgesic combination. This is the type of asphyxia seen most frequently when the operative incidence is great.

This is a matter which should be investigated. We clinicians have observed that almost invariably, following the use of morphine in women in labor, the offspring tends to be difficult to revive should a woman deliver under three hours after the morphine has been given, particularly if she receives any method of inhalation anesthesia during the actual delivery. On the other hand, those women delivered under spinal anesthesia or by cesarean section under local anesthesia apparently may receive morphine hypodermically within fifteen or thirty minutes of the time of delivery.

I agree with De Lee that the "three grand principles underlying the treatment of asphyxia neonatorum" are to (1) clear the air passages, (2) maintain body heat and (3) supply oxygen to the blood.

A few years ago an infant-sized model of the Drinker apparatus was devised by Dr. Douglas Murphy in conjunction with Dr. Drinker. This apparatus has been of great value but after some years of observation I have come to the conclusion that this method of resuscitation, based on the principle of a vacuum, can be of no value in cases in which there is blocking by a mucus plug or in which there is a definite condition of atelectasis. On the other hand, I am convinced that

the Drinker apparatus for infants is of great value for the reviving of the new-born infant which has once had normal respiratory action.

I know of no resuscitation methods or equipment which are so nearly ideal as that designed by Dr. Flagg. One is enabled, under sight, to clear thoroughly the air passages of mucus without danger of injury to the delicate infantile vocal apparatus. Next, one is able to supply the sensitizer and respiratory hormone, namely, oxygen and carbon dioxide, directly into the trachea under absolute pressure control. Almost immediately the faltering heart picks up, the color improves and precious seconds are saved. And seconds literally may decide the fate of the infant, because irreparable harm to the nervous system occurs very quickly in extremes of asphyxia. The Flagg apparatus stands in my delivery rooms ready for instant use, and each of my residents is trained in its use.

Within the past week I have had a remarkable illustration of the value of the Flagg apparatus in the adult. The patient, with a large fibroid tumor, was brought into the operating room under ether inhalation anesthesia. Just as the abdomen was opened she stopped breathing. Artificial respiration was instituted, with the result that after two minutes the patient commenced to breathe again. The hysterectomy was started, and again within two minutes the patient stopped breathing and, although her pulse remained fair, she made no respiratory effort. I finished the hysterectomy and closed the abdomen under artificial respiration, my two assistants taking turns working through sterile covers while I finished. As I was about to close the skin, one of the staff suggested that we try the Flagg apparatus with the adult laryngoscope. We had never before tried the apparatus on the adult. Within thirty seconds after the laryngoscope was placed and the apparatus began to function, the patient started to breathe and soon afterward was returned to the ward and has made an uneventful recovery to date. As to the cause of this asphyxia, I am not prepared to say. All that I know is that the combination of carbon dioxide and oxygen started her breathing normally, after fifteen or twenty minutes of definite artificial respiration.

I feel justified in drawing the following conclusions on which the work of resuscitation in my services is carried out:

1. Most of the old methods of reviving the new-born infant suffering from definite asphyxia neonatorum may and should be abandoned.

2. For asphyxia occurring in the infant in the first few days of its life, granting that it has breathed for some time normally, it would seem that the Drinker apparatus is of very considerable value.

3. For the resuscitation of new-born infants who do not breathe, the Flagg apparatus in the hands of properly trained house surgeons is now the best method of treatment of asphyxia neonatorum.

DISCUSSION

DR. H. J. STANDER, New York: In approximately 2,000 deliveries in eight months the Flagg apparatus has been used, and insufflation in fifty-one cases in which it was quite essential that some such method should be employed. I had a patient whose father-in-law was anxious that I deliver the baby at home. He said he would get all the nurses and facilities I needed. He came in later and said they had discussed the matter and decided to have me do it at the hospital. The father-in-law laid down the law. He told me it was his belief that a great number of babies are lost in hospital obstetrics, and certainly this baby was not going to be lost. The baby came in a posterior position. The head would not rotate. After three hours of second stage labor the heart started to go bad. Ultimately I decided to do the Scanzoni method of rotation, which was successful. The forceps application was simple. The baby lay and would not breathe. Fortunately, Dr. Flagg had been in the clinic two or three months previously and he had instructed the resident and the nursing staff in the use of the apparatus. The baby lay there for about five or ten minutes. I had a vision of this gentleman coming back into my office. The anesthetist got the apparatus, removed a plug of mucus from the throat of the baby and the respiration was begun. There is one further point I should like to mention. In the last month two deaths have occurred from aspiration pneumonia. I lay this before this society as one of the problems in obstetrics.

Principles and Applications of Differential Pressures

DR. POL N. CORYLLOS, New York: The following conclusions can be drawn: First, when the intrapleural pressure becomes equal to atmospheric, the lung remains collapsed, and, second, the intrapleural pressure varies with the variations of the ability of the lung to expand and to retract. Thus, when the lung cannot expand, as in atelectasis or fibrosis, the intrapleural pressure will become more negative; on the contrary, when the lung cannot retract, as in emphysema, the intrapleural pressure will become less negative. Weber, Straub and lately Birnbaum and I have proved that collapse of the lung, whatever may be its cause and origin, is always accompanied by a marked decrease in the circulating blood in the affected lung. This point is of paramount importance in the explanation of dyspnea and cyanosis following pneumothorax. In unilateral pulmonary tuberculosis the oxygen content of the arterial blood increases after the diseased lung is collapsed by means of artificial pneumothorax. It is immaterial whether air has entered the intrapleural space through an opening of the chest wall or through an opening, traumatic or pathologic, of the lung. It is equally without importance whether it is air or fluid that fills the pleural space. The important factors are the volumes and changes produced by them in the intrapleural pressures. With a large opening of the chest wall, air will rush into the pleural cavity; the lung will collapse and ventilation in that lung will cease; a number of phenomena will occur; namely, paradoxical respiration, pendulum air movement and especially mediastinal flutter. On the side of the open chest, air will enter the pleural cavity through the opening. On expiration, both hemithoraces collapse, the diaphragm rises, and the capacity of the chest cavities decreases. Air is expelled through the trachea from the lung of the healthy chest, whereas in the open chest the air filling the pleural cavity rushes out through the opening of the chest wall. This inrush and outrush of air through the chest wound constitutes the so-called traumatopnea. When the opening of the chest wall is small, as compared to the opening of the glottis, the lung will be able partially to expand and collapse during respiration. When a valve mechanism is present in the opening, allowing the air to enter during inspiration but not to be expelled during expiration, the dangerous complication called tension pneumothorax can develop, in which the intrapleural pressure becomes positive.

Changes occur in the mediastinum during unilateral open pneumothorax. During inspiration it is displaced toward the healthy side, since the intrapleural pressure on that side becomes more negative in inspiration; this displacement of the mediastinum encroaches on the size of the healthy chest and thus interferes with the inspiratory inflation of his lung. Conversely, during expiration the mediastinum is displaced toward the pneumothorax side and thus hampers the expiratory deflation of the healthy lung. In that way both inspiratory inflation and expiratory deflation of the good lung and consequently the renewal of air in it becomes deficient, so that oxygenation and elimination of carbon dioxide are impaired. This phenomenon is designated mediastinal flutter. Furthermore, during inspiration the little air contained in the collapsed lung is sucked into the good lung, and during expiration a part of the air expired from the healthy lung passes into the collapsed lung. Thus the collapsed lung expands during expiration and collapses during inspiration, giving rise to the pendulum movement of the air and so-called paradoxical respiration. This is especially marked during the forceful expiratory movements, as in coughing. Last but not least, sudden changes in the size of the collapsed lung produce corresponding sudden changes in the pressures in the large vessels and the heart, especially the right auricle, which may lead to disastrous results.

It is thus obvious that the degree of respiratory disturbances following open pneumothorax depends largely on the mobility of the mediastinum. With a rigid mediastinum, an open unilateral pneumothorax is without any marked ill effect. When the mediastinum is very flexible, the effects on the good lung are almost similar to the ones observed in bilateral pneumothorax. The unfortunate thing is, as Willy Meyer put it, that one cannot always know in advance with the desired degree of certainty which patients possess a rigid mediastinum. Oxygenation of the hemoglobin in open pneumothorax becomes defective

for three reasons: First, the respiratory and circulatory fields have decreased. Second, in the collapsed but not atelectatic lung, circulation is still going on so that blood passing through nonaerated channels arrives at the left heart not oxygenated and thus pollutes the systemic blood. Third, anoxemia acts on the nerve cells of the respiratory center and gradually leads to its fatigue; this is manifested by the lowering of the threshold of its excitability to carbon dioxide, causing rapid shallow breathing, which, in turn, causes excessive elimination of carbon dioxide from the alveolar air and the blood. Thus, acapnia (Henderson and Haggard) is added to anoxemia, further increasing the ill effects of the latter and causing lowering of the blood pressure by peripheral vascular failure (Eppinger) and by inhibition of the venopressor mechanism (Henderson). The amount of venous blood arriving at the right heart is decreased, and, as in excessive hemorrhage, leads to cardiac fatigue, as the heart contracts on an insufficient amount of blood. These phenomena can be greatly or totally relieved when oxygen with carbon dioxide is administered under high partial pressures. In the last analysis, the ill effects of an open pneumothorax depend on and are regulated by the changes of the intrapleural pressure and of the partial pressures of oxygen and carbon dioxide in the alveolar air, the blood and the body tissues.

Prevention and cure of the ill effects that follow open pneumothorax can be obtained in the following ways: 1. By rendering the intrapulmonary pressure higher than atmospheric. This is obtained by placing the head of the patient in a box in which the atmospheric air is maintained at from 10 to 15 mm. of mercury over the outside pressure. This is the positive pressure method. 2. By placing the body of the patient in a chamber in which a pressure of from 10 to 15 mm. below the outside atmospheric pressure is maintained. This is the negative pressure method. It is obvious that both these methods will counteract collapse of the lung although the chest is wide open. 3. By intratracheal insufflation, which is based on the same principles as the positive pressure method. The same result is obtained by applying, in an air-tight manner, an ordinary anesthesia mask on the mouth of the patient and administering air or any mixture of gases under positive pressure. 4. By raising the partial pressure of oxygen; that is, by increasing its percentage in the respired air.

A study of the different devices for differential pressures permits the formulation of a number of conclusions:

1. All elaborate and cumbersome apparatus have become unnecessary and obsolete. The only forms of differential pressure in use today are the mask method, with positive pressure, and endotracheal insufflation.

2. These methods are so closely connected to the administration of anesthesia that they can hardly be separated from it. This is especially true in intrathoracic surgery, in which the success of the operation depends in a great part on the skill and knowledge of the anesthetist.

3. In the group of "differential pressure procedures" belong the methods devised for resuscitation of patients in whom respiration has failed. The life of these patients depends entirely on the skill of the rescuer. As it was shown, it is not a mere question of routine. The accurate diagnosis of the form of asphyxia will dictate the method to be used. The time at one's disposal in these cases is short. It is measured by minutes and often by seconds. Immediate action adequately adapted to the case should be installed without loss of time and skillfully carried on.

4. From the foregoing it becomes obvious that, in the constantly enlarging field of gas therapy, there is need of men with special training, scientific and practical, who will be able to carry on and to develop further this new branch of treatment. These men must have an extensive knowledge of the physiology and the pathologic physiology of respiration and circulation, of the physiologic properties of the gases used and of the technic of their administration.

It seems, therefore, that the men prepared for this work are the anesthetists, provided they complete their general training by the highly specialized physiologic knowledge indicated. The effort that is being made today, and this symposium is a proof of it, shows that the point is near at which the anesthetist of today will develop into the gas therapist of tomorrow and will

assume the leadership in this new branch of therapeutics. I believe that these men will advance and perfect the treatment which is insured today by the emergency squads and the life savers. Whatever may be the team training, the courage and devotion to duty of these men, they are not always sufficient to replace scientific knowledge and scientific training.

DISCUSSION

DR. HORATIO B. WILLIAMS, New York: In thinking of asphyxial death it is a good plan to think of it a little more broadly than as just a matter of the movement of the chest and diaphragm and the passage of air in and out of the lungs, because essentially the circulation and the respiration are one function so far as respiration is concerned. In many cases in which artificial respiration is indicated there is also trouble with the heart, and sometimes this may be the primary thing. If the heart stops for any reason or goes into fibrillation, the respiration will stop presently, because no blood will be transferred to the center. Whether one can resuscitate such a patient depends largely on whether one can maintain a small supply of aerated blood through his respiratory center and through other important centers in the central nervous system until such time as the heart can be got going. No matter how well artificial respiration is performed, if the circulation is absent for a comparatively short time from the nerve cells in the central nervous system the patient will never live a normal life again. The great drawback to the type of artificial respiration apparatus that is used mostly in the physiologic laboratory is the fact that the use of this sort of equipment on patients can easily result in damage. It isn't at all hard to rupture the lung with a little too much pressure. Also another thing that can happen: We were using the insufflation of anesthesia method in the laboratory, and we had a manometer to control the insufflation pressure. On one occasion, we were surprised to notice that the blood pressure had dropped to zero suddenly. The insufflation pressure had risen enough so that the lungs were distended, and the circulation in the lung capillaries was completely cut off. If the circulation in the lung capillaries has been cut off, the whole circulation has been stopped. It doesn't require a great deal of pressure to distend the lungs enough, and in that way it embarrasses circulation. Only artificial respiration apparatus of the type in which air is forced in and out is going to be used by other than skilled physicians. It is going to be dangerous to use that type of thing unless it can be in the hands of very skillful operators. On the other hand, the method of putting a person in a negative pressure chamber seems to be about as safe as any procedure could be.

Practical Application to the Hospital and the Public

DR. JOHN F. McGRATH, New York: It is evident that death due to asphyxiation presents a major problem. To meet the high mortality and economic loss, it has been necessary to depend on the comparatively unsupported efforts of lay groups. It has been shown, however, that simple and direct methods of treatment by the physician may become available by a brief period of instruction and practice. The technic of laryngoscopy, suction and intubation performed with ordinary care is entirely nontraumatic. It is only by these procedures that adequate and immediate relief may be obtained for the completely asphyxiated emergency patient. It is only by this technic that oxygen and carbon dioxide may become immediately available to the impeded circulation and the depressed respiratory centers.

The foregoing consideration suggests the necessity of a coordinating agency whose duty it shall be to integrate and disseminate the facts bearing on the subject of asphyxiation. The Society for the Prevention of Asphyxial Death has been chartered for the purpose of bringing about this coordination. As a charitable organization it has no interest whatever in the sale or the popularization of any form of equipment. It is entirely nonpartisan in its medical and other affiliations, and because of this neutral position it is free to function for the direct relief of the asphyxiated patient.

By this conference, the Society for the Prevention of Asphyxial Death makes its first formal appearance as a national organization. The society plans to proceed by coordinating three broad lines of action: research, instruction and practice.

1. The coordination of research is to be accomplished through (a) the research departments of medical schools and universities, (b) the research departments of major utility corporations, (c) the research departments of private institutions and (d) the research departments of the federal and municipal governments.

Physical, chemical and biochemical problems bearing on asphyxial death will be proposed for solution to research groups at liberty to pursue the question at issue. It is hoped that funds will in time become available to underwrite the cost of such research. The results will be given wide publicity, first, through the organization contacts of the society, and secondly, by the second large activity to be encouraged; namely, instruction.

2. Instruction of first-aid methods to the layman and medical instruction to the untrained intern and practitioner presents one of the largest problems in the reduction of asphyxial death. It is hoped that this problem may be solved as follows:

(a) Publicity and continually increasing contacts are to be afforded the organized work of the Red Cross, the police department, the fire department, the Consolidated Gas, and other lay groups.

(b) Pending such time as the curriculum of the medical schools will permit of adequate instruction in modern methods of gas therapy, an effort will be made to supply such instruction to interns and practicing physicians. It is hoped that arrangements may be made whereby comprehensive lectures combined with thorough instruction and demonstration in this subject shall become available through the medical departments of the army, the navy and the Red Cross.

Hospital members of the society will be entitled to receive such instruction and supervision without additional cost.

3. Practice will bring in contact the physician and other persons who actually provide relief to the asphyxiated patient in the operating room; in the wards, in the ambulance, in general practice, in marine and industrial occupations, dentists in the course of their practice, and operating room nurse-technicians.

Clinical membership will be honorary and will be based on at least one authenticated rescue. The research, instruction and practice will become immediately available for the groups of institutions and corporations making up the membership of the Society for the Prevention of Asphyxial Death.

It will be of interest to consider the proposed organization of a coordinating agency. Groups representing common interests may be assembled as in the form of sections. For example, it is proposed to assemble a section on civic cooperation, on insurance, on medical schools, on carbon monoxide poisoning, on electrical shock, on submersion, on anesthetics, on equipment, and on other subjects. These sections will function as follows: The section on instruction, for example, would include the medical department of the army, the navy, the Red Cross and associated medical schools. It may have close contacts with the section on research. The section on carbon monoxide poisoning, consisting of gas companies, automotive engineers, mine operators, and so on, may be coordinated with the sections on research and instruction in order that it may receive without delay the conclusions of the biochemists made available through the section of instruction and the section of equipment. The section on anesthetics will be in direct contact with the section on research, on instruction and on equipment and will cooperate with the section on surgery, whose duty it will be to deal with the operative relief of extreme degrees of asphyxiation as it may be encountered in Ludvig's angina, laryngeal obstruction, and by infection inside and outside the airway, prescribing and demonstrating the operation of choice for emergency tracheotomy. And so through the section on insurance, on electricity, on asphyxia neonatorum, on submersion, on statistics, on hospitals, on civic cooperation, through cooperation will come mutual help.

The function of the society is to strengthen and deepen the effects of every agency now interested in the prevention of asphyxial death. As an initial activity designed to enlist civic cooperation and to clarify practice, it is proposed to establish a demonstration-medical ambulance service attached to a centrally located hospital.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

*Simple Mastoid Operation. J. A. Keyton, Dothan.—p. 350.
Malaria and Paresis. J. N. Baker, Montgomery.—p. 353.

Simple Mastoid Operation.—Keyton states that the simple mastoid operation should be done early in the course of the disease to avoid the dangers of delay while waiting for more definite indications for surgery. It is not necessary to perform mutilating operations in this region if early diagnosis is made and the surgeon is not afraid to risk his judgment on his diagnosis. Simple drainage will cure the disease usually, leave no scarring to mark the site of trauma and will materially lessen the patient's stay in the sickroom or on the invalid list. The author considers the following method a sufficient operation: The skin wound is from 2.5 to 3 cm. in length, and the superficial wound is crossed at intervals with horizontal scratches for later apposition of the skin edge. The cortex is removed gently with the gouge and when the first pneumatic cells are entered a small sharp curet is used to enter the mastoid antrum, which is then irrigated with physiologic solution of sodium chloride. When adequate drainage of the antrum has been ascertained and the cells adjacent to the entrance tunnel have been explored, the bony dissection is carried far enough into the tip to assure drainage from the most dependent point. Instillations of mercurochrome or other suitable germicidal agent into the wound follows thorough irrigation of the wound cavity, the antrum and the middle ear. After this thorough cleansing and medication, the skin wound is closed with silk-worm sutures spaced closely enough to get good approximation of the wound edges, a gauze wick being brought out at the most dependent point. The wound is dressed daily, and as soon as possible the auricle is excluded from the dressing for frequent irrigation and medication of the middle ear space.

"Pellagra-Producing" Diet.—Spies and Grant's experiments show that the restricted diet administered to pellagrins with improvement of their skin lesions is inadequate for the proper nutrition of young rats. These animals develop the characteristic appearance of vitamin G deficiency when they are given the basal diet alone or the basal diet and casein. They are protected from this condition by the administration of the basal diet and supplements of either desiccated hog stomach or yeast. Desiccated hog stomach possesses striking therapeutic properties, as demonstrated by the rapid and apparently complete recovery of the animals from this deficiency following the administration of desiccated hog stomach. The correlation of the results obtained in the authors' experiments with those showing that desiccated hog stomach is curative for pernicious anemia suggests that the substance in desiccated hog stomach which protects the animals from this inadequate diet may be vitamin G or some closely related substance, and that this material is possibly the extrinsic factor that Castle has discussed in the development of the deficiency state of pernicious anemia.

Studies in Human Neuromuscular Mechanism.—According to Bucy and Buchanan, the theory of "autogenous inhibition" as an explanation of the "lengthening reaction" rests on too little evidence to warrant the wide acceptance which it is accorded, although tension which actually endangers the integrity of the muscle and its attachment may produce inhibitory afferent impulses capable of protecting the muscle. A theory which they have termed the "subsidence of afferent flow," originally conceived by Fulton and Pi-Suñer and supported by others, that is, that during muscular contraction induced by a single break shock there occur two volleys of afferent impulses, the first with the onset of contraction and the second during the period of relaxation, explains the cessation of action currents during active contraction of the muscle. This theory not only will adequately account for the "lengthening reaction" but also explains many of the phenomena seen during the muscular response to the stretch reflex in human skeletal muscle. It has the advantage over the theory of "autogenous inhibition" that it does not require the addition of further theoretical mechanisms for its explanation.

Methylene Blue as an Antidote.—Brooks states that injections of methylene blue into rabbits after the administration of carbon monoxide gas showed that methylene blue in an antidote for carbon monoxide poisoning. In one experiment, the animals were allowed to breathe carbon monoxide gas until respiration had stopped. After from thirty to forty-five seconds, depending on whether respiration ceased before six minutes or not, injections of methylene blue were given intravenously and artificial respiration was begun by means of a respirometer. The author observed that 20 per cent of the controls recovered, whereas 90 per cent of the treated animals recovered. The dye was effective only while circulation was still in progress. It required from two to six minutes for the animals to recover, and nine minutes in one instance.

Antirachitic Activation of Milk.—Supplee emphasizes the fact that, since milk is the sole or major article of the diet of every child during the age of greatest susceptibility to rickets, the desirability of having available a milk containing an adequate amount of vitamin D for the prevention or cure of rickets is at once obvious. Such a product would provide a new type of prophylaxis, simple in application, economical and entirely free from the inherent handicaps involved in the use of the better known specifics. Such an achievement presupposes the correlation and control of basic factors concerned in the irradiation technic. The industrial application of methods for the direct irradiation of milk must take into account numerous interrelated factors. Facilities must be provided for the exposure of large volumes of milk to suitable ultraviolet radiations within short periods of time. In order that the cost of the treatment may be kept to the lowest possible minimum, the accessory equipment must be simple in construction and susceptible of efficient and uniform operation without the necessity of providing especially trained or skilled labor.

Multiple Myeloma.—Flax believes that the following criteria constitute the most reliable basis for a diagnosis of multiple myeloma: 1. Clinically, the history of acute (or, less commonly, gradual) onset of pain in the bones of the trunk, a chronic nephritis without increased blood pressure or retention of non-protein nitrogen, the finding of Bence-Jones protein, and a progressive anemia. 2. In the roentgenogram, the widespread distribution of multiple, sharply circumscribed defects in the marrow cavities of the bones of the trunk with high incidence of pathologic fracture and deformity. Other diseases sometimes to be considered in the differential diagnosis are: 1. Osteomalacia, which usually occurs in pregnant women and never shows rarefaction in the cranial bones. The absorption of calcium salts is diffuse, whereas the rarefactions in multiple myeloma are localized. Deformities in osteomalacia are due to bending of the softened bones, but in multiple myeloma the deformities are due to poor alignment of true fractures. 2. Endothelioma, which, when multiple, may be confused with multiple myeloma because of the similar distribution in ribs, vertebrae, skull and cancellous portions of the long bones. It can be distinguished, nevertheless, from the radioresistant multiple myeloma in its sharp initial response to irradiation. Further, endothelioma more commonly occurs in younger persons. 3. Paget's disease, or osteitis deformans, which as a fibrotic degeneration of bone with subsequent recalcification shows in the degenerated areas diffuse striations and trabeculations with new bone formation. This reformation of bone is never observed in multiple myeloma. 4. Syphilis, which, in the form of disseminated lesions, always shows soft tissue reaction and adjacent bone production. 5. Lymphosarcoma of bone, which, although extremely rare, might be confused with multiple myeloma in the similar distribution. However, the individual tumors are more irregular and lack the "punched-out" appearance of multiple myeloma. 6.

Chloroma, which is considered to fall in the same category as multiple myeloma. Grossly, the sectioned chloroma presents a characteristic, iridescent greenish color, while the myeloma is red; also, in chloroma, sternal and substernal involvement is extensive. Chloroma occurs in younger persons and is associated with a leukemia.

Uterine Hemorrhage.—Bowring and his associates report the results they obtained in the treatment of 418 patients whom they treated with radium for benign uterine hemorrhage. Patients whose uterus was larger than that produced by a four and a half months pregnancy or which contained fibroid tumors forming a pelvic mass of this size were not accepted as a rule for treatment with radium. From this study the authors conclude that, for benign hemorrhage of the menopause not related to uterine fibromyoma, intra-uterine treatment with radium is practically a specific. The major contraindication is the history or the presence of adnexal inflammatory disease, and with this complication both vaginal and external treatment with radium has proved a safe procedure in a limited number of cases. Among patients of the younger age groups, bleeding can be controlled and the condition cured by intra-uterine application of radium in the majority of cases; however, in a small percentage of cases premature menopause will occur in the presence of hypo-ovarian function that is not recognizable beforehand. Therefore the possibility of permanent amenorrhea and loss of reproductive power must be explained to the patient before treatment, and it is wise to employ all possible medical and minor surgical measures first. If radium is used, a small dose should be given, with a repetition in a few months if the desired effect is not attained. If radium fails, the final recourse is surgery. In the treatment of fibroid tumors causing menorrhagia, the selection of cases is too conservative. Intra-uterine treatment with radium, in conjunction with external application of radium or roentgen rays, affords good results even with large fibromas and is worthy of consideration if the pelvis is otherwise normal and the surgical risk excessive. If the diagnosis is at all questionable, operation is preferable. There is also a large group of patients with fibromas whose hemoglobin is of low concentration and whose resistance is so diminished that they constitute poor surgical risks; treatment with radium and roentgen rays, if not curative in itself, will build these patients up so that they are more suitable for subsequent operation. Therefore in the control of menorrhagia one has three agents at hand, and the results obtained depend on the careful selection of the method of treatment in the individual case.

Treatment of Uterine Neoplasms.—Norsworthy states that, in benign uterine neoplasms, the chief method of treatment should be considered under four divisions: (1) observation, (2) operation, (3) roentgen rays and (4) radium. A uterine neoplasm producing no symptoms, especially if indurated and nodular, should be let alone and observed. Removal by operation is indicated in the majority of cases encountered in general practice. Neoplasms calling for removal by operation are: (1) those larger than a four months pregnancy unless the physical condition of the patient is a contraindication; (2) calcified tumors, (3) pedunculated tumors, (4) tumors associated with symptoms of impaction, (5) tumors accompanied by inflammatory or adnexal disease, (6) tumors associated with acute or chronic pelvic infection, and (7) some cases of definite neurasthenia (radium phobia). Myomectomy and subtotal hysterectomy are the two operations of choice. While myomectomy has a greater operative mortality, it should be favored in young girls and child-bearing women. When myomectomy and subtotal hysterectomy fail to relieve the chief symptom for which the operation was performed, that is, hemorrhage, radium is indicated. Radium applied within the uterus is indicated: (1) in small neoplasms accompanied by hemorrhage, (2) in selected cases of large neoplasms, and (3) in operative cases when the patient is too ill for an abdominal operation. Radium will control hemorrhage, produce the menopause, arrest the growth of the neoplasm and reduce its size and, in a large majority of cases, cause complete disappearance of the neoplasm. In young girls or child-bearing women, radium may be used to check excessive menstruation temporarily, care being exercised that permanent menopause or injury to the ovaries is not brought about. Hysterectomy should be considered only in cases in which myomectomy would be unsafe and in which radium is contra-

indicated, except in women who prefer removal of the uterus to the use of radium. Sufficient radium irradiation to check the growth permanently or to remove a tumor would probably destroy the ovarian function and should be carefully guarded in child-bearing women. The successful use of radium in non-malignant neoplasms of the uterus is largely dependent on accurate diagnosis, properly selected cases, correct graduation of dosage, and the technic of application. The author found radium to be uniformly satisfactory in 287 cases of benign uterine tumors. In his 287 cases, a vaginal discharge persisted for from three weeks to several months, but the discharge ceased eventually in all cases. There were no deaths. The minimum dose used was 400 mg. hours and the maximum 4,800 mg. hours.

Lingual Purpura.—Rattner reports a case of lingual purpura in which the lesions of the tongue were so unusual as to make a clinical picture with which he was entirely unfamiliar. The patient, a mulatto, aged 20, was bitten on the forearm by an insect. The following day, purpuric lesions developed on the tongue, buccal mucous membranes, lips, pharynx, shoulders and legs. The lesions on the tongue were vesicular. None of the lesions caused discomfort. When the patient was seen again in three days, those in the mouth had disappeared, leaving no traces, and those on the skin were undergoing resolution.

Creeping Eruption and Myiasis.—Bedford and his associates report a second case of cutaneous myiasis observed in Manitoba and due to the first stage larva of *Gastrophilus intestinalis*. "Creeping eruption" is not an etiologic entity. At least seven different parasites have been found to be the cause of this skin condition. First stage larvae of *Gastrophilus*, the botfly, have been recovered in less than a dozen cases and reported in the literature. These cases have been found in the temperate zone of the United States, in Canada and in European countries.

Larvae from cattle grub flies also cause a "creeping eruption." Their tumors are deeper and larger than the *Gastrophilus* infections. Nematode infection due to *Gnathostoma* has been reported from the Orient. The thousands of cases reported from the Southern states have been due to *Ancylostoma braziliense*, the dog and cat hookworm, and it is considered by some authors that this may be the etiologic factor in most of the cases reported from tropical countries. In treating the eruption due to the *Gastrophilus* larvae it is essential that the onward course of the parasite be blocked. The larva should be removed if it can be seen. If the parasite cannot be located, excision or cauterization of the active end of the lesion should be tried. The injection of from 1 to 2 cc. of a 3 or 5 per cent solution of phenol has been used. Freezing by means of the ethyl chloride spray and carbon dioxide snow has been advocated. As there is usually some secondary staphylococcal infection from scratching, the use of mild antiseptic applications, such as weak ammoniated mercury ointment, a 2 per cent solution of mercurchrome, tincture of iodine or surgical solution of chlorinated soda may be necessary.

Solanum Tuberosum.—During the last six months, Wright and Kirk fed twelve babies, varying in age from 6 weeks to 6 months, on diets containing a large amount of baked potato. The potatoes were baked in their jackets for two hours in the oven of an ordinary large coal range. Immediately before feeding, the potatoes were opened and as much as possible of the potato flour removed. The following rules were observed: 1. Modified boiled whole milk formulas with the addition of sugar were employed. 2. Every infant received daily one dessert-spoonful of cod liver oil with viosterol 10 D. 3. Potato flour was offered twice daily, the amount not being restricted. (No orange juice or other antiscorbutic food was given.) 4. Iron was given daily to prevent the development of food anemia. No unusual discomfort, diarrhea or vomiting was observed. No scurvy has as yet made its appearance. One infant seemed irritable and early scurvy was suspected, but roentgenograms yielded negative results. Frequent blood counts have failed to demonstrate anemia. On the basis of their observations, the authors conclude that the potato can be satisfactorily substituted for cereal in infant feeding, and that, when used in about the same amount as cereal is ordinarily employed, it prevents the occurrence of scurvy.

Treatment of Sexual Immaturity.—Sevringhaus and Thornton gave twenty-three women who were sexually infantile, or had had long periods of amenorrhea or oligomenorrhea, concentrated preparations from human pregnancy urine. At least ten of the patients were stimulated to more regular and copious menstruation. Results were doubtful in seven and negative in six others. Hirsutism in fourteen of these women was not relieved. The urine extracts were given hypodermically five times daily. Each injection consisted of 1 cc. They were given for the first five days after the cessation of each menstrual period. When no menses were present to fix a time, the treatment was given at intervals of four weeks, five days at a time. The authors advise too little rather than too much treatment, since urine extracts are known to contain factors that stimulate luteinization and may cause the formation of atretic follicles. The only local reaction to the use of this

lifted up from the chest wall to serve as a handle. The dissection is continued until the entire muscle is detached, enabling the surgeon to detach and lift up the entire mammary gland without handling it at any time. The pectoralis minor muscle is next removed in a manner similar to that of the major. The cut surfaces of the muscles are carefully seared and further protection by warm pads now becomes necessary. The next step consists in the anatomic cleaning of the axilla. The authors insist on primary exposure of the axillary vein for a distance of about 2 inches, and block dissection of the axillary space. All branches of the axillary vein and artery, which run almost perpendicular to the direction of the vessels, are clamped with mosquito forceps and ligated with 00 catgut. Dissection is started from the axillary vein toward the axillary pit and the upper end of the arm, taking everything in its course except the respiratory nerve of Bell. The entire mass is removed. Additional cleaning of fat now becomes necessary above the axillary vein and perhaps toward the insertion of the serratus magnus muscle. This completes the essentials of the operation, as it presumably removes all the local pathologic structures. The cut surfaces of the pectoralis stumps as well as their surfaces are seared again. Finally the lower part of the incision is gone over with the high frequency knife until the upper end of the rectus muscle is exposed. Fascial coverings are incised with the knife perpendicular to the long axis of the rectus muscle, curving the incision inward and outward until the chest grooves are encountered, in order to cut off lymphatic connections between the sheath of the rectus muscle and the chest wall. A stab wound is made in the flap of the axillary line and a large cigaret drain inserted. The skin is approximated with silkworm gut only at two points, the rest of the incision being put on stretch and approximated with skin clips. The authors believe that the removal of the breast without handling it at any time obviates carcinomatous implants. Sealing all the margins of the incision and cutting off the fascial connections with the serratus magnus and especially the rectus muscle insures against local recurrence and early atypical lymph node metastases, such as those in the liver and pleura.

Treatment of Peptic Ulcer with Okrin.—Although the observation of Jones and his associates on the effect of okrin treatment in three patients suffering from intractable peptic ulcer has been of short duration, they believe that the results will be of interest. Because okrin relieved pain in their three patients who were not being relieved by other treatment, they believe that it has a palliative action which may be of value. The material was prepared as follows: Okra pods were washed and then ground in a food chopper, and the ground material stirred into ten volumes of warm water. After the mixture had been allowed to stand from one-half to one hour, it was strained through muslin. The residue was soaked again in water and strained. The extracts of the two strainings were combined, and 95 per cent ethyl alcohol was added to make a 50 per cent alcohol solution. The mucilaginous material gathered into long, tough strands, which were worked together and removed from the solution. This material was washed repeatedly with 95 per cent ethyl alcohol, then ground in alcohol, filtered from the alcohol, and washed with ethyl ether. It was necessary to remove the alcohol completely and quickly to keep the finished material from becoming insoluble. The material was dried and ground in a mortar to a fine gray powder. The amount of okrin given was a teaspoonful in water or milk every hour while the patients were awake. Pain, abdominal tenderness, nausea and vomiting disappeared in from two to three days.

Effect of Silicate Dusts on Lungs.—Dreesen studied the effect of silicate dusts on sixty-one men employed in tremolite talc and eighty in slate plants. In the clinical examination of

the tremolite talc group of workers, no cases were encountered that presented symptoms or signs of active pulmonary tuberculosis; and in the slate group only one person had clinically active pulmonary tuberculosis. Bronchitis was present in only 5 per cent of each group. No cases of cardiac decompensation were found. Disorders of the upper respiratory tract and enlarged tonsils were present in about the same proportion as is observed in the industrial population generally. In interpreting the roentgenograms, designation of the first, second or third stage of pneumoconiosis was made. Of the forty-eight cases of pneumoconiosis, all except five were in the first stage. The pneumoconiosis observed in the early or first stage cases resembled that induced by cement dust. The bronchial striations, however, were somewhat more prominent. There was always a moderate bilateral increase in the size and density of the hilar shadows with accentuations of bronchial striations, which extended well out into each lung field. The linear striations seemed "softer" in appearance and lacked some of the sharpness of detail that is usually observed in the roentgenograms of persons who have inhaled silica dust. This diffuse, fine, generalized fibrosis was chiefly confined to the lower two thirds of the lung fields.

Postoperative Antisepsis: Preliminary Report on Use of Ambazin with Series of Controls. M. Sabel, Philadelphia.—p. 491.

Study of the Vas Deferens.—Wolbarst's study of the vas deferens deals with two phases of the subject: a type of sterility due to stenosis of the vas without pathologic changes at either end, or to the isolation of pathogenic organisms in the vas. It is based on 124 vasotomies done in the last five years. In seventy-nine cases there was a history of gonorrhea. In all but twenty-seven cases, pathologic changes in the vesicles were distinctly evident and constituted the main indication for the vasotomy. Sterility was the complaint for which treatment was sought. The striking feature of these cases was the fact that there was no history or evidence of gonorrhea or other urethral infection. The vesicles were declared "apparently" normal owing to the absence of physical abnormality when examined by rectum, the absence of pus in an appreciable amount in the expressed vesicular secretion, and the absence of gross pathologic changes in the verumontanum and posterior urethra on urethroscopy. As all the patients were vigorous men between 25 and 39 years of age, it was concluded that the absence of sperm from the semen was not due to any failure or deficiency in spermatogenesis in the testes but rather to an obstruction to their passage outward, either in the vas or in the ejaculatory ducts. On the tentative diagnosis of stenosis of the vas, the author performed exploratory vasotomy to determine the location of the obstruction and to remove it if possible. The vas was exposed as close as possible to the epididymis, a fine puncture made in its wall and a piano wire or filiform introduced as far as it would go. This was followed by the injection of sterile water with the object of forcing the fluid through the stenosis or carrying the obstructive material along through the ejaculatory ducts to the posterior urethra and bladder. Bilateral stenosis was found in every one of the twenty-seven cases and thus established as the cause of the sterility. In twenty-three, the stenosis was located within 10 inches of the epididymis. In the remaining four, further investigation pointed to the ejaculatory ducts as the site of the stenosis. In sixteen cases, the fluid was eventually forced through the obstruction on one side with more or less difficulty; in six, on both sides; in five, the obstruction was not relieved on either side. When penetration of the stenosis

occurred, it was at once made evident by the diminished resistance to the flow. The author concludes that the vas deferens may escape infection when infection is present at either end or surrounding it; that it may be infected when there is no apparent infection at either end or surrounding it; that it may be a nidus for pyogenic organisms heretofore unreported in the vas, and that influenza and other systemic infections may possibly be a frequent, unrecognized factor in the production of a focal infection in the vas with resulting stenosis and sterility.

Embryonal Sarcoma of Kidney in Children.—Harrah points out that malignant tumor of the kidney should be looked for when there is progressive enlargement of the abdomen in a baby or young child. In many cases the abdominal enlargement is the only symptom for a long time. The usual absence of pain and hematuria, particularly the latter, early in the growth of the tumor is unfortunate from the standpoint of early diagnosis. The absence or late appearance of hematuria in renal tumor in childhood may be connected with the growth capacity of the young kidney, which enables its structures to keep pace with the growth of the tumor and thus to preserve their continuity for a long time. The author believes that the best results can be obtained with a combination of radiotherapy and surgery. He reports two such cases, in one of which the tumor was a recurrence after roentgen therapy. This tumor weighed 12 pounds and was the result of six months' growth after the onset of symptoms. It was present in a child, aged 2. The tumor in the other case was of still more rapid growth; it reached a weight of 7 pounds in a period of five weeks from the first observation of an enlargement of the stomach. Nephrectomy was done in both cases, and in both the tumor recurred and the children died a few months after the operation.

Treatment of Syphilis.—Wilson reports the results obtained by pyretotherapy in nineteen patients suffering from syphilis of the central nervous system in whom fever was produced by the following method: The patient is examined thoroughly in order to exclude cases of pulmonary and cardiac lesions, and of kidney diseases. Eyeground examinations for the present condition of the fundi and retinas should be invariably recorded, and repeated at weekly intervals during the treatment. The patient is given a course of trypanamide injections concurrently, consisting of ten injections of 2 Gm. each. The patient is given fever by intravenous injections of ordinary U. S. Army typhoid vaccine, the author always using the oldest stock, as the fresh vaccine has not produced fever satisfactorily. The vaccine is given in divided doses every other day until the patient has had ten days of fever. As Nelson suggested, the typhoid vaccine in divided dosage produces higher than the same total amount in one injection. Half of the desired dosage for the day is given, and (after experimentation to ascertain a desired time interval) the remainder is given two hours later. In from two to three hours after the second injection the peak of the temperature is reached, and in from seven to nine hours the temperature has dropped back to normal. On the first day 0.1 cc. of this vaccine, containing 100,000,000 killed bacteria, is given at each injection. At each successive treatment thereafter the dosage is increased by 0.1 cc., until on the tenth day each of the two injections contains 1 cc. or one billion killed bacteria. The patient is kept on a liquid diet on fever days. The common discomforts of fever (chills, headache, epigastric pain, nausea, vomiting, sweats) are present on fever treatment days. The author made a check up on seven of the nineteen patients six months after the treatment, as well as on two others immediately at the end of the treatment. Definite benefit has been shown, at least for the present. The idea of benefit

is based on the subjective report, the improvement or disappearance of positive physical signs, and the favorable change in the spinal fluid reports and in the blood serum reactions.

Pyuria in Children.—Wilson believes that there is sufficient evidence to warrant the attachment of a greater significance to pyuria as it occurs in infancy and also in childhood. For many years it was assumed that inflammation of the pelvis of the kidney was responsible for pyuria in most of the cases diagnosed "acute pyelitis." But this was an unproved assumption. From data now available it is apparent that the pyuria of the type ordinarily so diagnosed is due, in the majority of cases, to suppurative interstitial lesions of the kidney tissue itself. Hence a new significance is attached to the case of so-called acute pyelitis. The treatment of so-called acute pyelitis has been directed chiefly toward the urine and the urinary tract below the kidney. This fact perhaps accounts for many of the discouraging therapeutic results. With the establishment of the pathologic basis of the condition it is possible that more effective therapeutic procedures may be developed. Rest and quiet and fluids apparently still remain the most important factors in the treatment of so-called acute pyelitis. In patients who do not respond to treatment after a reasonable length of time, the urinary tract should be investigated for possible obstructions, and, if such a condition exists, it is often possible for a skilled urologist to relieve it. In children who suffer from recurrences of pyuria but in whom obstruction to the outflow of urine cannot be demonstrated, the evidence suggests that treatment should be prolonged in order to induce complete healing. Prolonged rest and quiet seem to be of special importance here. In this manner the foci of chronic inflammation which persist in the kidney substance may go on to complete healing, thus rendering recurrences less probable.

Chronic Indigestion.—Patterson and Lindley state that "indigestion" is a much abused term commonly used to cover all forms of stomach disease. Diagnosis of the basis of the patient's recital of symptoms without physical examination or analysis of the gastric contents or a roentgen series is too common. This explains the readiness with which practitioners resort to such terms as "indigestion," "dyspepsia," "catarrh of the stomach" or the equally indefinite term "stomach trouble" as a diagnosis. Intra-abdominal diseases most commonly giving rise to "dyspeptic" symptoms are cholecystitis, peptic ulcer, malignant disorders of the gastro-intestinal tract, colitis and chronic appendicitis, while those of extra-abdominal origin are pernicious anemia, pellagra, sprue and combined systemic disease. Unrelated conditions with "dyspeptic" symptoms as occasional secondary manifestations are acute infections, chronic infections (especially tuberculosis), circulatory and renal diseases, metabolic diseases, diseases of the genital organs, and functional and organic diseases of the central nervous system. The ideal routine of examination of patients suffering from gastro-intestinal disturbances includes a meticulous history, complete physical examination, roentgen series of

the gallbladder after tetra-iodide administration, gastric analysis of the fasting contents and after a test meal, and a complete gastro-intestinal roentgen series. After such a procedure, little of importance can escape one's attention and the percentage of one's mistakes is lowered to a minimum.

Multiple Erythema Doses Without Injury to Skin.—Liberson outlines a method of delivering multiple erythema doses without permanent injury to the skin, in which he uses a multiperforated sheet of lead from 1.5 to 2 mm. in thickness, with uniform perforations regularly spaced and comprising a definite percentage of the total square area. This perforated lead sheet is placed on the skin. The perforations obviously can be of different sizes and shapes, exposing more or less of the skin to direct radiation, and leaving greater or smaller isthmuses of normal skin, protected by lead, to act as centers of healing in case the radiation is of such magnitude as to cause ulceration of the irradiated skin. The dosage may be divided by having two holes of the perforated lead sheet of slightly different shape. These variations allow the marking of the skin with mercurochrome or any other dye nonopaque to the x-rays, in order that the perforator may be replaced over exactly the same area at the next session of the treatment. This enables the delivery of the total dose in more than one sitting. Sometimes a paraffin cast must be made and placed against a movable part, such as the neck or an arm, in order to assure the same position of flexion of the parts at subsequent sessions. The author observed that, since the remote effect on the skin of both rabbits and man is the same when three or four times as much radiation is delivered through the perforator as without it, the underlying tissue actually receives one and a half to two times as much radiation with the perforator as without it. Because of the increased dosage obtainable without permanent injury to the skin, the author proposes this method for the treatment of selected cases of malignant conditions.

Treatment of Carcinoma of the Thyroid.—Pemberton and Fricke base their study on the comparison and evaluation of different methods of treatment that have been employed in the Mayo Clinic. Carcinoma of the thyroid occurs in three distinct types: (1) papillary adenocarcinoma, (2) adenocarcinoma in adenoma, and (3) diffuse scirrhous adenocarcinoma. The group of patients selected for their study consists of 161 patients treated from 1921 to 1926, inclusive. They were chosen to enable them to determine the remote results of treatment over a period of from five to ten years. On analyzing the type of treatment given, they found that, in their surgical group of 107 cases, operation and irradiation were employed in all but ten

cases. Of the fifty-four nonsurgical cases, 61 per cent received treatment by both radium and roentgen rays; 28 per cent received treatment by radium only, and 11 per cent by roentgen rays only. In thirty-one of the fifty-four cases, biopsy was made. From these observations the authors conclude that irradiation only is a poor policy unless the growth is so extensive as to be totally inoperable; then, with irradiation only, palliation usually can be secured, and even cure in the occasional case (10 per cent of their medical series). Surgery only is not justifiable, even if the carcinoma is entirely removed. The facts that most carcinomas of the thyroid are low grade malignant tumors and that, in an appreciable proportion of cases in which operation cannot be performed, irradiation is followed by cure are evidence that these growths are sufficiently radiosensitive fully to warrant postoperative treatment. Because of the frequency with which carcinoma of the thyroid develops in a preexisting nodular goiter and the difficulty of distinguishing carcinomas in their early stages from benign tumors, surgical removal of all nodular goiters should be considered the treatment of choice, together with postoperative irradiation whenever carcinoma is found.

Circumscribed Cutaneous Myxedema.—Lord and Morrison present a case of circumscribed myxedema of the extremities in association with recurrence of clinical symptoms of hyperthyroidism in a patient who was previously thyroidectomized. The authors raise the question as to whether the thyroid alone is at fault in this association or whether the disease is one of "endocrine system" disturbance. While definite conclusions cannot be derived from one case, they advance suggestions and theories as to the strange mechanism that would produce areas of myxedema in a patient suffering from apparent hyperthyroidism.

Spasmodic Torticollis.—Spurling and Jelsma state that in true spasmodic torticollis there are few resemblances to the other varieties of torticollis, either in symptomatology or in pathologic anatomy. Knowledge as to the etiology of spasmodic torticollis is hopelessly inadequate. The theory which has received the most widespread support is that the disease is psychogenic in origin. Following this line of reasoning, many patients have been treated by psychoanalytic methods.

A few favorable results have been reported. There is a pronounced neurotic or psychopathic element in a great majority of these patients. The infection theory of spasmodic torticollis has also received wide support. The authors discuss the various operative procedures employed for the relief of spasmodic torticollis. They recommend the intradural section of the first three anterior and posterior cervical nerve roots and the spinal portion of the accessory nerve bilaterally.

Obstetric Analgesia.—During the past eighteen months, Plunkett used sodium amytal in 300 obstetric cases. From this experience he concludes that sodium amytal is not without danger to mother or child but, scientifically administered, is the least dangerous of the drugs at one's command today for obstetric analgesia. Ephedrine and caffeine sodiobenzoate should always be immediately available when sodium amytal is given. Oxygen should be given to the mother when the baby is about to be delivered and its administration continued until the pulsation in the cord ceases. When massive doses are given, the patient should not be left alone for an instant until she reacts from the drug. Complete analgesia and amnesia are obtainable in the great majority of cases. The drug can be given at any time during labor, but it is preferably given in the beginning. The patient's weight, blood pressure, muscular tone and the character of the uterine contractions should be one's guide as to the amount of the initial dose. The degree of restlessness and discomfort should be the guide as to repetition. Labor, as a whole, is not prolonged but is really shortened by the barbiturates. However, in many cases the second stage is prolonged unless episiotomies and prophylactic forceps are employed.

Nondiphtheritic Laryngotracheobronchitis.—The Kirkpatrick point out that the predominating organisms found in nondiphtheritic laryngotracheobronchitis are the staphylococcus and streptococcus. Low tracheotomy with mechanical removal of mucus is essential in severe cases. Prophylactic treatment in laryngitis always includes general measures to protect the child from any irritating external cause, such as cold winds or dust-laden air. Enlarged tonsils and adenoids should be removed. The resistance of the child should be built up by careful feeding, administration of cod liver oil and sun baths. All children should be given toxin-antitoxin mixture for immunization against diphtheria. Medical measures vary as the symptoms arise. The fluid level of the body should be maintained at all times. The administration of large doses of sodium bicarbonate at frequent intervals has given good results in some cases. Small doses of syrup of ipecac at frequent intervals help the milder cases. Apomorphine, atropine, epinephrine and inhalations are all of value in many instances. If the diagnosis is doubtful, diphtheria antitoxin should be given. Low tracheotomy is the operation of choice. Although some prefer intubation, the authors believe that the open tracheotomy tube gives much better access to the trachea for the removal of the thick, sticky mucus encountered in these cases.

Treatment of Cervical Ribs.—Adson states that patients who are found to have cervical ribs and do not have symptoms should not be informed of their condition, as such knowledge may predispose to the development of vague pains about the

neck and shoulder. Patients with mild symptoms do not require surgical intervention unless the blood pressure and radial pulse can be reduced or obliterated by elevation of the chin and rotation of the head to the affected side on inspiration. The anterior approach and tenotomy of the tendinous insertion of the scalenus anticus muscle is the operation of choice, since it is easier to perform, avoids injury to the brachial plexus, and is more effective in relieving compression and irritation of the subclavian artery and brachial plexus than is the trans-cervical or posterior removal of the cervical rib.

Treatment of Uterine Bleeding.—Chernosky says that, in all cases of uterine bleeding, the diagnosis of the exact pathologic condition is of vital importance, because each condition calls for a particular method of treatment. Surgery is indicated in the relief of definite surgical pathologic conditions, such as fibroids, myomas and malignant disorders of the fundus uteri, erosions and lacerations of the cervix, malpositions and malformations of the uterus, ovarian tumors, and allied demonstrable pathologic conditions of the ovary that may be definitely convicted of being causative factors in uterine bleeding. Medication with styptics, tampons, packing and curettage have been of some value in certain cases, but in reality these are only palliative measures and have been of little if any value in idiopathic bleeding. Radium and roentgen irradiation have a decided value in uterine bleeding. The intra-uterine application of radium and, in some cases, the external application of the roentgen rays are of decided value in bleeding from fibroids. No tumor that has attained a size greater than a three and one-half months pregnancy, nor a degenerating or pedunculated fibroid should be treated by these methods. Radium may be used in some cases of cervical and uterine polyp, the endometrial and myometrial lesions, and in some cases of ovarian dysfunction if bleeding is present. Radium and roentgen irradiation, when feasible, should be the treatment in all cases classed as poor operative risks, but pelvic inflammation or infection absolutely contraindicates it. In the treatment of idiopathic bleeding, intra-uterine applications of radium have served best. The dosage is from 25 to 50 mg. of radium placed in the uterus and left in situ for from three to six hours. The treatment may be guardedly repeated if the previous treatment or treatments have not given the desired results. Good results have also been noted after roentgen radiation of the ovarian regions.

Cardiovascular Syphilis.—Exner believes that the problem of prevention of the serious results of cardiovascular syphilis resolves itself into the early diagnosis and early treatment of syphilitic infection, and the diagnosis and adequate treatment of cardiovascular involvement in its early stages, before the heart and vessels have become seriously impaired. In regard to early diagnosis, the following points deserve emphasis: 1. Unremitting alertness against the possibility of syphilis entering into the pathologic picture will serve to clear many obscure cases and prevent serious damage or disaster. 2. All patients presenting signs of cardiovascular syphilis should be considered as having the disease until the contrary is proved. 3. Careful recording of case histories is essential, as they will often furnish the clue to an early diagnosis. 4. Careful and reasonably frequent periodic reexamination should be done of all syphilitic patients, with especial attention to the cardiovascular system. In patients with late syphilis the examination should include the routine use of the fluoroscope and the teleroentgenograph. 5. Repeated Wassermann tests should be made in all doubtful cases. 6. The therapeutic test should be used in young persons. The accepted scheme of treatment of early syphilis now commonly followed embodies the following essentials: (1) early diagnosis and immediate treatment; (2) complete physical and neurologic examination, accurately recorded, before treatment begins; (3) continuous treatment with courses of an arsphenamine, with interim courses of heavy metal and potassium iodide; (4) a Wassermann test at the beginning of each course of arsphenamine or of heavy metals, and a spinal fluid test after the second course of arsphenamine; (5) a Wassermann test every one or two months for one year after the completion of treatment, and, at the end of the year, a complete physical and neurologic examination, spinal puncture, and, if possible, fluoroscopic examination of the cardiovascular area, and (6) thereafter a yearly physical examination and a Wassermann test every six to twelve months.

Serum Reactions in Cancer.—The follow-up observations of Lowe in more than 100 cases of cancer show that his quantitative modification of the Bendien reaction will give evidence of progress after treatment, which cannot be so early obtained in any other way. It is possible to: 1. Observe the serum of a patient, suffering from a malignant condition and successfully treated surgically, gradually become and remain normal. 2. Observe, by the absence of the subsequent development of a normal or nonmalignant reaction after treatment, that the malignant condition in that case has not been eradicated and the recurrence or metastasis will probably follow such observations sooner or later. 3. Detect, by a change in the subsequent serum reactions from a normal or nonmalignant to one of malignant type, that recurrence is impending or metastasis developing: this has been shown in some cases months before clinical evidence confirmed it. 4. Demonstrate a satisfactory response to roentgen, radium or other forms of treatment by the gradual development of less positive and, finally, completely normal reactions in certain cases. 5. Foretell by the definite development of a more and more positive malignant reaction in the blood the fatal result that is impending in spite of the absence of immediate clinical manifestations in some cases. 6. Recognize by the finding of a markedly positive and malignant reaction of the first and second tube type that the prognosis is hopeless and that palliative treatment is all that can be expected from a therapeutic point of view.

Spontaneous Subarachnoid Hemorrhage.—Cookson reports eight cases of spontaneous subarachnoid hemorrhage. Two instances of a mild grade of the disease are recorded in which there was a slow oozing of blood leading to headache, pyrexia and symptoms of meningeal irritation. A good recovery followed. Examination of the cerebrospinal fluid is the key to the diagnosis, and the fluid is nearly always uniformly tinted, owing to the presence of blood. It may, however, be clear to the naked eye, yet red corpuscles can be discovered with the microscope. The author observed this in one of his cases in which the diagnosis was proved at necropsy. Intra-ocular changes are valuable in diagnosis and were observed in half

the cases. Clotting of the blood, so that it is prevented from entering the optic sheath, is one cause for their nonappearance. Periodic headaches are often complained of for years, either before or after the rupture of a cerebral aneurysm, or both. This was the case in five of the author's eight cases, one having the characters of migraine. Treatment consists in absolute rest and in the reduction of the intracranial pressure when the life of a patient is threatened and when the symptoms of meningeal irritation are severe and persistent.

Muscle Extract Treatment of Intermittent Claudication. M. Newman.—p. 611.

Dry Bronchiectasis.—Wall and Hoyle present twenty cases of dry bronchiectasis and express the opinion that the condition is comparatively common. Bronchopneumonia, usually following measles, whooping cough or influenza, during childhood or adolescence, is the commonest antecedent condition. A dry cough is the commonest symptom. Hemoptysis is not as frequent as the cases previously recorded would suggest. The condition is usually basal, and abnormal physical signs, dullness, weak breath sounds and crepitations often serve to indicate the affected area, though they may be entirely absent. Frank signs of cavitation are exceptional. Roentgenography after the administration of iodized poppy-seed oil is the only certain means of diagnosis. The explanation of dry bronchiectasis seems to be that, if for any reason air does not enter the alveoli during inspiration, the force of the inspiratory effort is transmitted to the bronchi to which the air has access. Treatment is governed by two main factors, the risk of sepsis and of hemoptysis. The authors suggest that lobectomy should be considered in each case.

Endometriomas.—The private and hospital records of Green-Armytage show that a state of endometriosis existed in 8.9 per cent of his last 1,000 consecutive abdominal operative cases. These patients had been treated for chronic tubo-ovarian disease, slowly growing innocuous tumors of the uterus, intractable dysmenorrhea, dyspareunia, lumbago, appendicular colic, hemorrhoids, or Bacillus coli infections. The author's cases of endometrioma indicate that there are five clinical types: uterine tumor, obstruction or invasion, tubo-ovarian mass, the symptomatic type in which only symptoms predominate, and the postoperative scar type, which is rare. The author states that surgical measures should be as conservative as possible, provided the whole area of endometrial cells and their cystic formation are removed. For instance, in an endometrial tumor of the uterus it may be possible to do a myomectomy or an amputation just below the level of the tubes, the two fallopian tubes being removed at the same time. When there are large cysts, general involvement of the pelvis or rectovaginal adenomyomas, the author does not hesitate to remove the tubes, ovaries and uterus. He believes that it is never necessary to excise a rectovaginal growth or that it is wise to attempt a total hysterectomy in such a case. In two patients in whom there was partial obstruction of the intestine due to secondary endometriomas, he performed a double salpingo-oophorectomy and partial hysterectomy. The two patients have had no recurrence of symptoms in eighteen months.

Urinary Acid Excretion.—Brunton, in his experiments on the influence of foodstuffs on the rate of urinary acid excretion of four healthy male subjects, adopted the principle recognized by Dodds that the amount of urine passed in unit time should be combined with the titration equivalent of unit volume of the urine, and that the amount of titratable acid in the urine excreted in unit time so obtained is more significant than the amount in unit volume of urine. The subjects took a standard breakfast at 8 a. m. and the chosen substance at noon or later, at which time Dodd's subjects had an "acid tide" in their urine. Duplicate 5 cc. portions of urine were titrated with tenth normal sodium hydroxide, neutral potassium oxalate being used as recommended by Folin. The accuracy of the titrations was ordinarily 0.25 per cent but occasionally only 1 per cent. In many experiments the "ammonia" was estimated by the formaldehyde titration method applied to the sample originally titrated to the end-point of phenolphthalein. The titrations to pH 7.4 were done with a quinhydrone electrode in a water bath kept within a degree of 25 C. by a gas thermoregulator. The author observed that water diuresis may cause a diminution of the titratable acid in unit volume of urine, but it does not, in normal subjects, produce a decrease in the output of acid per minute. In fact, the product of urinary volume and titratable acidity is remarkably constant contrasted with the wide variation in the single factors. He reports the output of acid per minute following the ingestion of certain single foodstuffs and a few of their combinations. If mixed meals are used to study the effect of gastric secretion on the urinary acid, the exact composition of the meal should be ascertained. Secretion of gastric juice may occur without a decrease in the output of acid per minute in the urine. Conversely, a decrease in the urinary acid output per minute occurs on waking without sufficient secretion of acid in the stomach to explain it.

Relation of Pregnancy to Nephritis.—On the basis of a statistical investigation covering a period from 1911 to 1931, Theobald states that pregnancy and childbirth have but relatively little causal association with chronic nephritis. All that can be said is that there seems to be a slightly higher mortality rate from chronic nephritis in married than in single women between the ages of 20 and 55. If, however, in any year no more than thirty additional deaths had occurred in single or seventy fewer deaths in married women and had been suitably distributed between the age groups from 20 to 55, the mortality rates for the two classes of women would have been the same. The differences in the mortality rates for chronic nephritis between married and single women during the childbearing period and for fifteen years afterward are so small as to be without marked statistical significance. It is true that mortality rates are used as a measure of the incidence of nephritis,

but if "puerperal nephritis" is merely a disability that does not end in death from renal or associated causes, it differs from any other form of nephritis and should be called by a different name. So far as nephritis is concerned, it causes a considerably higher mortality rate in single than in married women after the age of 55. The marked association of the mortality from this disease with advanced age supports the hypothesis that the associated kidney lesions are more often degenerative than inflammatory. It is necessary to refute the increasingly expansive and almost competitive estimates of the frequency with which chronic nephritis is caused by the so-called toxemias of pregnancy, both because such views will cause unnecessary anxiety and will inevitably lead to an increase in the number of abortions, and because they will tend to obscure the etiology both of the toxemias of pregnancy and of chronic nephritis.

Nutrition of Heart.—Smith states that the electrocardiographic abnormalities occurring in coronary lesions offer a sharp contrast to those appearing in nutritional or toxic disturbances of the myocardium. Coronary lesions cause changes principally in the ST or RT intervals and the T waves, opposite effects being produced in leads I and III. Such changes may be regarded as "localizing" and relating to focal myocardial changes. On the other hand, the changes in diabetes, myxedema, malnutrition in children, acute anoxemia, starvation in dogs, hypoglycemia, and other general parenchymatous defects in the heart are always in the direction of flattening or inversion of the T wave or depression of the RT interval, whether one or all leads are affected. These changes represent diffuse parenchymatous myocardial damage. That they are referable to defective glycogen metabolism and diminished production of lactic acid in the heart is the explanation which at the present time appears best to explain the known facts. An electrocardiographic study of severe anemia shows that in general myocardial anoxemia, although pathologic changes are often present, no corresponding abnormalities in the electrocardiogram can be demonstrated. From these facts it appears that a liability to anginal pain may be present when there is enhanced glycogen utilization in the heart, but only if the arterial irrigation of the heart falls short, or if insufficient oxygen is present to cause combustion of the lactic acid and other metabolites that are present, for example, in the anginal pain arising during effort, when local coronary sclerosis or spasm exists. The precipitation of anginal pain by the administration of epinephrine or thyroid, or in the course of thyrotoxicosis, depends essentially on the augmentation of the rate and force of the heart, lactic acid being rapidly formed, while the coexistence of coronary sclerosis with inadequate irrigation allows it to accumulate. Again, in severe anemia, enhanced glycogen utilization in the heart is accompanied by general anoxemia, the latter being responsible for slow destruction of lactic acid, while the coronary arteries, and therefore the factor of irrigation, may be normal. The author does not suggest that lactic acid is the pain producing substance, but it seems likely that accumulation of the former is proportional to the concentration of the latter. Liability to anginal pain also attends certain conditions in which there is perversion of metabolism in the heart as part of a general metabolic dyscrasia. Here the precipitation of pain is the direct consequence of defective glycogen metabolism. There appears to be no doubt that pure metabolic derangements of this type may induce anginal pain.

Diarrhea and Vomiting in Infants.—As a result of a large experience in the treatment of infantile diarrheas, Young places great reliance on gastric lavage, intraperitoneal saline solutions and the administration of large doses of kaolin delivered directly into the stomach through the esophageal tube and funnel. Splinting the infant's arms to avoid the possibility of auto-infection is considered to be an important point in treatment. In view of the frequency of parenteral infections, the prognosis of infantile diarrhea and vomiting still remains guarded. The outlined treatment has given him good results. In assessing the

prognosis of uncomplicated cases of diarrhea and vomiting, the following factors should be considered: the younger the infant, the more serious the prognosis; when there has been a recent infection, especially measles or whooping cough, the outlook is grave, and the worse the degree of dehydration before treatment is commenced, the more serious is the prognosis. If treatment is started early the prognosis is generally favorable.

Paroxysmal Auricular Flutter.—Bourne presents three cases of true paroxysmal auricular flutter. The first patient had a ventricular rate of 260 throughout the attack, with a 1:1 auriculoventricular ratio, a mechanism found in only four other such cases reported in the literature. The patient died suddenly. The other two patients reacted to digitalis in an unusual and identical manner. The pulse chart of one was characteristic of a complete attack of auricular flutter. The necropsy in the patient who died revealed as the cause of death a mechanism that may be fatal in all conditions in which attacks of prolonged and rapid tachycardia occur. The chief observations were the scars of old infarcts in the kidney, the presence of an antemortem clot in the left auricular appendix, the absence of any other source of embolism, and the finding of a small piece of lightly adherent clot in the lumen of the left coronary artery. The digitalis effect in the two surviving patients was contrary to that usually observed in permanent flutter. In each case massive digitalization resulted at first in the usual increase in the degree of block, but before the drug was withheld, and at a daily dosage, in both cases, of 80 minims (5 cc.) of the tincture, a reversion to the normal rhythm occurred. Clinical examination a day before the rhythm became normal suggested the presence of auricular fibrillation rather than of flutter with a varying block, for exercise increased the irregularity of the heart rather than the reverse. In one of the patients there was an abrupt rise of rate at the beginning and at the definite termination of the attack. In addition, after digitalization there were violent fluctuations in rate, the degree and suddenness of which were due to the great variations in the degree of block, and which were increased as the effect of the drug became more pronounced. It was noticeable that the ventricular rate would be low at this stage when the patient was sleeping or quiet but that if the patient was examined by a physician or visited by a number of students the block would be temporarily lifted to a marked degree. These temporary increases in rate were presumably due to an accelerator or supranal cause.

Acute Poliomyelitis.—Middleton gives the six recognizable types of poliomyelitis: 1. The spinal type, which is the common variety. 2. The meningeal type, in which a marked meningeal reaction takes place in the early stages and which is therefore commonly mistaken for meningitis. 3. The progressive ascending type, accounting for many of the fatal cases, the paralysis starting in the cord and mounting until the respiratory centers are paralyzed. 4. The bulbar type, affecting the brain stem. In this case there may be paralysis of the cranial nerves. 5. Poliencephalitis, giving rise to spastic forms of paralysis when the motor centers are affected, and being followed frequently by mental changes. 6. The ataxic type, which is an attack of poliomyelitis followed by ataxia of the type encoun-

tered in neurosyphilis, apparently as a result of destruction of the cells of the sensory root ganglions. The diagnosis of the common spinal type does not present many difficulties when paralysis has appeared. Diagnosis in the absence of paralysis is only a working possibility in the presence of a large number of cases. A vague febrile illness, especially if accompanied by a slight nasal catarrh or sore throat, followed by slight symptoms of meningism in the form of headache and a little pain in the back, will invariably be attributed to a cold, influenza or teething. In the presence of an epidemic of poliomyelitis, such a case should be accepted as one of poliomyelitis until proved otherwise. When an abortive or preparalytic case is suspected, a lumbar puncture should be carried out. The cerebrospinal fluid is usually increased in tension but clear in color. There is an increase in protein and in the lymphocytes. Occasionally a trace of blood is present. If the fluid is shaken in a test tube, the froth that forms tends to persist for more than half an hour. The fluid reduces Fehling's solution in most cases, and this fact often enables a differential diagnosis to be made from meningitis. Bacteriologic examination is negative. Apart from immune serum therapy, rest is indicated in the treatment of poliomyelitis in the stage of invasion. In the acute or paralytic stage, when paralysis has appeared, it is of vital importance that absolute rest to the paralyzed muscles be secured by skilled splinting in the ideal positions at the earliest possible moment. Serum may be used during this stage in the hope that it may limit the spread of paralysis. During the stage of recovery, the edema of the cord having subsided, the paralyzed muscles must still be kept relaxed by splinting, and the position of the limbs must be altered from time to time in order to keep the weakest muscles more relaxed than those which have partially recovered. The development of deformity from unbalanced muscle action is prevented by the same means. Reeducation of the recovering muscles by carefully graduated and assisted exercises now becomes of the greatest importance. The treatment of this stage must be continued for two years before the remaining paralysis can be said to be permanent. The first measure of treatment in a case of residual paralysis is the correction of a deformity, if present. Various operative measures may be utilized during this stage of the disease in order to stabilize flail joints, by arthrodesis of the knee or shoulder, Dunn's arthrodesis of the subtalar and tarsal joints, or astraglectomy. When the return of power is good, a weakened group of muscles may be strengthened by tendon transplantation from a stronger group. By such measures it is usually possible, in all but the most widespread cases, to enable a patient to walk.

*Treatment of Gastric and Duodenal Pain by Amino Acids. J. Lenormand.—p. 518.

Melanoflocculation Reaction in Malaria.—Alcay and his associates studied Henry's melanoflocculation reaction in patients with malaria of anopheline origin and in another group with inoculation malaria. The flocculation test was performed with melanin antigen provided by Henry and according to the direc-

tions first prescribed by him. Blood for the test is taken from the fasting patient. Five test tubes are required. The first two contain two dilutions of serum with melanin suspension diluted in redistilled water. The third tube (control) contains only serum and redistilled water. The fourth tube contains serum and melanin suspension diluted in redistilled water containing 0.3 per cent sodium chloride. The fifth tube (control) contains only serum and redistilled water containing 0.3 per cent sodium chloride. The reactions are read fifteen minutes after incubation of the tubes at 37 C. for two hours and three quarters. Among the forty-eight cases of malaria of anopheline origin (confirmed by microscopic examination), forty-four positive reactions were obtained in the first test and forty-seven in the second test. This shows the frequency of positive melanoflocculation reactions in malaria and also the importance of performing two tests at an interval of a few days. In eleven cases of inoculated malaria (*Plasmodium malariae*) in which serial tests were performed, the flocculation appeared with increasing intensity as the disease evolved; under the influence of treatment it gradually diminished in intensity and finally disappeared. In three cases in which the attacks were especially severe and numerous, superflocculations were obtained. An interruption of treatment after a decrease in flocculation is followed by an increased flocculation. With energetic treatment the flocculation test becomes negative rapidly, while with insufficient treatment the flocculation decreases slowly and sometimes remains subpositive. The test appears to have a diagnostic interest, as positive reactions were obtained before the first attack in two cases, and in one of them even before demonstration of the parasite in the blood. These observations corroborate the value of Henry's reaction as a guide to treatment and possibly, together with other clinical and biologic tests, as a criterion of cure.

Treatment of Gastric and Duodenal Pain by Amino Acids.—Lenormand has experimented with the treatment of gastric and duodenal ulcer by amino acids recently suggested by Weiss and Aron. He employed daily intracutaneous injections of 0.2 cc. of a solution of 2 per cent tryptophan and 4 per cent histidine. The treatment produced a rapid sedation of gastric and duodenal pain in all cases. The therapy is symptomatic. In one case, spasms and fleeting pain appeared between injections and a severe ulcerous crisis occurred two weeks after the last injection; in another case, the roentgenologic signs of ulcer remained unchanged after twenty injections. Furthermore, the sedative action of tryptophan and histidine is also observed in gastric pain that does not originate in ulcer. The author thinks the sedative action of the combined acids may consist in causing a hypersecretion of mucus rather than a reduction of the hydrochloric acid secretion. While it is too early to explain the mechanism of this therapy, it may be accepted as a rapid and efficacious method for treating gastric pain.

Presse Médical, Paris

*Electrocardiographic Modification During Experimental Left Cardiac Ventriculography. M. Racine and H. Reboul.—p. 950.

Cardiovascular Reactions to Injection of Contrast Mediums.—In experiments on dogs, Ravina and his associates studied the effect of the injection of various types of contrast mediums into the right auricle of the heart to discover the cause of the cardiovascular disturbances sometimes resulting from this procedure. They found that a number of contrast mediums are well tolerated, causing only slight modifications of the respiratory and circulatory rhythm. However, if salts in solution are used in excess of a certain concentration (variable with each salt), a disturbance of equilibrium is produced, resulting in precipitations. This occurs especially with sodium iodide if the concentration exceeds 70 per cent. For arteriography this substance should be replaced whenever possible by other compounds of iodine or derivatives of thorium. In some experiments, concentrated solutions of the kind necessary to make the cavities of the heart visible were used. In arteriography one may use less concentrated substances which are better tolerated. Iodine compounds, even if less toxic than sodium iodide, present a danger of pre-

cipitation if used in concentrations of over 70 per cent. Such accidents do not occur with compounds of thorium, which also have the advantage of being painless and are therefore valuable for arteriography. However, the rapid diffusion of thorium compounds into the blood may hinder the taking of certain roentgenograms. This is particularly marked in the cardiac cavities and makes it impossible to obtain good roentgenograms of them. Unstable compounds of thorium are extremely dangerous, as they may cause accidents of shock; it is therefore important to use only perfectly stable products in experiments of this kind.

Electrocardiographic Modification During Experimental Left Cardiac Ventriculography.—Racine and Reboul studied the electrocardiographic modifications during the course of left cardiac ventriculography in dogs to discover all possible dangers of this new method of cardiovascular examination before applying it to human beings. All the electrocardiograms taken during the hours or the day following the intraventricular injection were normal. The ventricular puncture did not cause any modification of the electrocardiogram or, at most, a few extrasystoles. The contrast fluids that were utilized, no matter what their concentration was, produced changes analogous to those produced by the same quantity of physiologic serum. The pressure of the injection is more important than the volume. A left intraventricular injection of 20 cc. under pressure of 1.25 Kg. does not modify the electrocardiogram, whereas an injection of 15 cc. under a pressure of 1.5 Kg. causes extrasystoles and, under a pressure of 2 Kg., paroxysmal tachycardia. Seven cubic centimeters under a pressure of 1.25 Kg. suffices for a good left ventriculogram of a dog, and 15 cc. under a pressure of 2 Kg. may cause paroxysmal tachycardia. This large margin of safety between the volume and pressure required for a ventriculogram and the figures that cause the slightest modifications of the electrocardiogram permit envisaging the application of this method to man in the future.

Haste and Incompetence in Reports of Abortions. P. Galfami.—p. 358.

Bleeding as Means of Treatment of Some Amenorrheas.—Merletti reviews the pathogenesis of amenorrhea and passes on to the treatment of emotive amenorrhea, amenorrhea due to general chilling and amenorrhea due to chloris of puberty by simple bleeding. The author states that emotive amenorrhea occurs after emotional psychic shock, especially during the menstrual flow. Menstruation depends on hypophyseal action as well as ovarian action. Since the regulatory seat of hypophyseal activity is in the floor of the third ventricle and secondarily in the ovary, the author believes that any nervous trauma such as pain and fright may inhibit the cerebral stimuli. He holds that the cerebral stimuli can be directly transmitted to the gonads and there can influence the trophism and activity of the ovary and the ovarian phenomena such as menstruation. A simple venesection rendered all the author's patients normal and stimulated the inhibited mensural flow. In amenorrhea due to general chill there is a great disturbance of all cellular exchanges, which necessarily involves all endocrine functional activities influencing menstruation. After venesection in patients with this type of amenorrhea, there is a cessation of the symptoms brought about by menstrual arrest: general malaise, cephalgia and acrocyanosis. Menstruation usually occurs after a single bleeding. Amenorrhea due to chlorosis of puberty is accompanied by cephalgia, greenish pallor, torpor, somnolence, vertigo and acrocyanosis. Patients with this amenorrhea were given a series of slight bleedings. These not only regulated menstruation but stimulated the hematopoiesis and blood crisis. According to Pende, the diminution in blood pressure due to the venesection introduces epinephrine into the circulation, thereby correcting a condition of hyposuprarenalism, a factor of chloro-

sis. He states that he does not know of any satisfactory theory to explain the beneficial action of bleeding in amenorrhea due to chlorosis.

- Slight Purpura and Early Hemorrhagic Meningitis: Case. F. D'Ambrosio.—p. 731.

Treatment of Psoriasis.—Ciarrocchi describes the technic of Toma's treatment, which consists of reducing the squamas to an impalpable powder, dissolving it in physiologic solution of sodium chloride to which is added a 0.25 per cent solution of formaldehyde, pouring the whole in a test tube kept at 37 C. for a week and shaking it to help eliminate the formaldehyde: the concentration of the emulsion must not surpass the deposit of twenty-four hours of sedimentation; that is, the height of 1 or 2 cm. Bacteriologic control is practiced after the mixture has remained for two days in an incubator. From 2 to 3 cc. of this vaccine is injected subcutaneously at intervals of from two to four days, the dose gradually rising to 10 cc. The results of this treatment on three patients were all satisfactory. The maximum amount of time required for complete cure was two months (twenty-one injections). The author modified the method by using a 0.5 per cent solution of formaldehyde. After keeping the tubes at the required temperature of 37 C. for a week, he shook them vigorously, placed them in a water bath at 58 C. for about an hour and then packed them in ice. This was repeated on two successive days, after which the emulsion was ready for use. All six of the author's patients were able to endure the test without notable disturbances and were completely cured. The author advocates treatment with extract of squamas in patients with generalized eruptions in which the use of chrysarobin is contraindicated. For women patients with psoriasis of the scalp, this treatment is advantageous in that it does not require the cutting of the hair. The author found that several slow cases responded most rapidly when squama treatment was combined with internal administration of solution of potassium arsenite. He states that the combined method entirely prevents recurrences or makes them less severe.

- *Vollhard's Dilution Test of Renal Function in Obese Persons. Teresa Malamud.—p. 1142.

Renal Function in Obese Persons.—Malamud says that the results of Vollhard's dilution test of renal function in obese persons are conflicting with those given by other tests of renal functions (determination of the total urea and nonprotein nitrogen in the blood and the phenolsulphonphthalein test). While the last mentioned tests give results that indicate a normal function of the kidneys, the elimination of urine during the first four hours following the ingestion of 1,000 cc. of tea is not equal to the quantity of tea ingested. In Vollhard's test, a subject with normal kidney function will eliminate during the four hours following the ingestion of tea a quantity of urine equal to and sometimes larger than the quantity of tea ingested. The author made determinations of the function of the kidney by the tests mentioned in fifteen obese persons presenting complications. The same tests were performed in a control group of ten patients with hepatic disturbances. Malamud concludes that the function of elimination of water is disturbed in obese persons. Clinically, the intensity of the disturbance seems to be related to the chronicity and intensity of the disturbances of the general water metabolism. The age, arterial pressure, tolerance to glusides and the presence of chronic cholecystitis have not a manifest action on the function of water elimination. Obesity and the circulatory disturbances complicating it, even if in a latent condition, are the factors of primal and secondary importance, respectively, which cause the disturbances of the elimination of water.

Pneumothorax Therapy in Dry Pleurisy.—Regenbogen directs attention to the prompt action of pneumothorax therapy of dry pleurisy. He relates the histories of six patients whom he recently treated with success. The inflation of air should produce complete separation of the layers of the pleura in order to abolish friction and pain. No other method effects such a rapid disappearance of the pains. It prevents the development of adhesions and, in some instances, it may even divide new adhesions. The introduction of comparatively small amounts of gas is generally sufficient in this form of pneumothorax therapy. The author found from 300 to 500 cc. adequate in all his patients, although others have administered from 600 to 1,000 cc. The small amount has the advantage of limiting to a minimum the irritative action of the gas. The pains generally cease after 300 cc. has been introduced, and one filling is usually sufficient. Its effects persist as a rule until the patient is completely cured. The pneumothorax can be refilled if friction recurs, but the author found it necessary in only one of his six patients. The development of an exudate is not to be feared, but whether a pneumothorax in dry pleurisy can prevent the development of an exudate is as yet undecided.

Roentgenokymographic Method in Diagnosis of Pleural Adhesions.—Von der Weth shows that total and partial pleural indurations can be diagnosed by means of the roentgenokymograph. The diagnosis can be based on the decrease in the diaphragmatic excursions toward the thoracic border, on the reduced synergy of the lung with the diaphragm compared to the normal side, and on the decrease of these intrapulmonary amplitudes of movement toward the border. In case of interlobar indurations there is an abnormal, especially a high reaching transmission of the diaphragmatic movements. The decrease in the diaphragmatic excursions as well as in the intrapulmonary amplitudes of movement toward the border are found only in these cases, if the parietal pleura is also indurated. Shrinking of the lung and pulmonary indurations may exert traction on the mediastinum. This traction assumes clinical significance if it acts on the heart, because it may cause disturbances in the cardiac rhythm.

Pulmonary Cirrhosis with Rare Etiology.—The anamnesis in the case reported by Bodmer and Kallós revealed that ten years previously (1921) a pachydermia laryngis had been diagnosed. Roentgenoscopies of the lungs during the following years revealed old foci of calcification. In 1929 there were areas of density over the lower fields, and this condition was still unchanged in 1932. Because the clinical symptoms did not correspond with the roentgenologic aspects, the diagnosis was extremely difficult. The patient's main complaint was a susceptibility to colds and a sensitivity to smoke, but he was in good general condition. Chronic miliary tuberculosis, malignant pulmonary tumor and lymphogranulomatosis could be excluded. The roentgenologic aspects seemed to justify the diagnosis of chronic pulmonary cirrhosis (Corrigan). This condition is the result of a chronic irritation. Questioning of the patient revealed a peculiar use of liquid petrolatum, which the author considers the cause of this condition. When the pachydermia laryngis was discovered, the patient was treated for a while with swabbings.

Later he began self treatment by instilling into his nose from 50 to 100 cc. of liquid petrolatum. When this reached the nasopharynx he intentionally aspirated some of it in order to "oil his vocal cords," disregarding the attack of coughing. He did this regularly every day for ten years. The author is convinced that this abuse of liquid petrolatum is the cause of the pulmonary cirrhosis. The treatment could aim only to combat or prevent sequelae, for it is impossible to remove entirely the existing changes. The author mentions another recently published case report of impairment of the lung by self medication with liquid petrolatum, in the therapeutic instillation of which he thinks these two cases indicate the need of precaution.

Retgression of Ovarian Changes Produced by Prolan.—In order to determine the further development of the ovarian changes produced in young mice by the injection of prolan, Zondek replaced the ovaries following their inspection for the prolan action. In order to do this, the ovaries were taken out through an incision in the back of the animals. Only those animals in which the macroscopic inspection revealed clearly the presence of blood dots and of corpora lutea were used for the further experiment. The animals were killed from one to four weeks after the prolan action had been determined, and the inspection of the ovaries revealed a gradual retgression of the changes. After four weeks they had completely disappeared, which proves that the ovarian changes produced by the action of prolan are reversible.

Positive Reaction for Syphilis in Pulmonary Tuberculosis.—Dünner and Mayer made the Wassermann, Meinicke clarification, Kahn, and Müller conglobation tests on 1,200 patients with pulmonary tuberculosis. In forty-three of the patients with positive syphilis reactions, the anamnesis, the clinical aspects or both indicated syphilis. However, in thirty-one patients in whom several serologic tests for syphilis were positive, neither the anemnesis nor an exact physical examination gave indications for syphilis. Observations on patients in whom the tuberculous process was progressive revealed in five instances that seroreactions at first negative became positive as the disease process became more severe. The authors conclude that a non-specific syphilis reaction in patients with pulmonary tuberculosis is possible, although this has not yet been proved.

Renal Glycosuria in Hematogenous Tuberculous Dissemination.—Mayrhofer gives the histories of three patients

who, as far as the pulmonary aspects are concerned, differ greatly from one another. The first patient had a tuberculous primary infiltrate in the right upper lobe, the second exhibited slight impairments of both pleuras without severe pulmonary involvement, and the third had a severe puberty tuberculosis with cavities on both sides. But it is noteworthy that in all three a hematogenous dissemination was followed by glycosuria. As long as the blood sugar values had not been determined, febrile or toxic glycosuria were thought of, forms which occasionally are observed in acute infectious diseases, and an impairment of the pancreas by miliary tubercle formation was also considered possible. When the blood sugar values were found to be within normal limits, it was apparent that the glycosuria could be only of renal origin. The patients had all the symptoms of a renal diabetes, except that the condition did not persist, lasting only as long as the hematogenous dissemination. It is difficult to determine the nature of the renal impairment in cases of this type. Attention is called to the toxic albuminuria that develops in the course of hematogenous proliferating tuberculosis. Although some consider this type of albuminuria an orthostatic form, the author is more inclined to believe that it has the same cause as the described renal glycosuria. He thinks that the hematogenous dissemination is the most important factor in the development of these symptoms. He points out that the temporary glycosuria has no significance for the patient but that the detection of hematogenous foci in the lungs does not complete the diagnostic work, because the hematogenous dissemination influences the entire organism.

Recognition and Treatment of Acute Necrosis of Pancreas.—Guleke says that necrosis of the pancreas is a destruction of the pancreas by its own activated secretion, a form of self digestion. The cause is not always readily determinable, but obesity and disturbances of the biliary tract seem to be predisposing factors. The clinical aspects of acute necrosis of the pancreas are typical. Suggestive symptoms are the fulminating onset of the pains, their rapid increase in severity and their persistence, as well as the statement of patients with biliary calculi that these pains differ considerably from those produced by the calculi. The beginning, following a big meal or after excessive drinking, is noteworthy. Generally the patient is in collapse. The pulse is small and at first not accelerated; it increases more slowly than is the case in peritonitis due to perforation. In the ultra-acute forms ending fatally within a few hours, the pulse may increase rapidly. The patients are generally restless. They are pale and sometimes cyanotic over the entire body, and the bluish marmorated appearance of the abdomen is noteworthy. Vomiting occurs in many cases, the intestinal activity is impaired and the abdomen appears inflated. An important aid in the diagnosis is in the demonstration in the blood or urine of the "deranged" ferments of the pancreas. The treatment has two objects: to check the local process and to counteract the intoxication due to pancreatic ferments in the blood. A means to counteract the intoxication directly was not discovered until recently. It was determined that the protein-digesting portion of trypsin together with the disintegration products cause the intoxication and that the point of attack of the trypsin is the reticulo-endothelial system, after the latter has been impaired by the protein substances that become liberated by the disintegration of the cells of the pancreas. More important was the discovery that the fibrin, which is increased by the protein disintegration, serves as a carrier for the trypsin and enables the latter to attack also the unimpaired cells of the reticulo-endothelial system. When it was found that heparin abolishes the carrier function of fibrin, patients with acute

necrosis of the pancreas were given continuous drop infusions, to which was added, every four hours, from 0.3 to 0.4 Gm. of heparin together with 1 cc. of an isomer of ephedrine. This treatment seems to give the desired results. Whether the administration of congo red for the purpose of detoxication will accomplish more remains to be proved. These treatments, of course, do not make the operative treatment unnecessary, for the necrotic tissues and pus accumulations have to be removed.

Early Puncture in Exudative Pleurisy.—Lommel believes that exudative pleurisy is generally treated too conservatively and that the expectant attitude may permit the development of adhesions that encapsulate the exudate, of indurations and of deformities of the lung and of the thorax. He aims to show that early puncture of the serous or of the serofibrinous pleural exudate with simultaneous air filling is the best procedure in most cases. The entirely open puncture brings comparatively favorable results, but it can be employed only in unilateral processes. Moreover, since undesirable conditions may result from a strong inflation, the author thinks a measured inflation advisable; that is, a puncture not completely open. The quantity of air to be introduced should only partly be determined by the amount of fluid withdrawn and should be done more according to the rules governing pneumothorax therapy. The author refutes the objections that have been made against early puncture and inflation. He points out that the new accumulation of exudate can be counteracted by renewed withdrawal, and that the development of adhesions and of shrinking processes are the less to be feared the earlier the puncture is resorted to.

Gonococci in Rectal Mucus.—Ruys and Jens found in seventeen children with gonorrheal vulvovaginitis that the culture method corroborated the existence of a gonorrheal inflammation of the rectum in every instance. This inflammation of the rectum, although not always clinically manifest, is extremely persistent and favors reinfection of the genitalia. In new cases it is generally possible to demonstrate the presence of gonococci in the rectal mucus both in the microscopic preparation and by means of the culture method. However, in children who have been treated and in whom cure is to be ascertained, the culture method is indispensable.

Endocarditis Lenta.—Falta states that the nonseptic form of endocarditis is observed most often in connection with acute articular rheumatism. The septic type may be either acute or chronic. Schottmüller, who differentiated the chronic septic form also with regard to its etiology in that he demonstrated *Streptococcus viridans* as the causal agent, coined the term endocarditis lenta. However, the causal significance of *Streptococcus viridans* has not been generally accepted, because cases of endocarditis lenta have been reported in which other types of bacteria were found. Moreover, since acute septic endocarditis can be caused by so many different types of bacteria, the author thinks it logical that in the chronic form this may likewise be the case. It has even been questioned whether *Streptococcus viridans* is a distinct type or only a weakened form of hemolytic streptococcus. Although the author observed a case in which once a hemolytic streptococcus was found and later *Streptococcus viridans*, he does not feel justified in deducing from this that the same strain at one time hemolyzes and at another produces a green zone, but he concludes that there are hemolytic streptococci of lesser virulence which may produce the syndrome of endocarditis lenta. The lack of uniformity in the bacteriologic aspects of the various forms of endocarditis has led the pathogenic research into a different channel. It is assumed that the different disease manifesta-

tions are not due to the difference in the pathogenic organisms but rather to the difference in the reaction of the organism to the infection that is dependent on the condition of the reticulo-endothelial system. In discussing the therapy of endocarditis lenta, the author points out that the surgical treatment of the port of entry does not always bring the desired results, since the endocarditis itself is a septic focus. He considers tonsillectomy advisable only in those cases in which there exists a chronic tonsillitis and in which it is proved that the infectious process is still limited to the tonsils. Treatment with autovaccines is not especially promising. The best therapeutic results are obtained with blood transfusions.

Action of Hydrosulphuric Acid on Capillaries.—Maliwa was induced to study the action of hydrosulphuric acid because the clinical analysis of so-called sulphur baths seemed to indicate that their efficacy is primarily due to the action of hydrosulphuric acid. He found that, if a gauze compress moistened with a saturated solution of hydrosulphuric acid in water is pressed onto the skin under water, there develops within from thirty to forty seconds a slight reddishness limited to the area of contact and disappearing after a few minutes. If an intracutaneous wheal is made with epinephrine, the wheal time is reduced to approximately half under the influence of the solution of hydrosulphuric acid. In the case of intracutaneous injection of physiologic solution of sodium chloride stained with methylene blue, the elimination of the dyestuff is hastened by hydrosulphuric acid. These tests as well as perfusion experiments on the isolated circulation of the ear of the rabbit indicate that hydrosulphuric acid effects a considerable dilatation of the vessels, which even overcomes the barrier produced by epinephrine. The author concludes that the alleviation of pain and the reduction in the feeling of tension produced by the so-called sulphur baths is due to the dilating action of hydrosulphuric acid on the vessels. He admits that the action of the "sulphur" baths is complex and that other factors are involved in their therapeutic action, but he thinks that their content in hydrosulphuric acid, in spite of the fact that its quantity is small, is the most important and most effective factor. He expresses the hope that it may become possible to utilize the described action of hydrosulphuric acid in another form for the treatment of rheumatic diseases of muscles and joints.

Tannic Acid Therapy of Burns.—Langer describes the mode of action of Davidson's tannic acid treatment and its technic and he stresses the advantages of the method. In comparing the results of the tannic acid therapy of burns with the results obtained in the treatment of burns before the tannic acid therapy was introduced, he found that tannic acid treatment combined with blood transfusions and intravenous injections of sodium thiosulphate reduced the mortality from 14.9 per cent to 7.7 per cent. The number of complications that developed following the burns was not noticeably influenced by the method of treatment.

Malarial Therapy of Gonorrhea.—Mucha and Rieger report their observations on patients who received malarial therapy for a syphilitic process but who also had gonorrhea. They found sixty-nine patients whose clinical history proved suitable for their inquiry. The malarial therapy was followed by cure in 69.6 per cent of these cases. The authors do not recommend the treatment for gonorrhea, because there are less radical methods that produce just as favorable results. More

over, it was observed that, in patients in whom the malarial therapy failed to cure the gonorrhea, other methods did. They point out that, since there is a possibility that gonorrhea patients later may contract syphilis so that malarial therapy may become absolutely necessary, the earlier malarial therapy would greatly reduce the therapeutic prospects, because it is known that a second inoculation of malaria does not give nearly as favorable results as does the first treatment. The authors think that resort to malarial therapy on account of gonorrhea is justifiable only in patients with severe adnexal complications, for it has been found that serious surgical interventions may thus become unnecessary.

Arsphenamine Allergy.—Schreiner discusses the cutaneous disorders that develop in the course of arsphenamine therapy, such as the angioneurotic syndrome, the fixed arsphenamine exanthem, the generalized exanthem and the arsphenamine dermatitis. After calling attention to similarities between the cutaneous disorders resulting from arsphenamine therapy and the known allergic diseases, the author describes tests by which he attempted to prove the allergic character of the cutaneous disorders. In order to determine the presence of specific antibodies, he made cutaneous tests, and he was able to demonstrate the allergic nature of the symptoms in eighteen of twenty patients presenting various forms of the cutaneous disorders.

*Rare Anomaly in Position of Child During Pregnancy. V. Král.—p. 1289.

Conception After Intra-Uterine Radium Treatment.—Karg discusses the history of three women in whom intra-uterine radium application, resorted to because of a metropathia haemorrhagica, produced a temporary amenorrhea. After ovulation and menstruation had become reestablished, two of the women conceived; but abortion followed and one of the women died of sepsis. However, the author thinks that the sepsis was the result of an exogenous infection and he considers the complete rejection of radium treatment of benign gynecologic disorders unjustified. He does not agree with those who maintain that radium therapy does not insure permanent sterilization. Because of the dangers involved in temporary radium sterilization, particularly because of the danger of abortion or of defective offspring, he thinks that temporary sterilization should be abandoned in favor of permanent sterilization. If this can be realized, radium therapy can be employed in metropathia haemorrhagica with the same justification as surgical therapy. The advantages of radium therapy, such as immediate cessation of hemorrhages, shortened convalescence and a reduction of the symptoms of abolished function, as compared to their severity following surgical or roentgenologic sterilization, even make it the method of choice. It is essential that the main portion of the radium rays be limited to the corpus uteri and that the ovaries receive as little radiation as possible. The aim of the treatment is to check the function of the endometrium. To attain this and to inhibit the restorative power of the mucosa, the intra-uterine radium application is best done following menstruation or after a curettage, for then the deeper layers of the mucosa will be reached by the soft gamma rays, which have about the same biologic action as the hard beta rays. The irradiation should be of short duration. The fixation of the radium preparation in the uterus should be done by gauze tamponade of the cervix. Vaginal tamponade is inadvisable. The author emphasizes that, if the ovaries are protected as much as possible, radium treatment of metropathia is the method of choice not only for women over 40 years of age but also for younger women.

Anomalous Position of Child.—In a primigravida, aged 36, Král observed an unusual position of the fetus. The enlargement of the abdomen corresponded to that of the last month of

pregnancy, but it was pushed downward and forward so that its deepest point was approximately at the level of the external genitalia. The dilated lower portions of the anterior wall of the uterus had yielded to the fetal head and had sagged downward, so that the head was anterior to the pubic symphysis. The uterine dilatation and displacement were made possible by the considerable diastasis of the rectus muscles, which, at the level of the umbilicus, measured 34 cm. The fetus was in the longitudinal position and the pelvis underneath the maternal costal arch. The maternal pelvis was empty. It was decided to perform a cesarean operation immediately following the onset of the labor pains. The child died on the second day after delivery. After the uterus had been sutured, the cause of the anomalous position was searched for and two subserous myomas were found on the posterior wall; one being the size of a fist and the other larger than a hen's egg. Both myomas were necrotic. The author assumes that these two myomas made the posterior uterine wall rigid and prevented its dilatation. As a result, the anterior wall was excessively dilated and became so thin that it could not resist the pressure of the head and bulged, a process that was promoted by the great diastasis of the rectus muscles. The author designates this abnormal fetal position *positio capitis praepubica*.

Treatment of Peptic Ulcer by Diathermy of Sympathetic.—Grot and Egorov report the results of diathermy treatment of the cervical portion of the vagus and the sympathetic nerves in twenty patients with peptic ulcers of the stomach and the duodenum. From five to fifteen treatments of thirty minutes duration gave excellent results. Epigastric pain, pyrosis and eructations disappeared and the acidity came down to a normal level. The symptom complex characteristic for these patients consisted of spastic pain, pylorospasm, increased acidity and increased secretion, symptoms resulting from increased irritability of the vagus nerve. They noted in several patients a peculiar syndrome suggesting partial lowering of the sympathetic tonus; namely, narrowing of the palpebral slit, ptosis of the lid, and hypotonus of the muscles of expression on one side of the face. The authors suggest that the effect of the diathermy current is conveyed along the trunk of the vagus to its ramifications in the wall of the stomach, thus lowering its irritability. At the same time the diathermy improves the tonus of the sympathetic nerve. To throw light on the nature of the effect of the diathermy, observations were undertaken on a number of other conditions, such as achylia, biliary colic, cholecystitis and angina pectoris. These will be reported at a later date.

Sedimentation Reaction: Review. M. C. Lottrup.—p. 489.
*Inheritance of Sporadic Goiter. T. Kemp.—p. 503.

Inheritance of Sporadic Goiter.—Kemp reports a family with seven or eight cases of sporadic goiter in three generations, all in women and appearing between the sixteenth and the forty-fifth year, the symptoms of exophthalmic goiter in one instance presumably having developed some years after the simple goiter. He says that of the families with sporadic goiter on a genotypical basis reported in the literature a number resemble this family and that the inheritance can be explained on the assumption that the disturbance depends on a dominant factor, present in the X chromosome, which causes not only development of goiter but also nondisjunction of the two X chromosomes in women. It can also be explained if the disorder is dependent on several genes of like action and is limited in sex to women.

VOL. 101, No. 6

CHICAGO, ILLINOIS

AUGUST 5, 1933

THE FIRST HALF-CENTURY OF THE SECTION ON PEDIATRICS

CHAIRMAN'S ADDRESS

FREDERIC W. SCHLUTZ, M.D.
CHICAGO

The Section on Pediatrics of the American Medical Association has passed the half-century mark. It is a fitting time to pass in review its past and to take note of the growth, the changing trends, the progress and the achievements of this important section, and to recall the names of colleagues identified with its development, not a few of whom were in the truest sense makers of American pediatric history.

The Section on Pediatrics was organized as an independent section of the American Medical Association at its thirty-first annual meeting held in New York City in 1880. Abraham Jacobi, whom probably quite a few in this audience will recall and who is regarded with reverence by all of us as the father of American pediatrics, was the founder of the organization.

After an eloquent address by Dr. Jacobi on the claims of pediatric medicine, Dr. S. C. Busey of Washington, D. C., offered a resolution creating the Section on Pediatrics as the sixth section of the American Medical Association. To quote from a chairman's address of many years ago, "Dr. Busey was the accoucheur on this happy occasion and Dr. Jacobi stood Godfather for the tender infant."

When asked in his later life how the organization of the Section came about, Jacobi had this to say, "There is no history, we just did it. It was a clear case of spontaneous generation. The Section was in the air and we were present when it condensed—that is all."

At the first regular meeting in Richmond in 1881, Dr. Jacobi presided as the first chairman, and Dr. T. M. Rotch of Boston was the first secretary. Dr. Jacobi's address at that meeting was on "The Progress in Knowledge of the Acute Contagious Diseases and Infections."

Previous to 1880, the work of the Section was done in the Section on Obstetrics and Diseases of Women, and consisted in an occasional paper on some pediatric subject. It was the time when a few lectures tacked on to the chair of obstetrics sufficed to fill the pediatric curriculum requirement of the medical school of that day.

In 1883 THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION first appeared, and it is from the date of

this meeting, the thirty-fourth held in Cleveland, that we have the first printed record of the doings of the Section.

The meeting place has always coincided with the meeting of the American Medical Association and has, including this session, been held in twenty-eight different cities of the United States. It is a strange coincidence that the 1893 meeting, during the Columbian Exposition, was held in Milwaukee, and again, forty years later, at the time of the Century of Progress Exposition in Chicago, the meeting is held in the same city.

The Section meeting in Milwaukee in 1893 was an excellent one. In the chairman's address delivered at the sixteenth session of the Section, the Milwaukee meeting of 1893 is lauded as the best one ever held by the Section up to that time, and the hope was expressed that future programs and conduct of the Section might be modeled after that memorable meeting.

I had not come across this item when the present Section meeting and program were organized, but I hope that you all will share with me the comfortable feeling that this meeting in Milwaukee is again going to be a memorable one, and that we are indeed living up to the hopes and expectation of our earlier colleagues.

Of the fifty-two past chairmen of the Section, twenty-six have passed on to their reward. Among these are some of the notable names of early American pediatrics and the founders of this organization.

There is no accurate record of attendance at the earlier Section meetings except an occasional allusion in a secretary's report. At the organization of the Section, forty members were present. At a meeting in New Orleans in 1895, 175 members attended the Section. The number has always fluctuated and depended somewhat on the meeting place of the Section. In later years, the number has often reached several hundred.

The early years of the Section were marked by a struggle for existence and independent identity. Tacked on as a tail end appendage to gynecology and obstetrics by our medical forefathers, pediatrics emancipated itself from this impracticable and archaic bond and union and under the leadership of Jacobi developed into the major branch of medicine which it is today.

The chairman of the Milwaukee meeting in 1893 speaks feelingly of the tottering footsteps of the childhood period of a great organization, of the difficulties which attended the development of an imperfectly differentiated section, of the lack of cohesion and cooperation which resulted from a diffuse and unstable membership, but speaks in praise of the fighting hearts

of the men of that day and the earlier time who made the Section what it was then and what it was destined to be.

It appears from the records that at the fortieth meeting of the American Medical Association, the ninth year of the Section, a motion was brought in to discontinue the Section on Pediatrics. The impassioned address at that time of Dr. Larrabee of Louisville, Ky., the chairman, and his convincing plea saved the Section, and such a motion was never again brought up.

At the same meeting a motion was also made that the secretary preserve the records of the Section and pass them on to his successor. To make the work more efficient and to establish the Section's autonomy firmly, the chairmen at the Milwaukee meeting of 1903 suggested the following propositions:

To cultivate a more intimate social relation among the members, the custom of some of the sections to hold an annual social reunion is to be commended, and the chairman recommends such reunions to be a fixture of the Association. (Except for the San Francisco meeting in 1894, when too few members attended, a Section dinner has been an annual feature of every Section meeting.) He recommended, also, the prompt publication of full reports of the proceedings of the Section and a careful preparation of the program for each meeting, the topics to be on timely and interesting subjects and such as will elicit good discussion.

At the fiftieth meeting of the Association and the nineteenth of the Section on Pediatrics, held in Columbus, Ohio, the chairman, Dr. Tuley of Louisville, mentioned it as one of the most dignified and important sections of the Association. He recorded with satisfaction a gradual increase in the recognition of pediatrics in the medical literature, in the schools of the day and in general and special practice. He recommended a permanent secretary for the Section and that the volume of the transactions should record biographic sketches of the members of the Section who died during the year.

The length and size of the Section program were about this time beginning to be a matter of growing concern. At the meeting in Baltimore in 1895, the rule was made that the papers of the members should not be longer than twenty minutes in the reading and that the discussor be allowed not more than fifteen minutes, and that this rule be strictly enforced. This rule became important as the Section began to grow and the programs grew to inordinate length.

The programs of the Section meetings of the late nineties often reached the prodigious size of more than thirty and even forty papers. In view of the length of the papers, one wonders how the chairmen of those days managed and emerged from a meeting with friendships intact. Section meetings which were originally intended only for afternoon sessions grew out of bounds and were held all day. At the fiftieth meeting of the Association, it was voted to hold the Section meetings only in the afternoon. At the fifty-second meeting of the Association in St. Paul in 1901, it was voted to limit the papers to members of the Section only, and one member could not present a paper in more than one section.

The following year at the Columbus meeting it was voted to limit the number of papers in any one section to forty. It is evident that the urge to write and the flood of literature are not altogether new symptoms and characteristics of our day.

Drastic limitations on the speakers, more careful selection of the program and the time element alone gradually reduced the program to reasonable size and content and one that could be managed within the allotted time.

At the sixtieth annual meeting of the Association in 1909 at Atlantic City, N. J., the Section presented a resolution that:

1. Pediatrics should be represented in the curriculum by a full professorship independent of any other chair.
2. The study of pediatrics should be compulsory and be required for graduation.
3. The time allowance for the course in pediatrics should not be less than two hundred hours.

These important resolutions were adopted and now form the basis on which the pediatric departments of practically all of the leading medical schools of the country are organized.

At the sixty-first annual meeting of the Association, held in St. Louis, the Section recommended to the trustees of the American Medical Association the establishment of a pediatric journal to be known as the *American Journal of Diseases of Children*. This was the beginning of what has today become one of the leading pediatric journals of the world.

At the seventy-second annual meeting of the Association, the forty-first of the Section, held in Boston in 1921, the chairman, Dr. Neff, recommended the creation of a fund to further scientific research, aid individual effort and defray the expenses of the secretary's office, the fund to be administered by a committee and to be known as the Abraham Jacobi Fund in honor of the founder of the Section.

By 1924 the accumulations of this fund permitted the committee to set apart a certain sum to be used in defraying, in part at least, the expenses of a foreign guest who might be invited. In 1924 the Section entertained as foreign guests Dr. Heinrich Finkelstein of Berlin and Dr. Leonard Findlay of Glasgow. In 1926 two distinguished Latin-Americans were the guests—Dr. Arturo Aballi of Cuba and Dr. Leon Velasquez Blanco of Argentina. In 1929 Dr. Giuseppe Caronia of Italy and Dr. Ernst Freudenberg of Germany were the guests. In 1930 Dr. Edward Mellanby and in 1931 Dr. Leonard Parsons, both of England, were the guests of the Section. Today we are honored by the presence of a distinguished colleague from Holland.

The conduct of the meetings of the Section during its infancy was delightfully informal. It was not unusual for the chairman, the secretary or both not to show up for the meeting, or not to appear until the second day—an unthinkable situation in our present day, but apparently complacently accepted at that time. The regular printed or announced program would often not be followed because the essayist likely as not would not show up. Volunteers were then called for and seemed to be available in abundance. Sometimes a volunteer read two papers at the same meeting. Thus it is recorded of a Dr. Earle of Chicago that he read his second volunteer paper on "A Plea for Pleasant Medication and a More Thorough Study of Infantile Therapeutics." At the same meeting, a Dr. Boothby of Wisconsin was excused from reading his paper on "Croup and Diphtheria, Their Unity or Duality," as a paper by a Dr. Harris from Virginia covered the same ground and embodied the same views.

If the discussion on papers grew too long, it was often postponed until the following day, just as a court is recessed. The meetings were not altogether without

discipline, as is shown by a motion that Dr. Casebeer, evidently an essayist on the regular program, read by title a paper which he had not thoroughly prepared.

At the eighty-first annual session in 1930, the section adopted a recommendation to change its name to "Section on Pediatrics." This recommendation, in the form of a resolution, was presented to the House of Delegates in 1931 and was adopted. The By-Laws, however, were not amended until 1932, at which time the change in name became effective.

The transactions of the Section and a complete printing of all of the papers given at the Section meeting have appeared since the year 1898.

A brief review of the programs of the last five decades reflects probably better than anything else the problems and the trend of thought of the period and the real progress that was made in meeting and conquering the successive difficulties which beset the pediatric practitioner in the development of our special field in medicine. It marks, also, the great advance we have made in the conquest of the diseases of infancy and childhood and in our knowledge of preventive care and protection.

The earlier programs of the decades from 1883 to 1903 still reflect some rather primitive pediatrics. Diphtheria and all its supposed dangers and causative influence on disease have a prominent place on the early programs. The subjects most discussed were diphtheria and membranous croup. No program was without several papers on these subjects. The subject next in importance was bloody discharges from the bowel. Poliomyelitis was first mentioned in the program of 1889.

The subject of child training and physical education in children is first discussed in the programs of the early nineties. Along with this newer thought, however, a bit of older pediatric teaching creeps in. On the program for 1902 appears the title, "Should Infants be Washed Directly After Birth," and another one, rather amusing but probably a sensible observation for the time, "On the Absence of Cow's Milk from Japan: Its Beneficial Consequences." As stated before, the 1893 Milwaukee program was memorable on account of its excellence and the diversity of subjects discussed. It introduced also for the first time the idea of symposiums on a given topic. Diphtheria and pneumonia in childhood were discussed.

The decade from 1894 to 1903 marks many distinct advances. The entity of diphtheria and the distinction between true and false croup were definitely established. The value of diphtheria antitoxin was clearly recognized. This fact and the practice of intubation had tremendously reduced the mortality of this dreaded disease.

There was a good deal of interest in enteric and typhoid fever, and no program was without a paper or two on alimentary disorders.

Increasing interest is shown in the subject of tuberculosis from the late nineties on.

This period marks the introduction of the milk laboratory and with it a new era in the sanitation of milk which in turn became a large factor in the reduction of infant mortality. The year 1896 to 1897 marks the first appearance as contributors to the section programs of some notable names in American pediatrics; Dr. Holt, Dr. Kerley and Dr. Griffith. Dr. Koplik had preceded them by several years, and they were followed shortly by Hollopeter, McClanahan, John L. Morse and our own Dr. Abt.

Rickets is discussed for the first time in a Section program in 1899.

The meeting of 1901 was marked by an imposing symposium on typhoid fever. At the same meeting the use of the x-ray as a diagnostic measure is first mentioned by Dr. W. W. Keen, who reported the location of a ureteral calculus by its aid.

Artificial feeding is given much space on the programs, and the meeting in 1903 at New Orleans had as a principal part of the program a symposium on artificial feeding and its relation to the diarrheal disturbances of childhood.

Breast milk and breast milk feeding were beginning to get considerable attention.

The decade from 1904 to 1913 marks new trends, new interests and again a distinct march forward. The sanitation of milk is much discussed, and in connection with it the various forms of bacillary dysentery. There is a distinct movement to return to breast feeding and to break away as much as possible from artificial feeding.

Jacobi's famous paper on "The Gospel of Top Milk" given in the 1908 session set up an entirely new line of clinical investigation in infant feeding, and foreshadowed many of the changes that were to come in later years in this important field of pediatrics.

Studies of metabolism in myxedema were first suggested in a paper given at the 1905 meeting. Treatment with rest for patients with anorexia, the use of lactic acid bacilli and of lactic acid in certain alimentary disturbances, feeding on the basis of calorie values for food and the use of vaccine and serum therapy were subjects discussed in the programs of the early section meetings of this decade.

It again marks the first appearance of a notable group in American pediatrics—Amberg, Rulrah, Royster, Freeman, Chapin, Knox, Pisek, Graham, Hamill, A. F. Hess, Howland, Blackfan, Talbot and Sedgwick—as contributors to the Section program. In the latter part of the decade one comes across the names of Porter, DeBuys, R. M. Smith, O. M. Schloss, Cooley, Brennemann, J. Hess, Gerstenberger, and Grulee with their first offerings.

This decade is characterized by a great awakening with reference to the problem of infant mortality. In the chairman's address of the twenty-eighth session of the Section in 1908, Graham deals with this subject. He pointed out that 50 per cent of the deaths of infants were preventable and listed a number of factors which he regarded as important in lessening infant mortality, among them inspection of milk, free antitoxin, improved sanitation, good food, antenatal care, teaching of hygiene in the schools, breast feeding and pasteurization of milk during hot weather.

Jacobi had pointed out publicly the enormous mortality in the founding institutions of New York City and as a consequence was asked to resign from the hospital staff.

The subject of infant mortality, child welfare and preventive pediatrics looms large on nearly all the Section programs from 1910 on, and is discussed by a number of the chairmen in their addresses.

In this decade occurred the first extensive epidemiologic studies of acute anterior poliomyelitis.

Allergy is discussed for the first time in the program of the 1912 meeting.

There is a continued interest in the subject of tuberculosis and the possible defensive mechanism of the body against it.

The pioneer work of Cooley clarified much about hemorrhagic diseases, and the value of the roentgen ray in pediatrics was first stressed by a number of authoritative clinicians.

This decade is notable, also, for the appearance for the first time on its programs of physiologic or biochemical studies relative to pediatrics; it marks the beginning of an era of scientific investigation which has placed American pediatrics on a high plane.

The decade from 1914 to 1923 is marked by consolidation and enlargement of the gains made in the previous one. The years of the World War fall within this period. The inevitable decline of European pediatrics was counterbalanced by our distinct rise.

Preventive pediatrics is a prominent subject for discussion on every program.

The splendid scientific investigation of Howland, Gamble, Marriott, Hess, Park Talbot and many others contributed much of the newer knowledge in the field of nutrition. Vitamins for the first time made their appearance on the programs.

The importance of sinus infections as possible disease factors is frequently discussed.

Two significant symposiums, one on poliomyelitis in 1917 and a later one on other contagious diseases, mark the great interest in this decade in these subjects.

Encephalitis appears for the first time on the programs as a subject of discussion.

The splendid studies of Jeans on syphilis fall within this period.

Children's teeth and their care are discussed for the first time.

The work of Bilderback, Beifield and Weston clearly established the identity of acrodynia.

Blood transfusions as a form of therapy were first advocated and quite extensively used during this period.

This decade also marks the first use of active immunization against diphtheria.

In this decade (July 10, 1919) falls the death of the beloved founder of this Section, Abraham Jacobi, one of the great figures and leaders in American pediatrics.

The remaining decade from 1924 to the present time is marked by progress in many fields. This is particularly true in the field of nutrition and in the study of deficiency diseases, such as rickets and scurvy.

The research on the photodynamic effect of light and the translation of such effect to therapeutic use resulted in many contributions on this subject.

The programs of this decade are marked by a number of important symposiums: one on appendicitis at the 1924 session, one on diseases of the upper respiratory tract in 1925, one on tuberculosis and on rheumatic heart disease in 1927, and one on diseases of the renal tract at the 1931 session.

Great strides have been made in the immunization against and the control of contagious diseases.

Preventive pediatrics no longer needs champions for its cause. It is now entirely accepted and quite universally practiced.

Child psychiatry and psychology, always a neglected field, is now a very live topic and one that has increasing interest for the Section.

The White House Conference, a magnificent inventory of all pediatric accomplishment to date, completed its work only a short time ago and marks a contribution hardly equaled anywhere for the usefulness and good that it may do.

We pause at the half-century mark; with pardonable pride the Section may regard the past, with courage and

confidence it may look to the future. The course is quite clear; we must live up to the past traditions and must build even better for the future. The Section should always remain a central rallying point of American pediatrics and should be our chief contact with the body at large of our profession. It must be one of the chief sponsors for any movement that makes for better child care, welfare and protection.

At least two factors are, I believe, of prime importance in accomplishing our ends. Considerable thought and much care must be used in the preparation of the Section program, and we must discourage in every way possible any movements or organizations which tend to dispersion or detraction of interest in the Section and its work.

Proper regard for these two factors will, I confidently believe, mean insured success and continued prestige for an organization of which we may justly be proud.

HYPERTENSION, OBESITY AND HYPERGLYCEMIA

J. H. MUSSER, M.D.

AND

D. O. WRIGHT, M.D.

NEW ORLEANS

The association of hyperglycemia and hypertension has been observed repeatedly and there has been a considerable literature accumulated which has to show that these two conditions are by no means unusual in combination.¹ The common relation of obesity to hypertension has likewise been appreciated for many years, but the frequency with which hyperglycemia occurs in obesity is a more recent observation. It would seem reasonable to expect that if hypertension and hyperglycemia are frequently associated, if obesity and hypertension are likewise often linked together and if hyperglycemia is common in the obese, it is quite likely that these three disturbed physiologic states would be prone to occur together, rather than in combination of any two of them. Such has been our experience. We have observed in a group of thirty obese patients with hypertension sugar tolerance curves that approach those of the diabetic patient. This group composed most of the elderly fat women not suffering from some acute infection who were admitted to a female medical ward in the Charity Hospital over a period of nine months. It is our impression that the syndrome of hypertension, obesity and reduced sugar tolerance is, as is to be expected and anticipated, quite common.

HYPERTENSION AND HYPERGLYCEMIA

Neubauer,¹ twenty-three years ago, was the first to note the occurrence of high blood sugar and high blood pressure and advanced the hypothesis that it was due to overactivity of the suprarenals. O'Hare¹ studied the dextrose tolerance curves of twenty-three patients

From the Department of Medicine, School of Medicine, Tulane University of Louisiana, and the Charity Hospital of Louisiana.

Read before the Section on Practice of Medicine at the Eighty-Fourth Annual Session of the American Medical Association, Milwaukee, June 16, 1933.

P.: Glucose Tolerance Test in Vascular Hypertension, *Am. J. M. Sc.* 160:366, 1920.

with chronic vascular hypertension with normal renal function. Seven of these patients showed nothing abnormal in regard to dextrose metabolism, whereas eleven showed a definite rise in blood sugar and five of the eleven cases presented a glycosuria at the end of three hours. He suggested that these patients were potentially diabetic. He was unable to correlate the dextrose tolerance test with the degree of arteriosclerosis present in these patients. In 1923, Herrick¹ studied patients with hypertension and found that increased concentration of the dextrose in conjunction with the elevated pressure indicated that there were four cardinal symptoms of the condition in addition to the two already mentioned, obesity and arteriosclerosis being likewise added. In six typical examples of this syndrome, all of them presented evidence of cardiovascular overstrain. Herrick suggested a subdivision of essential hypertension based on this symptom complex. The sequence of events, as he suggested, was low dextrose tolerance, hence overburden of the pancreas; this naturally would be followed by increase in weight and then by an increased tendency to arteriosclerosis and later by an increase in blood pressure.

Mohler,² in 1925, discussed hypertension and hyperglycemia in forty-six patients who had a systolic pressure of over 150 mm. of mercury, and glycosuria. Thirty-seven of these patients were obese. These patients did not show any greater evidence of peripheral vesicular sclerosis than would be anticipated from their age. Mohler advances the idea that degenerative changes take place in the body, affecting the structures involved in carbohydrate metabolism, impairing their efficiency and resulting in hyperglycemia. Obesity favors the development of such sclerotic changes.

Mosenthal³ lists a considerable number of authors who contend that there is a common relationship between hypertension and hyperglycemia and a somewhat smaller group who do not think that there is any association between elevated arterial pressure and increased glycosuria. He compared the blood pressure readings with thirty-one dextrose tolerance tests and found that there was no rise in blood pressure with the

survey was made of 453 records of patients who were in the Charity Hospital longer than twenty-four hours. Further, an effort was made to distinguish between those who were undernourished and those who were obese. The accompanying table gives the result of the blood pressure in these patients. It should be noted that the obese patients were not classified as such unless decidedly overweight. It is rather interesting to speculate on why there was a very much greater number of fat diabetic women than there were men, the percentage being more than double in the former. It can be noted also that in these fat diabetic patients the systolic pressure in the men was only 10 mm. higher than in the male diabetic patients who were not overweight, whereas in the female the average systolic pressure in the obese was 28 mm. of mercury higher than in the average woman who was not fat.

Chart 1.—Composite blood sugar curves of thirty obese hypertensive patients.

Hypertension in the diabetic patient is, of course, a frequent finding. As Joslin has so frequently pointed out, the diabetic patient sooner or later develops arteriosclerosis, so it is to be expected that hypertension will occur in the majority of cases as the disease progresses. It is of interest to note that the obese diabetic patient, an individual who presumably has mild diabetes, has, according to our figures, a considerably more elevated blood pressure than does the thin diabetic patient who represents a more severe type of case.

Kramer³ studied 570 cases of diabetes and found that 39 per cent (195 patients) had a blood pressure of 150 mm. of mercury or above. He states that "it is unlikely that diabetes through its hyperglycemia produces hypertension."

Comparative Blood Pressure Readings of Diabetic Men and Women

| Number..... | Men | | | Women | | |
|----------------|-------------|-----------------|-------------|--------------|------------------|--------------|
| | Obese 15 | Not Obese 72 | Total 90 | Obese 119 | Not Obese 133 | Total 254 |
| Systolic..... | 148 | 138 | 140 | 171 | 143 | 158 |
| Diastolic..... | 87 | 79.8 | 81 | 96 | 86.5 | 90 |
| | Average | | | Average | | |

temporary increase in blood sugar, demonstrating that transient hyperglycemia does not influence the blood pressure. Seven cases of diabetes presenting hyperglycemia of varying degree over a period of seven years failed to show an increase in blood pressure. He believes because of this finding that the hyperglycemia which is prolonged does not affect blood pressure, although it does not exclude the possibility that a hyperglycemia through increased polyuria with consequent tissue desiccation may favor the development of arteriosclerosis.

HYPERTENSION IN DIABETES

In an endeavor to determine the frequency of an elevation of blood pressure in the diabetic patient, a

OBESITY AND HYPERTENSION

The obese person characteristically has a hypertension. As expressed by White,⁴ it is common for the obese to have hypertension. It is not necessary to discuss in detail this particular phase of the obese-hypertensive-hyperglycemia syndrome. Preble⁵ studied the blood pressure of 1,000 obese individuals. His figures indicate that there is a definite, but by no means extreme, increase in the blood pressure, both systolic and diastolic, for the different age groups. Thus, in the group in the fifth decade of life, the average systolic pressure was 150 mm. and diastolic 98. In the present series, dextrose tolerance tests on thirty-one obese patients without diabetes or chronic nephritis were found to be within normal limits.

OBESITY AND HYPERGLYCEMIA

John⁶ reports twelve cases of obesity of which nine were in women, in whom the overweight ranged from 29 to 15 per cent. Glycosuria was present in two of

He compared the blood pressure readings with thirty-one dextrose tolerance tests and found that there was no rise in blood pressure with the

survey was made of 453 records of patients who were in the Charity Hospital longer than twenty-four hours. Further, an effort was made to distinguish between those who were undernourished and those who were obese. The accompanying table gives the result of the blood pressure in these patients. It should be noted that the obese patients were not classified as such unless decidedly overweight. It is rather interesting to speculate on why there was a very much greater number of fat diabetic women than there were men, the percentage being more than double in the former. It can be noted also that in these fat diabetic patients the systolic pressure in the men was only 10 mm. higher than in the male diabetic patients who were not overweight, whereas in the female the average systolic pressure in the obese was 28 mm. of mercury higher than in the average woman who was not fat.

Chart 1.—Composite blood sugar curves of thirty obese hypertensive patients.

Hypertension in the diabetic patient

is, of course, a frequent finding. As Joslin has so frequently pointed out, the diabetic patient sooner or later develops arteriosclerosis, so it is to be expected that hypertension will occur in the majority of cases as the disease progresses. It is of interest to note that the obese diabetic patient, an individual who presumably has mild diabetes, has, according to our figures, a considerably more elevated blood pressure than does the thin diabetic patient who represents a more severe type of case.

Kramer³ studied 570 cases of diabetes and found that 39 per cent (195 patients) had a blood pressure of 150 mm. of mercury or above. He states that "it is unlikely that diabetes through its hyperglycemia produces hypertension."

Comparative Blood Pressure Readings of Diabetic Men and Women

| Number..... | Men | | | Women | | |
|----------------|-------------|-----------------|----------------|--------------|------------------|----------------|
| | Obese 18 | Not Obese 72 | Total 90 | Obese 119 | Not Obese 135 | Total 254 |
| Systolic..... | 148 | 138 | Average 140 | 171 | 143 | Average 158 |
| Diastolic..... | 87 | 79.8 | 81 | 96 | 86.5 | 90 |

temporary increase in blood sugar, demonstrating that transient hyperglycemia does not influence the blood pressure. Seven cases of diabetes presenting hyperglycemia of varying degree over a period of seven years failed to show an increase in blood pressure. He believes because of this finding that the hyperglycemia which is prolonged does not affect blood pressure, although it does not exclude the possibility that a hyperglycemia through increased polyuria with consequent tissue desiccation may favor the development of arteriosclerosis.

HYPERTENSION IN DIABETES

In an endeavor to determine the frequency of an elevation of blood pressure in the diabetic patient, a

2. Mosenthal, H. O.: The Relation of Blood Sugar to Blood Pressure, *Am. J. M. Sc.* 176: 761 (Dec.) 1928.

OBESITY AND HYPERTENSION

The obese person characteristically has a hypertension. As expressed by White,⁴ it is common for the obese to have hypertension. It is not necessary to discuss in detail this particular phase of the obese-hypertensive-hyperglycemia syndrome. Preble⁵ studied the blood pressure of 1,000 obese individuals. His figures indicate that there is a definite, but by no means extreme, increase in the blood pressure, both systolic and diastolic, for the different age groups. Thus, in the group in the fifth decade of life, the average systolic pressure was 150 mm. and diastolic 98. In the present series, dextrose tolerance tests on thirty-one obese patients without diabetes or chronic nephritis were found to be within normal limits.

OBESITY AND HYPERGLYCEMIA

John⁶ reports twelve cases of obesity of which nine were in women, in whom the overweight ranged from 29 to 15 per cent. Glycosuria was present in two of

these cases and in eleven of them the fasting blood sugar was normal. Forty-two per cent of the group showed either the blood sugar curve of mild diabetes or definite diabetes. His suggestion is that the pancreas may be responsible, as a result of dysfunction, for obesity of the endogenous type. Allison,⁷ in studying a group of twenty patients who were overweight, found that approximately half of the group had a decreased sugar tolerance. In his group were included eight persons who had a preexisting glycosuria, so that of twelve who were simply obese only three had a sugar response which indicated that they had abnormal sugar tolerance.

SUGAR TOLERANCE CURVES IN THE OBESE HYPERTENSIVE INDIVIDUAL

We have studied a group of thirty patients who ranged in age from 34 to 67. They were all women and were all decidedly overweight. The average age of the group was 52.5 and their average weight was 192 pounds (87 Kg.). The average blood pressure with a mercury manometer was 204 systolic, 118 diastolic. The systolic blood pressure ranged from a high of 254 to a low of 174. The diastolic pressure ranged from the extreme of 144 to 88. None of these patients had glycosuria before the dextrose was given. Eight of them had mild glycosuria at the end of three hours. In only one instance was there more than a very faint trace of sugar, in which case it was 1 per cent. One hundred grams of dextrose was given by mouth and the first specimen of blood was taken at the end of one hour, the second two hours later and the third three hours afterward. The sugar estimations were done according to the method of Folin-Wu. The mean curve for the group showed a fasting blood sugar of 97.7 mg. per hundred cubic centimeters; one hour later it was 176.2; two hours later, 174.6, and the third hour, 163. A variety of curves were elicited which it seems useless to reproduce individually; consequently, they are presented as a group. As a whole, the patients all maintained the typical response to dextrose exhibited by the diabetic, prediabetic or patients who have a reduced tolerance to sugar. A corresponding control group of nine obese patients without hypertension was studied.

Chart 2.—Blood sugar curves of nine obese patients without hypertension.

In only one instance was there exhibited a curve comparable to that of the fat hypertensive person. In this instance, one hour response showed a rise of figures to 181, which subsided in two hours to 80. In the control group the average weight was 191 pounds (86.6 Kg.). The age averaged exactly ten years under that of the test group. The blood pressure in all these individuals was within normal range.

Further analyses of the curves were made in order to determine the effect of age on the sugar tolerance determinations. A group of eleven patients whose age was below 50, averaging 42.8 years, gave a curve that showed a fasting blood sugar of 91, rising to 162, falling to 142 at the end of the second hour and 133 at the end of the third hour. This age group compared with

the obese patients without hypertension, whose average age was 42.5. In the patients above 50, the average age was 58; the curve began at 95 mg. of sugar and registered 190 at the end of the first hour, 196 at the end of the second hour, and 171 at the end of the third hour. These two curves would seem to indicate that the hypertension might play an important rôle in the production of hyperglycemia. In other words, the age of the younger obese hypertensive individuals was almost exactly the same as those without hypertension, and yet their tolerance of sugar was markedly reduced. On the other hand,

it might just as well be argued that the diminished tolerance to sugar plays an important rôle in the production of hypertension. In the latter older group, in which it is safe to assume that arterial disease of various degrees was present, the curve certainly suggests that arteriosclerosis and degenerative changes, possibly

Chart 3.—Comparison of the blood sugar curves in obese hypertensive persons over and under 50 years of age and obese patients without hypertension.

in the arterial system and parenchyma of the pancreas, helped to exaggerate the lowered tolerance to sugar.

One or two interesting curves were noted. In one instance, a woman who weighed 278 pounds (126 Kg.) and was 5 feet 8 inches (172.7 cm.) in height, had a blood pressure of 230 systolic, 125 diastolic, with a fasting blood sugar of 100. At the end of the third hour the blood sugar was 20 mg. higher than at the end of the second hour; in other words, it was still ascending. Another patient had a very marked rise from a fasting blood sugar of 86 to 200, dropping in an hour to 130. The highest blood sugar at the end of two hours was 230 mg.; this occurred in a woman, aged 60, 5 feet 1 inch (155 cm.) tall, whose blood pressure was 245 systolic, 130 diastolic. The lowest figure was in a patient whose curve rose from a fasting sugar of 95 to 125, and fell to 119 in both the second and third hour observations. The blood pressure was 190 systolic, 100 diastolic. Patient 23 was a woman 5 feet 8 inches (172.7 cm.) in height, weighing 195 pounds (88.5 Kg.). She had a blood pressure of 188 systolic, 100 diastolic; the fasting blood sugar was 95, which rose to 181 and fell to 135 and then to 130. She was put on a low carbohydrate diet and with careful attention to her food intake lost 35 pounds (15.9 Kg.). Her blood pressure then was found to be 168 systolic, 100 diastolic; the fasting blood sugar was 90; it rose to 140 and fell to 125 the second hour and to 111 at the end of the third hour. The response to treatment will be reported in a later communication.

COMMENT

We have presented the average figures obtained from a group of fat women who had an elevated blood pressure and hyperglycemia. These patients were selected because they were fat and had high blood pressure, in order to study their blood sugar response to a given amount of dextrose administered by mouth. This was done to determine whether their obesity was associated with the inability properly to utilize carbohydrate and to see whether there was any definite relationship

7. Allison, R. S.: Carbohydrate Tolerance in Overweight and Obesity, *Lancet* 1: 537 (March 12) 1927.

between the hypertension and the sugar curve. It was found that all these patients exhibited a lowered tolerance to sugar, but whether or not this had any relationship to their hypertension cannot be definitely stated. It would seem that there is a definite syndrome in which obesity, hypertension and hyperglycemia are associated, probably with ultimate arteriosclerosis. However, in respect to the latter, in no one of our patients was arteriosclerosis clinically demonstrable. It is safe to assume that many of the patients did have arteriosclerosis, a statement which can be partially substantiated by the fact that the age group was ten years greater than in the control group and by the fact that it is rather difficult to conceive of pressures as high as some of the systolic and diastolic pressures in these individuals existing without a concomitant peripheral sclerosis.

In contrasting the group of younger hypertensive individuals with those of the same age period without hypertension, it is impossible to say whether the hypertension or the reduced tolerance to sugar was responsible, on the one hand, for the hyperglycemia or, on the other hand, for the hypertension.

The relation of the diminished sugar tolerance to hypertension is one about which a definite statement cannot be made either from the data that we have studied or from a review of the work of others. The correlation is so constant, however, that it would seem as if there might be some relationship to the lowered sugar tolerance other than that of the development of arteriosclerosis in a fat individual who has a hypertension. It might be possible to speculate and to advance many theories (impairment of carbohydrate storage mechanism as age advances,⁸ delay in secretion of insulin,⁹ kidney dysfunction and suprarenal action) as to why the obese hyperglycemic patient has a hypertension or why the obese hypertensive patient has a hyperglycemia, but none of these can be substantiated definitely.

In our group it is doubtful whether the factor of menopausal endocrine disturbances might possibly have some effect, as many of the patients had passed the menopause; some had not reached the menopause and only three of them could be said to be in the menopausal zone. We do not believe, therefore, that the syndrome of hypertension, obesity and hyperglycemia is a menopausal phenomenon.

The relationship of the obesity to the hyperglycemia is obvious. The obese individual is much more likely to develop diabetes than is the thin person. It naturally follows that several of the individuals of this group were obese hypertensive persons who could be classified as prediabetic.

It would seem to us that no one cause could be definitely stated as being responsible for the hypertension, the hyperglycemia, or the obesity in this group of patients who present all of these three abnormal conditions. Rather it would seem that the combination of the three conditions aggravating or intensifying one another would be the explanation for the greater pressure, the lessened response to sugar and possibly also the obesity for the group as a whole. All the factors taken together make a vicious circle which ultimately will develop in a well marked vascular sclerosis with its

attendant complications and remote effects. Fundamentally it would seem that the obesity was the most important physiologic-pathologic disturbance; the obesity is directly related to the hyperglycemia, evidenced by a diminished ability properly to metabolize food substances (carbohydrates).

In the obese individual the obesity is probably a constitutional state that is hereditary. The inherited tendency to fatness is exaggerated and intensified by the inability to take care of carbohydrates and in many instances by other factors, such as overeating and insufficient exercise. With the overweight there is an elevation of blood pressure and finally arteriolar sclerotic changes that may in turn intensify the blood pressure. These sclerotic changes, however, are certainly not early but rather late developments that occur tardily in the course of the syndrome. The fundamental basis for the syndrome would then seem to be obesity with its diminished sugar tolerance, and the control of the condition would seem to be in the adequate treatment of the obesity through carbohydrate reduction. Reduction in weight frequently produces lowering of the blood pressure and the return of the sugar tolerance curve to a relatively normal one.

SUMMARY

A group of thirty obese hypertensive women exhibited a marked lowering of sugar tolerance. A second group of fat individuals without hypertension are shown not to have a hyperglycemia. It seems reasonable to assume that there is no one factor definitely responsible for the combination of obesity, hypertension and hyperglycemia unless it is obesity. The reduction in weight is often associated with a lowering of the blood pressure and a return of a sugar tolerance curve to normal.

1430 Tulane Avenue.

ABSTRACT OF DISCUSSION

DR. HENRY J. JOHN, Cleveland: The incidence of diabetic curves during dextrose tolerance tests in a series of 459 cases summarizes effectively my experience along this line. There are nearly three times as many diabetic curves in the obese as there are in the normal weight patients. It coincides with what has been pointed out in the literature; namely, that obesity predisposes to diabetes. Next is the question of overweight in 528 cases of diabetes. Again the same criterion comes out forcibly; namely, that more than three fourths of patients who have diabetes are or have been overweight before the diabetes developed. This means that patients with normal weight lost weight because of diabetes. In 1,828 patients with diabetes in whom the blood pressure was studied, I found that one half of those of overweight had a pressure above 140, but only one fourth of those of normal weight. I feel, therefore, that the whole problem comes down to one important point; namely, the question of obesity. The treatment of obesity is, of course, very discouraging, and more thought ought therefore to be devoted to prevention. Those who have to treat obesity will agree that it is the most discouraging problem in the whole field of medicine, whereas the prevention of obesity is a much easier problem. I feel that the prevention of obesity will prevent many other conditions that accompany obesity.

DR. HUGO R. ROXY, Chicago: Low sugar tolerance is common in hypertension, regardless of the body weight. Therefore a specific connection between hypertension and low sugar tolerance with obesity could be claimed only if practically every hypertensive obese person would show a low sugar tolerance, and no obese person with normal blood pressure would have low sugar tolerance. This appears to be the case according to the authors' observations, but I am unable to confirm this on the basis of my own data. Out of my seventy-two cases of obesity, all in women above 30 years of age, forty registered blood pressures below 150 systolic, with an average of 130

8. Spence, J. C.: Some Observations on Sugar Tolerance, with Special Reference to Variations Found at Different Ages, *Quart. J. Med.* 14: 314 (July) 1921.

9. Woodruff, R. T.: Some Milder Forms of Diabetes, with Special Reference to Mild Diabetes in Elderly Persons with Arteriosclerosis, *South. M. J.* 17: 145 (March) 1924.

systolic, 83 diastolic. This group is considered a normal blood pressure group. In fifteen of these forty the sugar tolerance was decidedly low, twelve of them showing marked glycosuria during the test. Accordingly, more than one third of my obese patients with normal blood pressure showed a markedly or extremely low sugar tolerance. In thirty-two cases the systolic blood pressures were above 150, the average being 175 systolic, 110 diastolic. In this hypertensive group, seventeen cases showed low sugar tolerance, of which ten exhibited glycosuria at some time during the test. However, the sugar tolerance was normal or even high in fifteen cases; that is, in almost half of this group. These observations do not support the idea of some basic connection of obesity, hypertension and low sugar tolerance. It appears rather that there is some connection between the age of obese patients and the sugar tolerance. I observed that high sugar tolerance is frequent and that low sugar tolerance is rare in the juvenile obese patients, while the opposite is true for the adult obese patient. There are probably several factors instrumental in the frequent change in sugar tolerance with age in obesity. Some of these factors may be due to changes in the aging endocrine system. But the chief factor is probably exogenous in nature: young obese patients, having high sugar tolerance, crave carbohydrates, and with the increased carbohydrate intake overtax their mechanism for carbohydrate utilization, which in turn after years becomes exhausted and inefficient. Hence the shift in sugar tolerance with advancing age.

DR. FREDERICK A. WILLIUS, Rochester, Minn.: The emphasis of the authors on the clinical triad hypertension, obesity and hyperglycemia has been of importance. I wish to confine my remarks to the heart in obesity. The data have been derived from a postmortem study of 136 cases recently completed by Dr. H. L. Smith and me. In all cases the epicardial deposit of fat was increased, in some instances to such a degree that the heart was virtually encased in fat. In practically all cases the fat penetrated into the muscle substance, being deposited in large quantities between the muscle bundles and muscle cells, particularly of the right ventricle. There was not any instance in which a deposit of fat in excess of normal was found within the cytoplasm of the cells. The localization of the fat we believe to be important. Fat is deposited within the cytoplasm of cells predominantly in such states as phosphorus and chloroform poisoning, pernicious anemia, leukemia, and the cachexia of cancer. In 38 per cent of the cases, associated cardiac disease was not demonstrable. Varying degrees of heart failure occurred in 7 per cent of the cases in which pathologic changes other than the increased deposit and penetration of fat did not occur. Of the patients, 44 per cent had had hypertension, and 11 per cent miscellaneous forms of associated heart disease. The weight of the heart in all cases was increased. In the group of patients without associated disease of the heart the average weight exceeded that of the normal hearts of persons of average body weight by 38 per cent; in the group of patients with heart failure but without associated cardiac disease, by 65 per cent, and in the group of patients with hypertension, by 72 per cent.

DR. FRANCIS D. MURPHY, Milwaukee: Reports concerning the incidence of hypertension in diabetic patients have varied according to different authors. Figures have been given showing an incidence as high as 39 per cent and others as low as 14 per cent. In reviewing the complications in 827 cases of diabetes, I found hypertension in 102, or only 11 per cent. Of course, if obese diabetic patients alone were considered, the incidence of hypertension would be a great deal higher. I should like to know from the authors whether blood cholesterol determinations were made of any of the cases. The relationship of hypercholesterolemia to diabetes is well established. The relationship of hypercholesterolemia to arteriosclerosis is not so well established, while the relationship between hypercholesterolemia and hypertension is questionable. I had blood cholesterol determinations made on every patient with hypertension that came into the hypertension and nephritic clinic of the Milwaukee County Hospital for seven years and I came to the conclusion that there was no relationship between hypercholesterolemia and hypertension. More recent work, especially in Germany, has thrown a different light on the subject. It has been pointed out that the amount of blood cholesterol itself is not the deciding factor but that the disturbed ratio between the blood cholesterol

and the plasma protein, the albumin and the globulin, is the factor that influences blood pressure. The solubility of the cholesterol is dependent to some degree on the plasma albumin and globulin. It was shown that with a normal blood cholesterol there may be an oversaturation with cholesterol or that there may be an undersaturation of the blood with cholesterol. It was found that hypertension was associated with a supersaturation of the blood with cholesterol in 90 per cent of cases, while in nonhypertensive cases there was no oversaturation with cholesterol in any case.

DR. EMMET F. HORINE, Louisville, Ky.: The study of Drs. Mussey and Wright brings up some speculative problems. The question that arises is whether the relationship that exists between hypertension and diabetes above the age of 40 is not more apparent than real, since each disease is encountered with greater frequency in the decades above 40. This age incidence may also partly explain the well known association of arteriosclerosis with diabetes. Thirty obese hypertensive patients of the authors exhibited dextrose tolerance curves similar to those of diabetic patients. Their control group of nine nonhypertensive obese patients gave only one curve at all comparable to the fat hypertensive person; hence they conclude that there is a syndrome of hypertension, obesity and hyperglycemia. Hypertensive obese patients often have abnormal dextrose tolerance curves, but possibly it is the pathologic state accompanying the increased blood pressure that provokes the peculiar response to dextrose, and not the obesity. Since widespread involvement of the arterioles throughout the body exists in essential hypertension, it would seem that arteriosclerosis in the pancreas and especially in the islands might be the cause of the changes in carbohydrate metabolism noted by the authors. Thus a study of a series of patients with advanced essential hypertension, regardless of whether they are fat or lean, should reveal a preponderance of abnormal dextrose tolerance curves. Actually, O'Hare, in a study of the dextrose tolerance in hypertension, came to the conclusion that many hypertensive patients are potentially diabetic. Recently in analyzing 233 cases of diabetes admitted to the Louisville City Hospital, I found that 85 (36 per cent) had hypertension. Normal blood pressure levels were found in 106 (46 per cent) and levels below normal in 42 (18 per cent). I may say that before the fortieth year diabetes and essential hypertension rarely occur together but that after this period they are frequently observed in the same individual because of the same age incidence and probably because of the additional factor of disturbance of carbohydrate metabolism secondary to arteriolar changes in the pancreas of the potentially diabetic hypertensive patient. The more I study essential hypertension the more firmly convinced I become that, aside from a hereditary background, its causation cannot be explained at present.

DR. F. R. NUZUM, Santa Barbara, Calif.: I would call attention to another function of the pancreas that may be concerned with hypertension. Abelson and Bardier in 1903 first called attention to a depressor substance in the urine. Pribram and Herrnhiser in 1902 recorded that the nondialysable fraction of human urine caused a fall in blood pressure when injected into experimental animals. E. K. Frey and H. Kraut in 1928 reported exhaustive experiments with this vasodilator substance present in the urine, which, they found, was elaborated by the pancreas, circulated in the blood, and had to do with the regulation of the peripheral circulatory balance. They believe this is a hormone. This substance is an epinephrine antagonist. From work by Frey and Kraut and from that by my associate Dr. A. H. Elliot and myself, this substance has been shown to exert a regulatory influence on arterial tonus. Since it opposes the most powerful pressor substance in the body, epinephrine, and since its presence and amount in the urine can be accurately determined, we have approached the problem of hypertension by measuring the amount of this so-called hormone in the urine of normal persons and of those with essential hypertension. The urine of fifty persons with systolic blood pressures over 150 mm. of mercury was studied. As a control series, the urine of fifty adults with systolic pressures under 140 mm. was used. We found that the excretion of this substance bears a definite correlation with the age of the individual. In the control group under 40 years of age, the twelve-hour output averaged 3,800

units; from 40 to 60 years, 2,773 units, and over 60 years, 1,530 units, a drop in each group of, roughly, 1,000 units. In the group of fifty individuals with essential hypertension, those under 40 years of age averaged a twelve-hour output of 1,695 units; those between 40 and 60 years averaged 1,333 units, and those over 60 years averaged 635 units. The possibilities of this hormone as related to treatment are pertinent. The pancreas elaborates this material, which neutralizes the effect of the vasoconstrictor, epinephrine. Our studies have shown a lessened output of the hormone in hypertension. There is as yet no accurate method of determining the amount of epinephrine in the circulating blood; but if it is present in an abnormal amount or if its constricting action is not sufficiently opposed by a depressor substance, hypertension might well result.

DR. JOHN H. MUSSER, New Orleans: Dr. Wright and I do not mean to imply that every fat woman who has passed the age of 40 and who has a hypertension necessarily has to have a hyperglycemia, nor do we mean to imply that every fat woman past the age of 40 who has a hyperglycemia necessarily has to have a hypertension. A goodly number of them do, however, and I think they present a rather interesting syndrome. In the majority of instances their outstanding complaints are cardiovascular rather than metabolic, yet it is through the control of the metabolic process, which I believe is fundamental, that the cardiovascular disturbances are kept in check. I can answer Dr. Murphy by saying that we have not made cholesterol estimations on these people.

PRESENT POSITION OF OUR KNOWLEDGE OF ANTERIOR PITUITARY FUNCTION

HERBERT M. EVANS, M.D.
BERKELEY, CALIF.

One of the most dramatic chapters in the progress of modern medicine is the story of the evolution of our knowledge of the pituitary body, that minute glandule situated almost in the mathematical center of the head, regulating as it does those fundamental mechanisms of growth, reproduction and even the power of the body to conduct its normal metabolic machinery. The story, too, is only typical for what may be told of other parts of the endocrine mechanism of the body so that I trust that this meeting of the Congress of American Physicians and Surgeons may gain significance in the future as having marked a turning point in the kind of interest displayed toward certain fields of medical research.

We are conceivably at the inauguration of a new era, an era which shall witness the same startling disclosures and confer on us the same beneficent instruments of prevention and control as characterize what I may term the bacteriologic epoch so gloriously inaugurated by the labors of Louis Pasteur and Robert Koch. Endocrinology, which suffered obstetric deformation in its very birth by the extravagant claim of the septuagenarian Brown-Séquard that he had magically restored his youth with testicular substance, has continued to suffer the same sort of obloquy through similar claims of the modern Steinach school, whereas to be an endocrinologist among the practicing profession today means too often to be primarily concerned with making fat ladies thin. In research, matters are hardly better. No institute of any importance devoted to medical or biologic research has concerned itself wholly or even partly with the field of the endocrines, and few uni-

versity departments have done so. Yet this kind of inquiry has given to medicine the greatest single new therapeutic achievement in our day—the discovery of insulin. And the domain of endocrinology, both for clinical study and for laboratory investigation, affords a realm where, in many phases, exactitude in observation and quantitative results may be assured.

It is of special significance, too, Sir, that you¹ preside at this meeting. It was you who had the courage to attack the problem of the essentiality or nonessentiality of the pituitary gland for life itself and to show error in the claims of the Rumanian surgeon Paulesco that, following complete hypophysectomy, death need inevitably supervene. It is to your early efforts that we owe the first experimental production of the adiposogenital syndrome in animals—it is to them that we owe the earliest inquiry into the upset of carbohydrate metabolism, which is so thrilling a chapter in the narrative of current discovery, so that quite apart from the production by you² in 1912 of a clinical monograph which shall forever be a landmark in this subject, we owe a series of studies into the physiology, normal or disordered, of the pituitary, the most recent but surely not the last of which, is your recognition of the new clinical syndrome furnished by basophilic adenomas³—studies so abundant that with them alone my whole brief hour here could easily be concerned.

To the historian of science it will perhaps appear remarkable that so long a time was consumed by the period of indecision as to whether the hypophysis was or was not essential for life; he will, of course, be aware of the fact that in this epoch surgical technic was in full possession of asepsis, anesthesia and the control of hemorrhage and had not hesitated to enter the calvarium, succeeding, for instance, in the difficult removal of brain neoplasms and other intricate procedures.

To what, then, may be attributed so long a dispute as that waged by skilful experimenters over the dispensability or indispensability of the gland? This may be attributed to two causes: first, to the deaths that followed mysteriously within a few days the operations of very skilful surgeons, where the complicity of infection and hemorrhage were eliminated but where we now know brain injury was inevitable; and, second, to the tardiness with which successful experimenters furnished that indubitable proof of complete removal given by subsequent sacrifice of the animal and microscopic exploration by serial section of the whole contiguous base of skull and brain; persisting fragments are now known to exercise a beneficent influence which is outstanding. As regards this point, seven pieces of research have now adequately furnished the criteria essential for establishing the fact that no portion of the hypophysis is essential for the continuance of life itself.

As regards the first point, in spite of great skill, misfortune attended those early investigators who chose a dorsal or lateral temporal opening of the calvarium from which the singularly deep hypophysis is hardly accessible without contusion of the brain. Thus the features of the syndrome once designated as cachexia

1. Reference is made to Dr. Harvey Cushing, president of the congress.

hypophysiopriva were really all due to the almost unavoidable brain injury and none of them to injury to the gland itself.

Approach from below, through the sphenoid, either through the nose, mouth⁴ or pharynx,⁵ especially in forms like the rat, in which not only is the cavity of Turk's saddle well separated from the cavum crani by the diaphragma sellae but the pituitary is fortunately not firmly attached to its sheath and can be aspirated without traction on or rupture of the diaphragma, or again the clever use of Weed's contrivance for physiologic "shrinkage" of the brain by intravenous hypertonic salt solution⁶ has enabled a considerable and growing number of operators to remove the whole gland in a high proportion of all cases without immediate postoperative fatalities. The achievements of Smith,⁵ Dandy and Reichert,⁶ Reichert,⁶ Van Dyke and Wallen-Lawrence,⁷ Pencharz,⁸ Selye⁹ and others have answered in the negative once and for all the question as to imminent death from removal of the pituitary. Complete removal of the gland is compatible with the continuance of life. Future research will sustain me, however, in stating that it will be possible to prove that mal-effects from the ablation occur immediately and continue to grow graver even though they do not for a considerable time imperil life.

Complete ablation of the gland invariably leads to a serious abnormal state variously tolerated by various individual animals. Some long survivals and many moderately long ones have been secured by the investigators mentioned. Most hypophysectomized animals, surviving the operation, succumb from this cachexia before anything like a normal life span has been passed. It can be confidently predicted that the marked limitation in the life of hypophysectomized animals will become apparent as soon as even approximate statistics become available concerning the fate of large numbers of such animals under ideal conditions; i. e., when submitted to no subsequent procedures and surrounded with every hygienic care. It cannot be said that investigators have intentionally obscured this truth by failure to publish their mortality data; they have merely had more immediate duties—they have wisely employed such animals in various physiologic tests involving risk and they have intentionally sacrificed most of them for study.

These surgical triumphs have in a way, then, closed one era in experimentation in this field; but in a more important sense they have inaugurated another one, for they have now furnished the most conclusive test objects conceivable for replacement therapy—the only final answer as to whether or not all the essential chemical substances furnished by the gland have been captured in extracts.

THE GROWTH HORMONE

The condition produced by complete removal of the hypophysis is, as has been explained, an abnormal one, although adult animals, save for genital regression, may not for some time show external deviation from normality and thus disguise the fact that both function and structure of the body have suffered serious change. Moreover, it is a safe prediction that as increased analysis of the bodily mechanism of hypophysectomized animals is made, other features of the state which can be strictly designated cachexia hypophysiopriva will increasingly come to light. On the other hand, when the gland is removed from young animals, the most impressive evidence that normal processes have been interfered with is soon furnished by their failure to grow.

If the anterior lobe has been completely removed, growth stasis is immediate and almost, if not quite, absolute and careful postoperative registration of body dimensions by the measurement of skiagrams¹⁰ will bring conviction here. It is indeed only in this way that proof may be secured of the totality of the removal. The growth stasis carries with it also the survival of the status quo as far as the childlike proportions and many if not all juvenile structural peculiarities—such as the possession of only milk dentition, the characteristically fine (lanugo) hair coat, and open epiphyseal cartilages. Yet this state is hardly the desirable one of "perpetual youth," for the capacity of the body in many measurable ways has been injured. Nor, structurally, have we permanent youth, for we now know that many abnormal anatomic changes begin to intervene slowly—changes which mark off these dwarfs as peculiar—e. g., the actual shrinkage of the epiphyseal cartilages, the gradual obliteration by dentin of the pulp cavities of the incisors,¹⁰ and so on. There seems no question but that we have to do with disturbance of calcium metabolism after hypophysectomy, as reflected in the decreased calcium content of the blood; whether this is due to the correlated subnormality of the parathyroid glands remains to be established. Changes in the parathyroids as a result of hypophysectomy have not been adequately studied as yet. It is difficult to view the cessation of growth of the skeletal system as essentially due to disturbance in the inorganic metabolism; it is more justifiable to refer it to a singular failure in cartilage proliferation in the epiphyseal disks and, of course, the dwarfism is participated in by all the organs and tissues of the body. The experimental production of hypercalcemia in hypophysectomy by means of parathyroid extract has not yet interested any experimenter.

To what extent have the growth defects of hypophysectomized animals been remedied by the conveyal to them of growth hormone? To a complete extent. In the cases of a very great number of hypophysectomized dwarf rats and in several hypophysectomized puppies completely normal stature or stature slightly in excess of normal has been thus obtained. Reichert's work with hypophysectomized puppies warns us that such growth hormone extracts must be free of gonadotropic effect else the provocation of sexual maturity may be associated with epiphyseal closure and the cessation of growth.

Hypophysectomized animals are enormously more sensitive to growth hormone than are normal ones and

10. Schour, I., and Van Dyke, H. B.: Effect of Hypophysectomy on the Incisor of the Rat, *Proc. Soc. Exper. Biol. & Med.* 28: 934 (June) 1931.

they thus constitute the test material *par excellence* for quantitative measures of the growth hormone in extracts. But since they are not easy to produce in large numbers or to maintain in good health, it is fortunate that satisfactory growth tests¹¹ can be carried out by administering growth hormone to certain mammalian forms in which, though adulthood is reached, epiphyseal closure is singularly delayed and power to grow under stimulus retained for most of the span of life. I refer to rats and mice. Like some of the lower vertebrates, fish and turtles, the rat grows almost throughout life but it does not do so with anything like a uniform rate. Though its epiphyses are open, its adulthood is indicated by a sharp change, even if not a halt, in the growth rate and by very slow accretions of body substance after that date. We are always safely past this knuckle of the growth curve by the fifth month of life in the case of the female and the seventh month in the male, and we now use just these animals on which to confer by our various extracts unusual growth. That this growth is not adiposity but is participated in by all the tissues of the body is shown by roentgenograms of the skeletal system and by the chart of their various organ weighings. The point I wish to bring out at present is that in our modern efforts to get the growth hormone in pure form we no longer feel compelled to treat animals for many weeks or months but select animals at any time between the fifth and the ninth month of life, when they are on the so-called growth plateau. We follow the accretions of their body weight at five day intervals for three or four weeks, and if an approximate plateau can be demonstrated for an individual we call it a satisfactory test animal and convey to it intraperitoneally any supposed growth-containing extract. In the case of impotent solutions, no significant growth results; but with potent solutions sooner or later an outspoken response is met. We are in this way forced to observe animals in the preexperimental period merely for three weeks and in the experimental period for three weeks. Hundreds of test creatures can be stored and when the time comes easily observed and studied in this simple way.

The production of gigantism has not been limited to the rat. It has not been difficult to produce it in the dog, in which, however, knowledge of the stature to be expected in a pure genetically known strain must be insisted on. In such a strain of pure bred dachshunds, in which, moreover there were litter-mate brothers and sisters, we have in five months produced monstrous animals;¹² they are not only much greater in size and weight than their controls, but they already show peculiarities which one expects to continue when epiphyseal closure determines the cessation of growth of the long bones. I refer to specific widening changes in the skull and to overgrowth of the skin shown in remarkable ringlike folds about the legs and in the head and neck, which almost close the eyes and produce laplike appendages to the cheeks or jaws. The American anatomist Stockard¹³ prophetically assigned these skin changes seen, for instance, in the Saint Bernard but not in the Great Dane, to acromegaly, though at the time of his statement last spring no one had yet produced them.

Three years ago, Putnam, Benedict and Teel¹⁴ of Cushing's laboratory reported acromegalic changes in an English bulldog treated for over a year, but in this form they had unfortunately chosen a skull type already distorted by chondrodystrophy and in which, therefore, their end-result presented the effects of two disorders. The changes provoked in the face and long thin head of the shepherd by administering the growth hormone, whereby a grotesque shift to a caricatured bloodhound type has been produced, enable me, I believe, to state that for the first time specific changes have been produced by administering a specific agent to a form in which these changes never normally occur.

The question will be asked, To what degree of purity has the growth hormone been brought? It is easy to produce a white hygroscopic powder stable for months at room temperature in dry, air-exhausted chambers and capable of promoting maximal growth in adult female rats in doses of considerably less than 0.5 mg. daily. The powders have almost 15 per cent of nitrogen all in the form of protein or a protein-like body, and it is difficult to break them down further without losing efficacy. It appears that just as they are proving helpful in the isolation of enzymes, selective adsorption methods will be of great importance here.

THE GONADOTROPIC AND LACTOGENIC HORMONES

Most impressive, perhaps, of the changes caused by removal of the pituitary is the failure of development of the genital system in hypophysectomized youths or infants; indeed, the regression of the system in adults, whether in male or female. The testes shrink to vestigial structures in which the atrophic tubules, while never free from spermatogonia, no longer contain the four cell layers of epithelium, the accessory organs (prostate, seminal vesicles, Cowper's glands, and so on) are minute; in the female, similar recession of the uterus, tubes and ovaries ensues, but microscopic examination of the ovaries shows fairly abundant primordial ova and young follicles, overtaken, however, by atresia before any considerable enlargement has taken place.

While, then, clearly in the female, and also in the male, it is impossible to say that all germ cells have disappeared, and while, as I shall presently recount, germ cell production can be reinvoked in such animals by the conveyal to them of the "sex" hormone of the anterior lobe, the growth and maturation of germ cells is absolutely in abeyance and furthermore that other activity of the gonads—both male and female—their endocrine as well as gametogenic activity, is suspended. I refer to the internal secretions—from whatever gonadal tissue they spring—which are responsible for the production of the male and female true sex hormones and thus for the secondary sexual characters and characteristics. These animals show no more structural evidences of their sexual dimorphism than were present at the time of the operation and never manifest sex interest or desire.

Just as the antithesis of dwarfism can then be produced by the gigantism of hyperpituitarism, so also a similar antithesis exists as regards the sex hormones in the anterior hypophysis; for here also the sexual infantilism seen after ablation of the hypophysis can be contrasted with a stimulation of the organs of sex by conveying hypophyseal tissue or hormones to animals be they infantile or adult.

The circumstances that had led up to the detection of the sex hormone of the hypophysis are interesting in the extreme. In the spring of 1926, Zondek and Aschheim¹⁵ of Berlin, seeking to influence the immature genital system in rodents (rats and mice) by various endocrine products and implants of endocrine tissues, happened to introduce bits of anterior hypophyseal tissue under the skin, to find the complete establishment of sexual maturity in these infants in from three to five days. In the same year and without knowledge of the Berlin experiments, which were only mentioned, indeed, in the briefest possible way in a note in the *Klinische Wochenschrift*, Smith,¹⁶ of our laboratory, made the same discovery. Though there is evidence of corresponding stimulation of the youthful male gonads, it is the ovary which gives a speedily ascertained and unassailable picture of this effect, for large follicles and, above all, corpora lutea appear there for the first time.

Just as it is possible to extract the growth hormone from the hypophysis, so also we can now extract the gonad-stimulating hormone from hypophyseal tissue. Another and more convenient source of this hormone, however, was thought to have been discovered by Aschheim and Zondek,¹⁷ and the circumstances of its discovery are dramatic. During pregnancy, for reasons quite unknown to us, the estrous hormone, or folliculin, is produced by the body in great quantity—at a time, indeed, when, according to our present very limited ideas, physiologic demands for it must be nonexistent. It was encountered by Loewe,¹⁸ Laqueur, Zondek and others in great quantities in the full-term placenta and finally also in very considerable quantities in the blood and in the urine of pregnant women. It has been known for many years that the hypophysis is strangely enlarged in pregnancy, though the cause for that enlargement has been obscure. What more natural thing than to search not only for the ovarian but for the hypophyseal sex hormone in the fluids and tissues at the time of pregnancy? It also occurs in great abundance at this time in both the placenta and the urine and, in contradistinction to the ovarian hormone, occurs so early in pregnancy as to constitute the means of recognizing conception as soon as the first missed period has occurred, twenty-one days from coitus, a diagnostic possibility not hitherto possessed at so early a date. A unique advantage has accrued through the occurrence of this hormone (prolan) in the urine, in which, normally, much contaminating protein is absent. The ovarian hormone admixed with it can also be practically all withdrawn by virtue of its greater solubility in organic solvents (such as ether). By devices of this sort, over three years ago, my associates and I easily obtained colorless solutions of this urinary hormone, protein free and almost nitrogen free, which could be reduced in vacuo to a white powder and stored at low temperatures, to be redissolved later. Our tests of its efficacy tally with those of Wiesner. In the purest form in which it is prepared by routine in our laboratory, it can produce effects in young rodents in a total dose of 2 mg. Two claims of crystallization of

this substance have recently been made. This is not the sex hormone of the anterior hypophysis. Our capacity to distinguish this particular substance, also a hormone—prolan—from the true sex hormone of the hypophysis rests on clear evidence, presently to be detailed, of a characteristic difference in the biologic effects worked by prolan and by the true anterior hypophyseal sex hormone.

No questions exceed in interest those relating to the origin and true nature of prolan. First as regards its site of origin, Philipp¹⁹ and others abroad and Collip in this country have championed the view that involves its production by the placenta. The cases presented by genital carcinoma and especially by chorio-epithelioma, whether in male or in female, cannot well be considered as decisive for either view. On the one hand, this tissue could itself elaborate prolan just as do the young normal chorionic villi (if they do), for in most cases implants of the actual tissue in question show it housing lively amounts of prolan. On the other hand, these tissues may really only store the hormone which they stimulate the hypophysis to overproduce. Yet, recently, peculiar instances of the class of cases in which prolan is ordinarily always abundant have been found with prolan practically absent and they have been cleverly drawn into the support of the view of the placental origin of prolan. I refer to cases of hydatidiform mole and last month's report of a remarkable instance of ovarian pregnancy with a living fetus, in both of which cases an exceedingly thick boundary zone (*durchdringungszone*)—a massive fibrin layer—was interposed between fetal and maternal tissues—a zone conceivably preventing (as Robert Meyer first suggested) the diffusion maternalward of prolan, shown by implants to be present in those membranes. The adherents of the view of the fetal origin of prolan also point out that in most cases the death but retention of the fetus involves the prompt cessation of the Aschheim-Zondek reaction in the urine. Nor have these investigators failed to turn their attention to the hypophysis itself. They remind us that whereas prolan is abundant in the blood and urine shortly after the first missed period, characteristic changes in the hypophysis itself, above all the appearance of the so-called pregnancy cells, are not found before the end of the second month, or in primiparas even later. Finally, they point to the fact that the human hypophysis in pregnancy is even devoid of the hormone, as determined by the ineffectiveness of implants.

Now I should like to call attention to recent experiments and developments which are crucial in my estimation for the contention of a hypophyseal origin of prolan; these relate to its prompt appearance in the blood and urine of males or females after complete surgical ablation of the gonads. It is true perhaps that absolute rigor of proof of hypophyseal origin here will demand simultaneous hypophysectomy with gonadectomies, and we are involved in such a research program.

Now, as regards the nature, chemical and biologic, of prolan, the hypophysis-like substance occurring in the urine of pregnant women, our little group of workers perhaps deserves the distinction of having first shown that prolan, while gonadotropic, is a different and less effective substance than the true gonadotropic hormone as found in the hypophysis itself. Let me

enumerate the differences in biologic action which have now been made out with regard to prolactin in contrast to the true gonadotropic hormone of the hypophysis: 1. We²⁰ early discovered that there is a sharp limit to the effects which may be secured in 100 hours by administering any amount of prolactin, no matter how frequent the interval between doses given young normal immature animals (rats), whereas increasing amounts of the true gonadotropic hormone from anterior lobe tissue always give increasing effects on the genital system of the young recipients. In this way it can easily be shown that the substance in the blood stream and placenta as well as in the urine of pregnant women is prolactin unadmixed with the true hypophyseal gonadotropic hormone. 2. Prolactin is ineffective in increasing the development or weight of the testes in young birds (chicks or pigeons).²¹ 3. Prolactin will apparently not cause "reddening" of the sexual skin in *Macacus* and related forms, whereas hypophyseal hormone accomplishes this readily.²² 4. Finally, prolactin is strikingly ineffective in hypophysectomized animals. We were able to show that, even with massive doses, chronically administered, prolactin may be ineffective in stirring the sexual system of hypophysectomized animals and is always less effective than in normal ones.²³ This experience led us to the conviction that the hypophysis itself must aid, in some obscure way, the action of prolactin, and it led us to seek for that hypothetic substance in hypophyseal extracts. We found it abundantly present in the simple alkaline aqueous extracts which we were accustomed to making for securing the growth hormone, and for a time it seemed possible to us that the growth hormone itself might be transformed into the gonad-stimulating hormone. Certain only was the fact that these hypophyseal extracts conferred on prolactin a strangely increased potency—a potency now comparable to or exceeding the best that could be secured in extracts of the hypophysis containing the gonadotropic hormone itself. These facts, which we designated the activation of prolactin, were quickly confirmed by other investigators (e. g., Leonard²⁴) and it was also shown that extracts of the glands rich in the gonadotropic hormone itself and free of the growth hormone could equally well be still further activated in their gonadotropic properties by the addition of prolactin. The research of the last few months at the Rockefeller Institute, where I am a guest, has enabled us to show that this hypophyseal constituent is, however, not the well known gonadotropic hormone of the anterior lobe but is a body having different chemical and biologic characteristics.²⁵ This body, the so-called activator of prolactin when it is added to the latter, confers a stimulus to the gonads in excess of anything we have hitherto

observed, save that produced by the highly concentrated gonadotropic hormone of the pregnant mare's blood stream. The hypophyseal substance has made it possible to rival easily or to exceed the maximal effects secured by the equine hormone and will probably prove the supreme agent for gonadotropic therapy in the future. By means of it, the ovaries of infantile rats are increased from 15 to 300 mg. in weight in ninety-six hours and approach in size the dimensions of the kidneys.

Besides its therapeutic importance, an equally important consequence of the detection of the new hypophyseal substance is the fact that it furnishes an important new tool with which to recognize the presence of prolactin-like bodies in the blood and urine of animals, both in pregnant and in various nonpregnant conditions. And we cherish the hope—I speak of the studies of the last few weeks—that by means of this new weapon we can clear up the hitherto puzzling enigma of the presence of prolactin-like bodies in primates but their absence in all other animal forms.

Highly interesting are the recent clear evidences of a direct relation of mammary secretion to hypophyseal influence—a field opened by the studies of Corner²⁶ and to which Riddle²⁷ has brought evidence which will soon, if it does not indeed now, convince critical workers of the existence of another hypophyseal hormone—the lactogenic. When it was discovered a few years ago that the condition of pseudopregnancy involved the elaboration of secreting alveoli in the mammary tree, it was settled that these things owe nothing to the presence and possible internal secretion of the fetus, extracts of which in Sir Ernest Starling's²⁸ hands had seemed to evoke the same response. The question was now only which one of the endocrines was concerned in mammary development and from the work of the Bouin school in Strasbourg it seemed likely that this could be shown to be a direct effect of the hormone of the corpus luteum. It was fortunate, then, that the discoverer of the luteal hormone, Corner, should have made it clear that this substance alone is powerless to achieve these effects. The story is only complicated by the fact that a structurally perfect mammary tree must be built up before the lactogenic hormone can provoke, as it does, true milk secretion.

RESPIRATORY METABOLISM AND THE THYROID HORMONE

The important clinical studies of Loewe, of Zondek and of Brütt and Knipping²⁹ showed strikingly low basal metabolic rates in cases in which the diagnosis of cachexia hypophysiopriva was confirmed by the finding of definite pituitary destruction or impairment at the autopsy table. Furthermore, a marked lowering of the specific dynamic action of food has been reported in pituitary disease, especially in the Frölich adiposity (Rolly, Plaut, Bernhardt). Yet it is evident that, for conviction here, all studies should be carried out on animals in which purposeful isolated injury of the hypophysis without concomitant brain injury has been made. It was therefore only when nonadipose dwarfs

from hypophysectomy were available that satisfactory studies could be made, and the work of Foster and Smith³⁰ represents the only critically acceptable research here. They have shown a very marked lowering of the basal metabolic rate. When the posterior lobe alone was removed, no such decrease was observed.

Highly interesting were their conclusions regarding specific dynamic action. Hypophysectomized rats fail entirely to show specific dynamic action. The authors correlate this with the invariable injury to thyroid function caused by absence of the hypophysis in view of the discovery of Baumann and Hunt³¹ (which they confirm) that thyroidectomy obliterates the specific dynamic action. Now the implantation of anterior lobe alone, or of posterior lobe, did not repair this failure to respond to glycocholl but implants of the whole gland did so. This is the only instance known to me of the synergism of the anterior and posterior pituitary lobes so often asserted but in no other respect established.³²

Four years ago, these investigators showed a remarkably increased sensitivity to thyroid on the part of hypophysectomized rats, and it is of interest that the effect of thyroid was almost twice as great in hypophysectomized animals as in thyroidectomized ones. In thyroidectomized animals the increase in basal heat production caused by thyroid was about four times that in normal animals given thyroid, but in hypophysectomized animals it was about eight times greater. An explanation of this has not as yet been furnished.

The thyroid epithelium in the hypophysectomized rat becomes reduced to the squamous type and the nuclei are flattened; the vesicles contain approximately the normal amount of colloid, and possibly for this reason the reduction in weight of the glands is not so pronounced as it would otherwise be.

Subnormality of thyroid function is always evident after hypophysectomy in the very low basal metabolic rate, but it is highly interesting that complete ablation of the thyroids cannot cause so low a basal metabolism as supervenes after hypophysectomy, so that other factors contribute to produce the great lowering and the injured adrenals may contribute to it, since Ant, Forman and Bright (1922) and Zweimer (1929) have shown a fall in metabolism after suprarenalectomy. Anterior hypophyseal extracts quickly restore the thyroid, as determined by complete change of squamous to cubical or cylindric epithelium, which may come to look like that of exophthalmic goiter, and by rapid rise of the basal metabolic rate. The hypophyseal hormone accomplishing these results, the thyrotropic hormone, may be clearly separated from the growth hormone, for unlike the latter it is not completely precipitated from aqueous extracts of the gland by trichloroacetic acid.

Now just as growth and sex hormones can be tested by their action on normal young or old individuals, so also the thyrotropic hormone can be adequately tested. In fact, convincing evidence of the existence of this hormone was first furnished by Loeb in this country and Aron³³ of Strasbourg in the rapid change it pro-

voked in the epithelium of the thyroid vesicles of young guinea-pigs. Schockaert showed that ducks are particularly sensitive to its administration, and by it he produced for the first time experimental exophthalmos, an achievement recently similarly secured in the mammal by Anderson³⁴ of Collip's laboratory, and only yesterday by Marine³⁵ of New York.

Entirely enigmatic at present is the singular rather rapid wearing out of thyrotropic effects with continuous administration of the hormone.

ADIPOSITY

An important contribution was made by Camus and Roussy³⁶ of Paris in 1921, when they showed that the adiposities with which pituitary ablation had been so often accompanied could be produced by slight injuries to the superficial gray of the tuber cinereum near the hypophysis but with the hypophysis itself perfectly intact. This story was confirmed by Bailey and Bremer, by Smith and by others. All recent hypophysectomies have shown convincingly that without brain injury one can regularly secure perfect dwarfism from hypophysectomy without traces of adiposity. The conception of a direct relation of the hypophysis to fat metabolism has hence lost caste.

In 1931, Anselmino and Hoffmann³⁷ reported the occurrence of a substance in the anterior lobe which, when injected into rats, rabbits, dogs and human beings, causes a rise of the acetone bodies in the blood. This substance is in its physical and chemical properties similar to the other known anterior lobe hormones. But it is separable from the growth, gonadotropic, thyrotropic and lactogenic hormones by means of ultrafiltration. So this principle is not identical with any other known principle. It occurs in the blood stream and has been isolated from the urine by Casimir Funk.

It has been found by Anselmino and Hoffmann that under physiologic conditions the substance appears in the blood stream only when fat is burned. After a fatty meal or in hunger, when the acetone bodies in the blood rise, the substance is found in the blood and can be assayed with the rat test. From various facts the authors conclude that this substance has a regulatory function in the fat metabolism. These facts are: primarily the physiologic occurrence of the substance in the blood only when fat is burned, not under other conditions; secondly, the well known connection of acetone bodies with fat combustion or transformation; and, finally, the old clinical observation of a connection of the anterior lobe with certain forms of obesity, just recently again shown by Cushing³ in his new anterior lobe syndrome, the basophilism. It is this group of facts, at any rate, which have induced these authors to call this substance, not yet completely characterized, the fat metabolism hormone of the anterior lobe.

CARBOHYDRATE METABOLISM AND A DIABETO-GENIC HORMONE

That the hypophysis is related in some way to carbohydrate metabolism did not escape either experimenter or clinician and when, in the pioneer ablations of Cushing, adipose dwarfs were created, he was not surprised to detect in them an increased tolerance for carbohydrates, for this stood in his mind in proper contrast to the association of diabetes with acromegaly. However, the whole question of the relation of carbohydrate metabolism to the anterior lobe waited for its secure establishment from the series of researches by Houssay and his colleagues in Buenos Aires, which was ushered in by the Houssay-Magenta³⁸ discovery of the increased sensitivity to insulin shown by hypophysectomized dogs, a fact which has been abundantly confirmed by Geiling³⁹ of Baltimore and by Kobasashi of Tokyo. But the most remarkable disclosure by the Houssay school is perhaps that relating to hypophysectomy as strangely ameliorating diabetes produced by ablation of the pancreas. The complicity of the anterior lobe here seems clearly established by their demonstration that implants of it (not of the pars posterior or intermedia) immediately bring on hyperglycemia in such animals. The detection of just which of the anterior hypophyseal hormones is responsible for the pancreas-pituitary relation would seem possible by study of the potency of various extracts in reinvoking diabetes after the double operation (hypophysectomy and pancreatectomy) or of the capacity of such extracts to control the toxicity of insulin in hypophysectomized animals. Such preliminary work as has been done in the latter field is as yet unsatisfactory.

The Houssay school has shown that morphine and epinephrine hyperglycemias are less in hypophysectomized animals. They have in fact shown that hypophysectomized animals are peculiarly susceptible to hypoglycemias from fasting alone, hypoglycemias that may prove fatal. It is strange that for so long a time these facts were overlooked. Pencharz with us has found the striking picture of hypoglycemic collapse in hypophysectomized guinea-pigs on coming to the laboratory in the morning and has been able to provoke a Lazarus-like resurrection with dextrose by stomach tube or needle.

Though many physicians may take sharp issue here, modern experimental work, as has already been explained, seems to challenge the complicity of the hypophysis itself in conditions that have long been called hypophyseal adiposity. On the one hand, adiposity does not result from discrete injury to the hypophysis or its removal and, on the other hand, we have seen the invariable production of adiposity by slight injury to brain areas adjacent to the gland. It is highly important, then, to inquire as to whether contiguous brain injury in hypophysectomies, be it ever so slight, has not actually been the true cause of the upset in carbohydrate metabolism. Possible nervous origin for such an upset has been known, of course, from the time of Claude Bernard's sugar puncture in 1858, and we know the modern studies of hypothalamic metabolic centers. Nor can sugar upset with pituitary tumors bring any decision here, for a possible encroachment of the neoplasm on these centers is obvious. It would seem of maximal importance, therefore, for us to be

able to say that we have provoked true diabetes in normal dogs, with nervous system of course intact, by the administration of alkaline extracts of the hypophysis.⁴⁰ This experience would seem to possess crucial value in establishing an hypophyseal causation of diabetes by humeral channels, that is, by an overproduction of one of its hormones, diabetogenic in its effect. The method of action of this hormone, its possible repression of the functioning of the Langerhans tissue, is as yet entirely unknown; nor has separation of the diabetogenic hormone from the growth and thyroid or epinephrine-affecting hormones been accomplished. I can only state that our work shows that the gonadotropic hormone is clearly not involved.

AN ADRENALOTROPIC HORMONE

Perhaps the most deeply interesting changes as a result of ablation of the pituitary are those provoked in the adrenal; while the body weight in these dwarfs is much below that of their normal litter mate controls, an even more striking atrophy overtakes the adrenals and this reduction is due almost solely to the atrophy of the cortex of the suprarenal, which becomes little more than a shell.

On account of the well known essentiality of the adrenal cortex for life, it was only natural that we should inquire as to whether the ultimate strange sickness and death of hypophysectomized animals was not due to cessation of adrenal cortical function. Hence it was that we administered Swingle's adrenal cortical hormone to hypophysectomized animals that had begun to decline many months after the operation. This vitally important adrenal substance did not modify their decline, a decline dramatically changed to improvement the moment we gave them aqueous alkaline extracts of the anterior lobe. The sudden resuscitation which one can invariably produce in this way is attended not only with abrupt general body growth but regrowth toward normality of the adrenal cortex. Adrenal cortical tissue therefore needs for its normality some constituent of the anterior hypophysis. Since our prolonged series of experiments has shown that replacement of the adrenal cortex in hypophysectomized animals is never provoked even by concentrated dosage with the gonadotropic hormone⁴¹ and since it is invariably produced by certain extracts of the growth hormone but not by other highly purified ones, it would appear inevitable for us to recognize the existence of an adrenalotropic hormone, the properties of which as distinguished from the thyrotropic, lactogenic and other possible hormones will emerge, I trust, from the research of the three or four laboratories engaged in this study in the course of the next few months. Concentrated preparations of the adrenalotropic hormone should make it possible to provoke more readily the hypertrophy of accessory adrenal tissue after complete excision of these glands. Nor is it altogether out of the question for us to hope that the hypertrophied fragments will more readily undertake normal functioning and that Addison's disease may thus be attacked not by replacement therapy, as is at present the case and is the case with diabetes, but by a new type of therapeutic procedure, one that will stir the defective tissue itself to resume its normal task.

CONCLUSION

I realize that the bewildered reader of my exposition will desire to be assured of the justification for the recognition of such a perplexing number of apparently discrete internal secretory substances or hormones furnished by a bit of tissue in which at most but three or four distinct cell types have been recognized by modern histologic methods. Pending the time the biologic chemist develops methods for the further concentration and, above all, for the complete isolation of these substances, preferably in crystalline purity, one will desire to know briefly whether or not biologic workers have perfected a methodology adequate for the identification of truly discrete effects. I can only state that fortunately at the present time sufficiently sensitive test objects would appear to have been found for each of the five substances—the growth, gonadotropic, thyrotropic, lactogenic and diabetogenic hormones—and that in many cases, but not yet in all, we have assurances of relative, even if not absolute, freedom from any but a single effect.

One may also challenge the assumption that these various isolated and clear-cut effects are all the direct result each of a peculiar hormone substance acting on a particular end organ. Might not some of them be secondary, that is, indirect, effects of two or three fundamental hormones like those which govern growth and sex?

I am of the opinion that this vitally important criterion will also quickly be met. The effect of the growth hormone is, of course, general. But the effects of the gonadotropic and thyrotropic hormones have been recently shown to be exercised directly on their recipient tissues, for these secretions cause their characteristic effects when they are placed in contact with gonadal or thyroid tissue fragments in the Warburg chamber.

Fortunately the biologic chemist has now joined forces with the biologist or, in the example of Professor Collip, has taken charge of this whole affair, and one will sympathize with the impulse that leads me to the prediction that through the use of some of the most modern tools of biologic chemistry, those for instance that have been so useful in vitamin and, above all, in enzyme research, ultimate identification of these substances will not be long delayed.

Twelve years ago, Cushing⁴² rightly stigmatized behavior which if not outright charlatanism condoned extravagant conceptions of our control of basic phenomena in the body and said, to present an extreme example, "The Lewis Carroll of today would have Alice nibble from a pituitary mushroom in her left hand and a lutein one in her right and presto! she is any height desired."

I have presented you today with giants possessing infantile sexual systems, or young creatures still suckling their mother and yet themselves sexually mature; moreover, with the experimental counterpart of that South American male savage seen by Alexander von Humboldt to be suckling his child. These mysteries, therefore, are at hand. We are not living in a dream but have worked with exactitude and need not cry out, then, for deliverance from the dream, "Alice, where art thou? for it must be you, surely in this queerest of worlds, who hath taken us by the hand."

ACUTE LEUKEMIA IN CHILDREN

JEAN V. COOKE, M.D.

ST. LOUIS

Leukemia may be defined as a systemic disease of unknown etiology in which the normal mechanism for the production of formed blood elements is permanently damaged, with the appearance in the circulating blood of abnormal types of leukocytes. Three common forms of the disease are readily recognized, each of which is a clinical entity with a relatively characteristic blood picture: (1) Chronic myelogenous leukemia, or chronic myeloid leukemia, in which large numbers of granular leukocytes and myelocytes occur in the blood. This is the common form of the disease seen in adults, but is relatively rare in children. It is characterized by a great enlargement of the spleen, muscular weakness and a duration of from one to several years. (2) Chronic lymphoid leukemia, a less frequent type found in older persons and clinically similar to the chronic myelogenous form, but characterized by the presence of very numerous small nongranular mononuclear leukocytes resembling normal lymphocytes. This form of

the disease is unknown in children. (3) Acute leukemia, or acute lymphoid leukemia, the common or usual form of the disease seen in children. It occurs also in adults, but is less common than the chronic myeloid type. The characteristic blood changes consist in anemia, thrombocytopenia and a relatively high percentage of nongranular abnormal mononuclear cells. The actual number of leukocytes varies from a few thousand to several hundred thousand, and the disease is always fatal in from a few weeks to a few months. Practically all cases of leukemia are easily classified in one of the foregoing groups, although rarely in an atypical case this is difficult.

In this paper is presented an analysis of the clinical manifestations in fifty cases of acute leukemia in children which have been observed in the last fifteen years at the St. Louis Children's Hospital. During this period three cases of typical chronic myelogenous leukemia have also occurred in children, and two other instances of acute blood dyscrasia which were difficult to classify from the blood picture. Two of the three children with chronic leukemia were boys, 8 and 12 years of age, and one a girl of 9 years. The blood picture and clinical symptoms in all the cases were typical of the disease as seen in adults. One child is still under observation ten

months after the apparent onset, while the other two lived fourteen months and two years, respectively.

Certain general characteristics of the group of fifty children with acute leukemia relating to the age, sex and duration of the disease deserve comment. If the three five year periods in table 1 are compared, it will be seen that there is little apparent difference in the age incidence in boys. A very striking decrease, however,

TABLE 2.—Total Duration of Acute Leukemia in Fifty Children

occurs in the incidence of the disease in older girls, since twelve of the eighteen girls with the disease were in the first six years of life and only six were between the ages of 6 and 15 years. In all published reports of acute leukemia, including cases in both children and adults, males have regularly predominated over females in a proportion of 2:1, a figure closely approximated in this series of children (thirty-two boys and eighteen girls), but it is of some interest that the disproportion in sex incidence does not apply to younger children.

The three cases occurring in infancy may be briefly mentioned. In one the disease was congenital, the first symptoms being noted on the fourth day of life; the baby died on the twenty-third day. The onset in the second case was at the age of 10 days, and the baby lived three months. In the third case, the apparent onset was in the third month, and death occurred three months later. All the cases were typical clinically and had characteristic blood pictures.

The total duration of the disease was somewhat difficult to determine since the onset is usually insidious; however, the duration has been tabulated (table 2) as accurately as possible from the first onset of symptoms. More than half the cases were fatal in three months or less. About one third of the patients lived between three and six months, while only six, or one-eighth, lived from six to nine months. As there has been a tendency to speak of the cases of children with agranulocytic leukemia who live longer than a few months as chronic lymphatic leukemia, it is of interest to mention briefly the type of the disease in the six children who lived longer than six months. One was under observation for almost three months with a mediastinal leukemic tumor, but without leukemic blood changes, and lived three months after the leukemic picture developed in the blood. The cases of four of the remaining five children were of the leukopenic type, and there were only transient periods of moderate leukocytosis. Two of the children who were examined at necropsy showed typical leukemic infiltration of the organs. It seems preferable to limit the term chronic lymphatic leukemia to the well recognized type which occurs in adults and to consider that in a small proportion of children with acute leukemia the disease may have a moderately prolonged course.

BLOOD PICTURE

The fifty children with acute leukemia had blood pictures of the type commonly called acute lymphatic leu-

kemia. The granular polymorphonuclear cells formed only from 1 to 15 per cent, and usually less than 10 per cent, of the leukocytes; these cells were in various stages of maturation as the *stabkern* and *jungengliche* cells of Schilling, as well as segmented cells, were always present. Myelocytes were rarely found. The remainder of the cells were mononuclear, nongranular and oxydase negative, and varied in size and in amount of protoplasm. Although these cells are often referred to as lymphocytes or lymphoblasts, there is considerable evidence that they originate in the marrow and are probably myeloblasts. The leukocyte count in the children of this group varied from 250 to 815,000 per cubic millimeter in different patients. Certain patients also had much variation at different times during the disease. For example, a reduction from 200,000 to 5,000 in three days occurred in one child, and in another a decrease from 107,000 to 11,500 four days later. Other somewhat less striking variations occurred without apparent cause. In order to illustrate the variations in the number of circulating leukocytes in this series of fifty children, the highest and the lowest counts while under observation have been tabulated.

It will be seen, for example, that in nineteen children the total count reached 100,000 or more, but in only seven did it remain constantly above that figure, and while nineteen children had counts of less than 10,000 at some time during the disease, in six the leukocytes never went above this figure. Patients with low counts, often referred to as having aleukemic leukemia or leukemia without leukocytosis, showed no clinical differences from those with leukocytosis or hyperleukocytosis, and a considerable proportion of the patients showed leukopenia at some time during the course of the disease.

In addition to the leukocyte changes, all the children had anemia and thrombocytopenia. About three fourths of them had well marked anemia when first seen. Only rarely were normoblasts present, and there appeared little tendency to erythropoiesis. Twenty-three of the forty-three children who were under observation during the later stage of the disease had red counts of less than 2,000,000, two counts being less than 1,000,000; fifteen had counts between 2,000,000 and 3,000,000, and in five the count was between 3,000,000 and 4,000,000.

One group of children of particular interest included five who were under observation for varying periods after the onset of symptoms which were probably of leukemic origin, but before any leukemic change could

TABLE 3.—Leukocyte Counts

| | More Than 100,000 | 50,000 to 100,000 | 20,000 to 50,000 | 10,000 to 20,000 | Less Than 10,000 |
|--------------------|----------------------|----------------------|---------------------|---------------------|---------------------|
| Highest count..... | 19 | 6 | 13 | 6 | 6 |
| Lowest count..... | 7 | 7 | 10 | 7 | 19 |

be detected in the blood. Four of them had mediastinal masses of sufficient size to give dyspneic symptoms one month, six weeks, two months and three months, respectively, before the development of leukemic blood changes, while the fifth child had fever and very severe rheumatoid pains for six weeks previously. During this period none of the children had anemia or thrombocytopenia.

The characteristics of the blood picture in acute leukemia, therefore, were: (1) agranulocytosis with the presence of immature polymorphonuclear cells, (2)

anemia of the aplastic type, (3) thrombocytopenia and (4) the appearance of varying numbers of abnormal nongranular mononuclear cells.

The possible influence of preceding infection on the production of acute leukemia has interested many investigators. In only a few of the children in this series had a recent infection been noted. In thirty-seven no infection had occurred within six months preceding the leukemia; one had pertussis and bronchopneumonia five months before, one chicken-pox four months before and two scarlet fever two months previously. Of the nine who had infection within one month of the apparent onset of the disease, three had follicular tonsillitis, two infection of the upper respiratory tract, two impetigo, one measles and one diphtheria.

THE CLINICAL SYMPTOMS

The first symptom of the disease noted by the parents is of interest. This symptom consisted in pallor and asthenia in seventeen cases; enlargement of the cervical gland in nine, skin hemorrhages in seven, cough and dyspnea in five, rheumatoid pains in five, stomatitis in two, abdominal pain in two, neurologic symptoms

he had no objective swelling of the extremities, there was general muscular tenderness on moderate pressure. Physical examination gave negative findings except for palpable small anterior and posterior cervical lymph nodes. At times he would awaken from a short sleep crying and moaning with pain in the muscles, especially in the legs. A pea-sized rheumatism-like nodule was noted at the proximal end of the right metacarpal bone, and clusters of similar nodules were found in the occipital aponeurosis. A faint systolic murmur developed at the apex, although an electrocardiogram showed a normal mechanism, and no cardiac abnormality was detected. Fever and pain persisted. There was no anemia, and the blood showed a moderate leukopenia of from 4,000 to 6,000 with a normal differential count. The child was considered to have rheumatic fever until more than three weeks after admission, when hemorrhages occurred in the skin and mucous membranes, the cervical glands became enlarged, and the leukocytes increased to 20,000 with the picture of acute leukemia. Death occurred one week later.

4. *Hemorrhages*.—Although petechial or ecchymotic hemorrhages, as well as bleeding from mucous membranes, are relatively common in acute leukemia, in certain children this hemorrhagic tendency overshadows other symptoms by its extent. The patients in this

(paralysis of the bladder and severe headache) in two and enlargement of the abdomen in one.

For purposes of description of the clinical manifestations the children have been divided into several groups on the basis of the most prominent or striking clinical phenomena of the disease, although there was, of course, some overlapping of the symptoms and signs. These groups are as follows:

1. *Asthenia*.—This familiar type included twenty-two children in whom the principal symptoms were weakness and pallor.

2. *Dyspnea*.—In this type the symptoms are due to pressure of a leukemic tumor in the anterior mediastinum. The cases of the seven children in this group have been described in detail elsewhere,¹ and it will be mentioned only that the symptoms consisted in cyanosis of the neck and face, with cough and dyspnea which tended to be paroxysmal and were often accentuated by muscular effort.

3. *Rheumatoid Pains*.—Pain in the extremities and in the joints is often a prominent symptom of acute leukemia and is not always sufficiently emphasized. A brief summary of one of the cases in this group follows:

A 14 year old white boy, two days after having had slight fever and sore throat complained of pain in the elbows, knees and ankles, which continued and became so severe that walking was painful. On examination two weeks after the onset the boy had a fever of 40.4 C. (104.7 F.) and was apparently suffering from severe pain in the knees and head. Although

group had extensive bleeding in the skin and also from the mucous membranes (the nose, mouth, intestine or urinary tract).

5. *Cervical Adenopathy*.—Marked enlargement of the cervical lymph nodes was quite inconstant, but in a certain number of cases formed the most striking clinical manifestation.

6. *Abdominal Pain*.—In two instances symptoms of acute peritoneal irritation dominated the illness, with very severe abdominal pain, muscular spasm and vomiting. At necropsy, one child had a perforated appendix, the wall being very friable from extensive leukemic infiltration, while the second child had widespread subserous hemorrhages over the appendix, cecum, transverse colon and sigmoid. Both had great enlargement of the abdominal lymph nodes. Four other children suffered from somewhat less severe abdominal symptoms.

7. *Stomatitis*.—Ulcerative stomatitis associated with Vincent's fasospirolosis was relatively infrequent, being noted in only four children. In two it was quite severe, one case developing into noma of the cheek.

8. *Neuropathic Symptoms*.—In two patients the chief symptoms were referable to the nervous system. One was a 13 year old boy in whom, during the course of a week, signs of transverse myelitis developed, with complete flaccid paralysis of the legs and urinary and fecal incontinence. There were at this time no other signs of leukemia, and only an examination of the blood revealed the diagnosis. He died two months later. There was no necropsy, but it seemed likely that a leukemic infiltration in or pressing on the spinal cord pro-

1. Cooke, J. V.: Mediastinal Tumor in Acute Leukemia, *Am. J. Dis. Child.* 44: 1153 (Dec.) 1932.

duced the symptoms. The second child, a 10 year old boy, was ill less than three weeks. He complained constantly of very severe frontal headache, pain and hyperesthesia and paresthesia of the legs. A few days before death he became lethargic and completely disoriented when aroused, although he had only slight fever and had not seemed toxic. In addition to a leukocyte count of over 500,000, he had enlargement of the spleen and the liver, a few petechiae of the skin and some small hemorrhages in the ocular fundi. The encephalitic symptoms were attributed to cerebral leukemic infiltration. Four other children had varying degrees of deafness; one became practically deaf toward the end of the disease, and the other three were only partially so.

Certain of the more common clinical manifestations tabulated in table 4 may be commented on briefly. Enlargement of the cervical lymph nodes was present to a sufficient degree to render them visible in only eighteen children; in twenty-seven others they were palpable and were considered to be slightly enlarged, and in five they were normal. The axillary and inguinal nodes were often slightly larger than normal and firm, but were never greatly increased in size. The spleen was firm and swollen in every case. In only twelve instances did it reach the umbilicus, while in fifteen the organ was felt only 1 or 2 fingerbreadths below the costal margin, and in the remaining twenty-three the size was between that in the foregoing groups. Hemorrhages were observed in forty of the fifty children and were somewhat more common in the skin (thirty-five) than in the mucous membranes (twenty-eight). While hemorrhage was apparently related to the thrombocytopenia, certain children had very low platelet counts without any visible bleeding.

Fever was present at some time in all children. In many it was only around 38 C. (100.4 F.), but almost all had periods, often toward the end of the disease, during which there was striking clinical evidence of general systemic disturbance with pyrexia. These periods were apparently not due to intercurrent infection but were attributable to the disease itself. A certain number of children suffered from intercurrent acute infections, such as tonsillitis, otitis and mastoiditis, during the course of the acute leukemia. On account of the lack of granular leukocytes in the blood, it was feared that the power of resistance in such children would be low. It was therefore surprising that several patients recovered from such infection quite satisfactorily; one lived more than a month after mastoidectomy, while another recovered from a streptococcal infection of the ear and septicemia; in this case blood cultures were positive on two occasions. Certain others, however, died of terminal pneumonia. Many seemed to succumb to the effects of the leukemia without demonstrable infection.

The effects of blood transfusion varied greatly in different children. In some definite improvement continued for a week or more after transfusion, and it could be repeated several times, while in others few effects could be noted. The tendency to continued severe hemorrhage was often counteracted temporarily by transfusion. In general, however, the transient effect and the certain eventual outcome of the disease made the use of transfusions of questionable value. They produced no change in the leukocyte picture, not even a temporary increase in granular cells. The few children with leukemia treated by roentgen irradiation did not improve, and certain of them seemed more toxic after such treatment and died in a short time. The

impression gained was that irradiation is contraindicated. In only one group was such irradiation of value, viz., in children who had massive mediastinal infiltration producing compression of the trachea and vessels with dyspnea. In this group irradiation produced an almost immediate disappearance of the mediastinal tumor and of the compression symptoms in the patients in whom leukemic blood changes had not yet appeared, although the leukemic blood picture developed from a few weeks to several months later. On the other hand, in children in whom irradiation was employed after the characteristic blood picture was present, it was without benefit. The opinion has been expressed that such patients with mediastinal tumors but without leukemic blood changes really have mediastinal lymphosarcoma which was transformed into leukemia by the irradiation. This seems quite unlikely: (1) because of the large number of instances of massive mediastinal infiltration in which acute leukemia develops without irradiation, (2) because many patients with mediastinal or other lymphosarcomas receive irradiation without the later appearance of leukemic changes and (3) because other patients, the case of one of whom is cited in this paper, are ill for more than a month with symptoms referable to the leukemic state but without leukemic blood, but in whom a leukemic blood picture develops without previous irradiation.

ABSTRACT OF DISCUSSION

Dr. F. C. RODDA, Minneapolis: Dr. Cooke's careful study and analysis of fifty cases of acute lymphatic leukemia is very instructive. A well developed case may be readily recognized, but as to the onset this is not so. I have in mind two instances in which colleagues with operative proclivities removed the tonsils and adenoids shortly after the onset of leukemia. One survived for a short period, and the other died promptly from hemorrhage. Infiltration of various parts of the body may be easily recognized and, again, easily overlooked. An increase in the size of the spleen is expected. The infiltration of the mediastinum, from the resultant dyspnea and striking demonstration from the roentgenogram, is readily recognized. It is not as well known, however, that infiltrations may involve such other organs as the liver and the kidneys. Formerly it was taught that an acute lymphatic leukemia would always be accompanied by a high white count. As Dr. Cooke has shown, this is not necessarily true. While the differential count is tremendously important at times, it may be very hard to be sure of the diagnosis. It is sometimes not possible to say that a particular type of cell found in the blood is absolutely indicative of an acute leukemia. Then one is thrown back on the history, the physical examination, the blood examination and the clinical course of the disease, which Dr. Cooke has so well outlined.

Pseudo-Ivory and True Ivory.—A chemical analysis of true ivory shows that its composition is similar to that of human bone, both differing only in the amount of magnesium phosphate and calcium carbonate they contain. Ivory contains about 43 per cent organic matter, while dentin contains only 25 per cent. Ivory substance has the tensile strength essential to the permanency of shape and is of a morphologic structure similar to that of bone without showing any tendency toward absorption. Its chemical and morphologic similarity to human bone explains why it is a nonirritant to the tissues. Clinically, it has been proved in my experience for the last twelve years that ivory remains in the tissues if introduced aseptically and in proper shape. This also has been proved in cases in which ivory has been found unchanged in human structures for thirty years. . . . Strict differentiation of true ivory from the so-called pseudo-ivories is essential, as their behavior in the tissues depends on their composition.—Maliniak, J. W.: Cartilage and Ivory, *Arch. Otolaryng.* 17:649 (May) 1933.

anemia of the aplastic type, (3) thrombocytopenia and (4) the appearance of varying numbers of abnormal nongranular mononuclear cells.

The possible influence of preceding infection on the production of acute leukemia has interested many investigators. In only a few of the children in this series had a recent infection been noted. In thirty-seven no infection had occurred within six months preceding the leukemia; one had pertussis and bronchopneumonia five months before, one chicken-pox four months before and two scarlet fever two months previously. Of the nine who had infection within one month of the apparent onset of the disease, three had follicular tonsillitis, two infection of the upper respiratory tract, two impetigo, one measles and one diphtheria.

THE CLINICAL SYMPTOMS

The first symptom of the disease noted by the parents is of interest. This symptom consisted in pallor and asthenia in seventeen cases; enlargement of the cervical gland in nine, skin hemorrhages in seven, cough and dyspnea in five, rheumatoid pains in five, stomatitis in two, abdominal pain in two, neurologic symptoms

he had no objective swelling of the extremities, there was general muscular tenderness on moderate pressure. Physical examination gave negative findings except for palpable small anterior and posterior cervical lymph nodes. At times he would awaken from a short sleep crying and moaning with pain in the muscles, especially in the legs. A pea-sized rheumatism-like nodule was noted at the proximal end of the right metacarpal bone, and clusters of similar nodules were found in the occipital aponeurosis. A faint systolic murmur developed at the apex, although an electrocardiogram showed a normal mechanism, and no cardiac abnormality was detected. Fever and pain persisted. There was no anemia, and the blood showed a moderate leukopenia of from 4,000 to 6,000 with a normal differential count. The child was considered to have rheumatic fever until more than three weeks after admission, when hemorrhages occurred in the skin and mucous membranes, the cervical glands became enlarged, and the leukocytes increased to 20,000 with the picture of acute leukemia. Death occurred one week later.

4. *Hemorrhages*.—Although petechial or ecchymotic hemorrhages, as well as bleeding from mucous membranes, are relatively common in acute leukemia, in certain children this hemorrhagic tendency overshadows other symptoms by its extent. The patients in this

(paralysis of the bladder and severe headache) in two and enlargement of the abdomen in one.

For purposes of description of the clinical manifestations the children have been divided into several groups on the basis of the most prominent or striking clinical phenomena of the disease, although there was, of course, some overlapping of the symptoms and signs. These groups are as follows:

1. *Asthenia*.—This familiar type included twenty-two children in whom the principal symptoms were weakness and pallor.

2. *Dyspnea*.—In this type the symptoms are due to pressure of a leukemic tumor in the anterior mediastinum. The cases of the seven children in this group have been described in detail elsewhere,¹ and it will be mentioned only that the symptoms consisted in cyanosis of the neck and face, with cough and dyspnea which tended to be paroxysmal and were often accentuated by muscular effort.

3. *Rheumatoid Pains*.—Pain in the extremities and in the joints is often a prominent symptom of acute leukemia and is not always sufficiently emphasized. A brief summary of one of the cases in this group follows:

A 14 year old white boy, two days after having had slight fever and sore throat complained of pain in the elbows, knees and ankles, which continued and became so severe that walking was painful. On examination two weeks after the onset the boy had a fever of 40.4 C. (104.7 F.) and was apparently suffering from severe pain in the knees and head. Although

group had extensive bleeding in the skin and also from the mucous membranes (the nose, mouth, intestine or urinary tract).

5. *Cervical Adenopathy*.—Marked enlargement of the cervical lymph nodes was quite inconstant, but in a certain number of cases formed the most striking clinical manifestation.

6. *Abdominal Pain*.—In two instances symptoms of acute peritoneal irritation dominated the illness, with very severe abdominal pain, muscular spasm and vomiting. At necropsy, one child had a perforated appendix, the wall being very friable from extensive leukemic infiltration, while the second child had widespread subserous hemorrhages over the appendix, cecum, transverse colon and sigmoid. Both had great enlargement of the abdominal lymph nodes. Four other children suffered from somewhat less severe abdominal symptoms.

7. *Stomatitis*.—Ulcerative stomatitis associated with Vincent's *fasospirillosis* was relatively infrequent, being noted in only four children. In two it was quite severe, one case developing into noma of the cheek.

8. *Neuropathic Symptoms*.—In two patients the chief symptoms were referable to the nervous system. One was a 13 year old boy in whom, during the course of a week, signs of transverse myelitis developed, with complete flaccid paralysis of the legs and urinary and fecal incontinence. There were at this time no other signs of leukemia, and only an examination of the blood revealed the diagnosis. He died two months later. There was no necropsy, but it seemed likely that a leukemic infiltration in or pressing on the spinal cord pro-

1. Cooke, J. V.: Mediastinal Tumor in Acute Leukemia, *Am. J. Dis. Child.* 44: 1153 (Dec.) 1932.

duced the symptoms. The second child, a 10 year old boy, was ill less than three weeks. He complained constantly of very severe frontal headache, pain and hyperesthesia and paresthesia of the legs. A few days before death he became lethargic and completely disoriented when aroused, although he had only slight fever and had not seemed toxic. In addition to a leukocyte count of over 500,000, he had enlargement of the spleen and the liver, a few petechiae of the skin and some small hemorrhages in the ocular fundi. The encephalitic symptoms were attributed to cerebral leukemic infiltration. Four other children had varying degrees of deafness; one became practically deaf toward the end of the disease, and the other three were only partially so.

Certain of the more common clinical manifestations tabulated in table 4 may be commented on briefly. Enlargement of the cervical lymph nodes was present to a sufficient degree to render them visible in only eighteen children; in twenty-seven others they were palpable and were considered to be slightly enlarged, and in five they were normal. The axillary and inguinal nodes were often slightly larger than normal and firm, but were never greatly increased in size. The spleen was firm and swollen in every case. In only twelve instances did it reach the umbilicus, while in fifteen the organ was felt only 1 or 2 fingerbreadths below the costal margin, and in the remaining twenty-three the size was between that in the foregoing groups. Hemorrhages were observed in forty of the fifty children and were somewhat more common in the skin (thirty-five) than in the mucous membranes (twenty-eight). While hemorrhage was apparently related to the thrombocytopenia, certain children had very low platelet counts without any visible bleeding.

Fever was present at some time in all children. In many it was only around 38 C. (100.4 F.), but almost all had periods, often toward the end of the disease, during which there was striking clinical evidence of general systemic disturbance with pyrexia. These periods were apparently not due to intercurrent infection but were attributable to the disease itself. A certain number of children suffered from intercurrent acute infections, such as tonsillitis, otitis and mastoiditis, during the course of the acute leukemia. On account of the lack of granular leukocytes in the blood, it was feared that the power of resistance in such children would be low. It was therefore surprising that several patients recovered from such infection quite satisfactorily; one lived more than a month after mastoidectomy, while another recovered from a streptococcal infection of the ear and septicemia; in this case blood cultures were positive on two occasions. Certain others, however, died of terminal pneumonia. Many seemed to succumb to the effects of the leukemia without demonstrable infection.

The effects of blood transfusion varied greatly in different children. In some definite improvement continued for a week or more after transfusion, and it could be repeated several times, while in others few effects could be noted. The tendency to continued severe hemorrhage was often counteracted temporarily by transfusion. In general, however, the transient effect and the certain eventual outcome of the disease made the use of transfusions of questionable value. They produced no change in the leukocyte picture, not even a temporary increase in granular cells. The few children with leukemia treated by roentgen irradiation did not improve, and certain of them seemed more toxic after such treatment and died in a short time. The

impression gained was that irradiation is contraindicated. In only one group was such irradiation of value, viz., in children who had massive mediastinal infiltration producing compression of the trachea and vessels with dyspnea. In this group irradiation produced an almost immediate disappearance of the mediastinal tumor and of the compression symptoms in the patients in whom leukemic blood changes had not yet appeared, although the leukemic blood picture developed from a few weeks to several months later. On the other hand, in children in whom irradiation was employed after the characteristic blood picture was present, it was without benefit. The opinion has been expressed that such patients with mediastinal tumors but without leukemic blood changes really have mediastinal lymphosarcoma which was transformed into leukemia by the irradiation. This seems quite unlikely: (1) because of the large number of instances of massive mediastinal infiltration in which acute leukemia develops without irradiation, (2) because many patients with mediastinal or other lymphosarcomas receive irradiation without the later appearance of leukemic changes and (3) because other patients, the case of one of whom is cited in this paper, are ill for more than a month with symptoms referable to the leukemic state but without leukemic blood, but in whom a leukemic blood picture develops without previous irradiation.

ABSTRACT OF DISCUSSION

DR. F. C. RODDA, Minneapolis: Dr. Cooke's careful study and analysis of fifty cases of acute lymphatic leukemia is very instructive. A well developed case may be readily recognized, but as to the onset this is not so. I have in mind two instances in which colleagues with operative proclivities removed the tonsils and adenoids shortly after the onset of leukemia. One survived for a short period, and the other died promptly from hemorrhage. Infiltration of various parts of the body may be easily recognized and, again, easily overlooked. An increase in the size of the spleen is expected. The infiltration of the mediastinum, from the resultant dyspnea and striking demonstration from the roentgenogram, is readily recognized. It is not as well known, however, that infiltrations may involve such other organs as the liver and the kidneys. Formerly it was taught that an acute lymphatic leukemia would always be accompanied by a high white count. As Dr. Cooke has shown, this is not necessarily true. While the differential count is tremendously important at times, it may be very hard to be sure of the diagnosis. It is sometimes not possible to say that a particular type of cell found in the blood is absolutely indicative of an acute leukemia. Then one is thrown back on the history, the physical examination, the blood examination and the clinical course of the disease, which Dr. Cooke has so well outlined.

Pseudo-Ivory and True Ivory.—A chemical analysis of true ivory shows that its composition is similar to that of human bone, both differing only in the amount of magnesium phosphate and calcium carbonate they contain. Ivory contains about 43 per cent organic matter, while dentin contains only 25 per cent. Ivory substance has the tensile strength essential to the permanency of shape and is of a morphologic structure similar to that of bone without showing any tendency toward absorption. Its chemical and morphologic similarity to human bone explains why it is a nonirritant to the tissues. Clinically, it has been proved in my experience for the last twelve years that ivory remains in the tissues if introduced aseptically and in proper shape. This also has been proved in cases in which ivory has been found unchanged in human structures for thirty years. . . . Strict differentiation of true ivory from the so-called pseudo-ivories is essential, as their behavior in the tissues depends on their composition.—Maliniak, J. W.: Cartilage and Ivory, *Arch. Otolaryng.* 17:649 (May) 1933.

THE SYSTOLIC MURMUR

ITS CLINICAL SIGNIFICANCE

SAMUEL A. LEVINE, M.D.

BOSTON

The physical causes or mechanism of the systolic murmur and its clinical significance have been matters of much discussion for many years. There was a time, not so very long ago, when on hearing a systolic murmur over the heart, even in the absence of any other important abnormalities, the physician would pronounce the ominous verdict that the patient was suffering from organic heart disease with mitral insufficiency. He would also imply in this diagnosis a serious prognosis and institute restrictions in the mode of life for his patient. More recently, systolic murmurs have been found so often to be benign that an entirely opposite point of view has developed. It has become the teaching in many localities that "systolic murmurs have no significance whatever," that "organic mitral insufficiency does not exist except with mitral stenosis" and even that "auscultation is of no great importance," for it is not the valvular but the myocardial state that determines the efficiency of the circulation. The extreme position in this controversy is indicated in a remark that Sir James Mackenzie frequently made: that "the stethoscope should be thrown away and the physician should learn how to elicit the early symptoms of heart failure." It is not my purpose in this paper to analyze the physical factors that produce a systolic murmur but to indicate how its presence should be regarded from a clinical point of view, when it should be considered important, and when it may be viewed lightly. It will also be made clear that a proper understanding of the systolic murmur may at times serve as the starting point of the correct diagnosis in cases that otherwise are misinterpreted.

At the outset it is necessary to define the systolic murmur, so that there may be no misunderstanding concerning terms. The term should be limited to a bruit that has an appreciable duration, lasting for a considerable interval of time between the first and second heart sounds. It must have a significant duration entirely apart from its intensity. Frequently systolic murmurs are supposed to be present when on careful auscultation one merely hears a slightly prolonged first heart sound and a perfectly clear and silent interval between the first and second sounds. Because systolic murmurs are regarded as insignificant, physicians, hospital interns and medical students frequently state that they hear such a faint murmur, knowing that no great attention will be paid to it and fearing that some one else might hear one if they did not. Repeatedly after the most careful auscultation I have failed to find any systolic murmur whatever when others have said they had heard one. The first requisite, therefore, is that the bruit must have an appreciable duration after the first heart sound and last into systole.

A second necessary prerequisite in this discussion is that the intensity of the systolic murmur must be estimated. We all indicate the amount of albuminuria or glycosuria in quantitative terms. A slightest possible trace of albumin in the urine has a different meaning than a very large trace. The former would be very

rare during the height of so-called nephrosis, and the latter would be rare during the febrile course of a simple pneumonia. Likewise, the intensity of the Wassermann reaction, the presence of globulin in the spinal fluid, and many other conditions are customarily indicated by terms such as +, ++, +++, +++++. Similarly, for some years I have expressed the intensity of the systolic murmur in six gradations. Grade 1 is the faintest bruit that can be heard on careful auscultation. Although faint, it must have a definite duration into systole. This can be called a slightest possible murmur. Such murmurs are frequently overlooked in general practice. A murmur of grade 6 intensity is extremely rare and may be applied to the few instances in which the murmur can be heard with the naked ear held even at some distance from the chest wall. This one may be called the loudest possible murmur. Murmurs of grades 2 to 5 are intermediate and may be designated slight murmur, moderate murmur, loud murmur, and very loud murmur. It is remarkable that with a very little experience independent observers will designate the same murmur with practically identical terms. Physicians who have worked with me for a short time will differ by no more than one gradation, and in the majority of instances there has been absolute agreement. This has been gone into in some detail, because I believe that without such a nomenclature there will be only confusion and no progress in the clinical interpretation of systolic murmurs.

It is current knowledge that systolic murmurs occur in the presence of organic valvular disease and in congenital and other types of heart disease. It is also known that they are present under conditions in which the heart is not diseased. If there is regurgitation of blood through the mitral valve, there will be a systolic murmur at the apex of the heart. The experimental production of mitral insufficiency in animals results in a systolic murmur, and clinical conditions in which all the evidence points to a regurgitation of blood through the mitral valve also show apical systolic murmurs. The presence of mitral insufficiency and a systolic murmur, however, does not necessarily indicate disease of the mitral valve. The valve may be incompetent but not diseased. Patients with hypertensive, syphilitic or myocardial disease of any sort may have a sufficiently dilated left ventricle so that the mitral orifice is increased in size, and normal valve leaflets may be incompetent and fail to prevent reflux of blood with systole. On the other hand, there will be a systolic murmur from mitral insufficiency without any appreciable dilatation of the left ventricle if the valve itself is diseased and the leaflets are retracted. The former condition one may call relative or functional and the latter, organic mitral insufficiency. It does not follow that the patient with relative mitral insufficiency has a less serious condition than the one with organic. In fact, the contrary is often the case, because the underlying organic disease of the heart muscle is the more important consideration. It is only when there is no important disease at all and a systolic murmur is present that it can truly be called benign or insignificant.

When a systolic murmur is heard and its intensity has been gaged, further evidence of organic cardiovascular disease must be sought. It is sound practice to assume that there is cardiac disease if the heart is found to be enlarged and except for very rare instances when a diastolic murmur is also present. If there are indications that the patient is having or has had a rheu-

matic infection, it is likely that the systolic murmur indicates a structural or organic defect of the valve. But it must be borne in mind that a large proportion of patients who have gone through a rheumatic infection are not aware of it. A systolic murmur in a young person, therefore, is often an important and sometimes the only clue that the patient is rheumatic.

When a patient with a systolic murmur shows no other obvious evidence of cardiac disease, what other factors must be considered that may be related to the production of this murmur? The important ones are hypertension, anemia, hyperthyroidism, fever and increased heart rate. Although these conditions are by no means invariably associated with a systolic murmur, an extensive experience teaches that in some way they are often related to the presence of the murmur and that the murmur may disappear as these factors are controlled. How the systolic murmur develops under such a variety of conditions is not clearly understood. There is one mechanism that deserves more consideration than it has obtained: the speed of blood flow. In hyperthyroidism, fever, and marked anemia, and after or during physical effort, the speed with which the blood stream is ejected from the heart and travels through the circulation is increased. A snapping character of cardiac systole is common to all these conditions and it may be that this snap and rapid ejection of blood may produce the bruit which disappears as the heart quiets down. In the past, such murmurs were often ascribed to relative dilatation of the mitral valve or to changes in the blood itself. Directly after a brisk effort in normal persons there is practically invariably a systolic murmur that develops temporarily at a time when the heart is not dilated, when the sounds are hyperactive, and when the velocity of blood flow is increased. This mechanism probably explains many systolic murmurs in otherwise normal hearts and possibly in some diseased hearts.

It may now be asked how often systolic murmurs are encountered in general practice or in so-called normal individuals. In a recent study,¹ 1,000 cases were carefully examined with this in mind. The relative frequency and intensity of the murmur at the apex and base of the heart, whether it was louder with the patient upright or recumbent, and its occurrence in the two sexes were analyzed. The cases were chosen from the wards of a children's hospital, the surgical wards of the Peter Bent Brigham Hospital, a tuberculosis sanatorium, and among normal nurses and physicians. Only a small number of medical ward cases were included, so that there would not be many patients with primary organic heart disease. The distribution was about equal between the two sexes. Many normal and all sorts of abnormal conditions were included. There were seventeen instances in which a systolic murmur of grade 3 intensity or louder was heard. In every one of these cases, obvious cardiovascular disease was present. In most instances the cardiac condition was an incidental finding during the course of some other illness, such as fracture of the femur or herniotomy. This strongly emphasized the importance of estimating the intensity of the murmurs, for the louder ones were invariably associated with some form of organic heart disease.

There were 196 patients (19.6 per cent) out of the 1,000 examined in whom a murmur of grades 1 or 2 was heard. When the cases were carefully analyzed to eliminate all possible contributing factors such as

obvious heart disease, a past history of rheumatic fever, hypertension, anemia, hyperthyroidism and fever, there remained only forty-five patients, or 4.5 per cent, who had a systolic murmur, and in thirty-four cases the intensity of the murmur was grade 1. The important point was that frequently when a murmur was present an investigation of all the data elicited a reasonable or possible clinical explanation of it. One must not infer that, even when an explanation was found, the condition was to be regarded as serious. In fact, most of these patients were well and probably will continue so for many years. Some, however, probably will later develop hypertension or rheumatic valve disease or subacute bacterial endocarditis, although it is not possible to predict what will happen in any individual case.

It has become the custom among many physicians, especially those examining for insurance companies and civil service commissions, to auscult the heart before and after effort and to draw certain inferences from the finding of a systolic murmur brought out in this way. In a study of ten normal medical house officers it was found that in nine a systolic murmur of grade 1 or 2 intensity developed after a brisk effort, which was not present before. Its appearance can therefore be regarded as a normal phenomenon under these circumstances.

To illustrate the application and value of the point of view expressed, in relation to a systolic murmur, a few experiences will be cited. During the routine examination of forty first-year students at the Harvard Medical School sometime ago, I found only one with a systolic murmur. The intensity of the murmur was grade 2. The young man was well and had practically no complaints. The murmur could not be dismissed and on closer scrutiny a few suspicious evidences of hyperthyroidism were detected. The basal metabolism was then found to be elevated and he was subsequently treated for hyperthyroidism. Here the systolic murmur was the first clue to the proper diagnosis of hyperthyroidism. Although the systolic murmur here might be regarded as benign and certainly did not indicate any organic disease of the valves or the heart itself, it did require interpretation.

A second patient came into the hospital with a diagnosis of left renal stone. He had been working when a pain in the left loin, radiating down to the groin, suddenly developed. Following this, he passed bloody urine. This was confirmed on urinary examination and the case was demonstrated in the hospital as one of renal colic. I found that he had an apical systolic murmur of grade 2 intensity, which led to a more direct questioning concerning his health. He had not been in his usual health for a month before this acute pain occurred and admitted that he had had a heart murmur for many years, since an attack of rheumatic fever. The provisional diagnosis of subacute bacterial endocarditis with renal embolus was made, which thereby explained the presence of the murmur. A blood culture taken that day, although the temperature was only 99.2 F., showed *Streptococcus viridans*. This also illustrates the importance of the consideration of a systolic murmur in diagnosis.

The development of subacute bacterial endocarditis in patients who have had a "benign" and symptomless systolic murmur is by no means rare. I have repeatedly seen this occur, and it emphasizes the fact that, although these systolic murmurs were not accompanied by any impairment in the efficiency of the circulation, they must have indicated some minor irregularity in the

1. Freeman, A. R., and Levine, S. A.: *Ann. Int. Med.*, to be published.

integrity of the mitral valve on which a subsequent bacterial endocarditis developed.

There is a further group of patients in whom a so-called benign systolic murmur subsequently developed into an organic condition. Reference is made to those cases that years later show definite evidence of mitral or aortic stenosis. I have repeatedly seen patients who had a systolic murmur at the apex or base of the heart and gave no other objective or subjective evidence of heart disease. In some, a past history of rheumatic infection could be elicited, and in others it was absent. In the course of some years, definite evidence of stenosis of the mitral valve or the aortic valve occurred. The follow-up study of these murmurs showed that, although originally unassociated with any impairment of the circulation, they were organic and not benign.

Systolic murmurs unaccompanied by other significant evidence of heart disease occur not infrequently in so-called nervous hearts or neurocirculatory asthenia. They are then apt to be faint, not greater than of grade 2 intensity and generally of grade 1 intensity. They are also seen in patients with vasomotor instability and hyperactive hearts. Such patients often show blood pressure readings in the upper limits of normal and not infrequently develop real hypertension later. This is by no means invariable, for some individuals carry a slight systolic murmur for a great many years and die of old age without ever having any embarrassment from their hearts.

It follows from these considerations that a systolic murmur will have greater significance if the heart rate is slow, when there is no fever, anemia or hyperthyroidism, and when the blood pressure is low. If present in the absence of such circumstances a systolic murmur of grade 2 intensity will probably be found to be due to some organic changes in the heart. That does not mean that the patient should be restricted in his activities if there is no other reason for protecting the heart. He may even carry on quite normally and indefinitely, but there is some likelihood of heart disease such as mitral or aortic stenosis, hypertension, or bacterial endocarditis developing further. Systolic murmurs of the faintest intensity (grade 1) are not very rare and occur in a sufficient number of persons who are otherwise normal that their diagnostic value is extremely slight, although they also are found associated with organic disease.

CONCLUSION

Systolic murmurs do occur but are not common in normal individuals. The louder ones are always associated with some form of cardiovascular disease. All systolic murmurs deserve consideration. Many such murmurs, although frequently regarded as "benign" because the individuals feel well and have no symptoms of cardiac insufficiency, are due to organic changes or indicate potentialities for the subsequent development of stenosis of the mitral or aortic valves, hypertension and subacute bacterial endocarditis. Others are truly benign in the sense that no deleterious effects result, even after an indefinite period.

270 Commonwealth Avenue.

ABSTRACT OF DISCUSSION

DR. JAMES B. HERRICK, Chicago: It seems to me that our fathers in physical diagnosis, when they wrote the chapter on the diagnosis of heart disease, put in the systolic murmur to make it more difficult; but it is there and I do not think we are justified in eliminating it. It is our duty to interpret it,

even though there are difficulties and dangers of misinterpretation. I agree with Dr. Levine that we should take what might be called a middle course. He has referred to the fact that the murmur may call attention to the existence of something other than heart disease, perhaps anemia or hyperthyroidism. There are two conditions in the heart itself that may be betrayed early by the systolic murmur: a rheumatic heart and a beginning sclerotic change in the valves. We should not be compelled, even though the textbooks tell us so, to defer our opinion concerning every systolic murmur until the heart is large, the second sound accentuated, the patient cyanotic or with râles in the chest. The early recognition through this murmur of remote dangers may enable us to advise the patient how he should live and thus postpone the day of evil. I have practiced medicine long enough to see a crop of these systolic murmurs that I recognized ten, twenty and thirty years ago come to fruit, sometimes with the same murmur that the patients had, and in as good health, but many times with broken down hearts of one type or another. In the war, much emphasis was laid by the medical department on the innocuousness of the systolic murmur. I know from observation that there were tragedies that followed the prescription of some individuals. Back in the fifties, men like Bamberger and our own Austin Flint spoke of the inorganic murmur, the hemic murmur and the accidental murmur. Mackenzie was by no means the first one to emphasize the fact that misrepresentation of the murmur was often made, and with calamitous results. I wish to endorse Mackenzie's emphatic disapproval of the treatment of a murmur in the treatment of a heart merely because it has a murmur. Many of these heart murmurs are in patients who need no digitalis, who need no rest. Some of them need not even be told that they have a murmur. In the other case, a word of caution without undue alarming of the patient is entirely in order.

DR. FRED M. SMITH, Iowa City: The systolic apical murmur occupies an unusual position in cardiac diagnosis. The mere fact that it is so common and so often not indicative of organic disease leads to many mistaken diagnosis. The organic systolic murmur gives information with reference both to the endocardium and to the myocardium, and in each it is frequently among the earliest and most conspicuous signs of structural change. The murmur that occurs during the early stage of a rheumatic infection is for the most part dependent on the dilatation of the auriculoventricular ring. If the patient is seen at a later stage, the systolic murmur may again be the most noteworthy observation and again probably largely responsible for the diagnosis. Then, too, as pointed out by Dr. Levine, the systolic murmur may be the first to suggest the possibility of a subacute bacterial endocarditis or lead to the diagnosis of a thyrotoxicosis. Finally, in the degenerative form of heart disease the systolic murmur over the apex is taken into consideration in estimating the extent of the myocardial damage. All physicians have encountered systolic apical murmurs which at the time of the examination could not be classified as functional or organic. In questionable cases all aspects of the problem must be taken into consideration, including the past history with particular reference to rheumatic fever, the presence of a possible infection, and the associated cardiac condition. In the absence of a history of rheumatic fever or of an infection, the significance of the murmur is determined wholly by the associated manifestations, and of these the size and configuration of the heart are by far the most important. If one can demonstrate to one's satisfaction by physical and roentgenologic examination that there is no alteration in the size and shape of the heart, organic heart disease is for the most part excluded. Occasionally, however, it may be necessary to postpone final judgment until there is time for further possible developments.

DR. SAMUEL A. LEVINE, Boston: It is not necessary to change a patient's mode of life merely because one hears a murmur. As Dr. Herrick said, one does not treat the murmur. The attitude of trying to interpret the systolic murmur is warranted because it may give a clue to what may be going on in the heart. It will be found that some of the patients who have been well all the time will develop outspoken aortic stenosis or mitral stenosis ten years later. One hasn't erred in the meantime, and it has been illuminating in picturing the development of a certain disease. That type of knowledge, I think, will prove fruitful.

THE CLINICAL VALUE OF HUMAN
CAPILLARY STUDIES

IN FEVER, MENTAL DEFICIENCY, NEPHRITIS, VASCULAR DISEASES, CLUBBED FINGERS, ARTHRITIS, TOBACCO SMOKING AND ARGYRIA

IRVING SHERWOOD WRIGHT, M.D.

NEW YORK

Although the capillaries as a group exercise the most profound influence on the functions of the living body, their activity, especially in man, has been susceptible of direct study for only a short era in the history of medical science. A great volume of instructive work has since been produced, much of which has been confined to animals other than man. My purpose in this discussion, however, will be to outline briefly some of the more recent observations concerning the activities of the minor vessels of the skin in man which appear to have some value clinically, either (1) in adding evidence which results in changes in certain conceptions of physiology in normals, or pathologic variations in disease processes, or (2) in giving information of direct value in the study of single patients or groups of patients with similar diseases.

It should be clearly stated at the outset that although the capillaries may, under certain conditions, appear to have some independence of action, any studies such as those to be outlined must consider the capillaries as part of, and acting in relation to, the entire circulatory system and, indeed, the body as a whole. The vessels of the skin are also influenced by environmental factors.

The nailfolds offer the most favorable area for capillary study. Whenever indicated, however, observations have been made elsewhere on the body surface. The methods used have been previously described.¹

OBSERVATIONS ON THE MECHANISM OF FEVER

Observers have noted that the surface temperature rises in fever and that during a chill there is actually a sudden drop in temperature, which is followed by a rise again, often to a higher level than before. With a rise in temperature a great increase in the number of active capillaries and the rate of flow can be readily seen under the capillary microscope.

With the hope of helping to explain the cause and significance of this activity, we² made the following observations on man:

By means of a potentiometer and a thermocouple junction in the tip of a hypodermic needle, we were enabled to take temperature readings of the circulating blood and other tissues, following the work of Foged³ and others.⁴ In a series of afebrile patients it was found that the intravenous temperature, taken in the median cubital, jugular or branches of the saphenous veins, was always lower than the oral, hence rectal, tem-

perature.⁵ The least difference between the oral and intravenous temperature was 1.2 F.; the greatest difference thus far noted was 13 F. In a small series of patients the intra-arterial temperatures were also lower than the oral temperature but higher than the intravenous temperature. Foged reports two cases in which he secured intra-arterial readings. In one, the temperature equaled the rectal temperature, and in the other, it was lower than the rectal temperature. Further readings are necessary to establish definitely the relative position of the arterial temperature.

The intramuscular temperature was found to be uniformly higher than the oral temperature.

We then studied the relationship between the oral, the intravenous and the intramuscular temperature in fever under four groups: (a) fever produced by a disease process, i. e., pneumonia, Hodgkin's disease, rheumatic fever, pulmonary tuberculosis, bacterial endocarditis and the like; (b) fever produced by the hyperdiathermia machine (General Electric) as high as 105.0 F. by mouth; (c) fever produced by a 36 meter wavelength condenser machine (hyperthermy spark gap-Lepel) as high as 104.5 F.; (d) fever produced by the intravenous injection of *B. typhosus* vaccine.

In all cases, whatever the etiology of the fever, the same general relationship was maintained; namely, intravenous lowest, then mouth, and intramuscular temperature highest.

The greatly increased capillary activity, with the consistently highest intramuscular temperatures, and the lower blood temperatures seems to indicate that the object of the additional blood supply may be not a direct increase in local heat but rather a means of supplying the cells, especially of the muscles, with an increased food supply for metabolic activity and associated heat generation. There is inevitably a diffusion of this increased heat from the blood by conduction and radiation.

THE RELATIONSHIP BETWEEN CAPILLARY DEVELOPMENT AND MENTAL DEVELOPMENT

Jaensch and his co-workers⁶ in Berlin have clearly shown that in cretinism and certain other mental deficiency diseases the lack of mental development is paralleled by the lack of development of the capillaries of the skin. If thyroid extract is given to cretins early in life, the increase in intelligence accompanies increase in capillary development. The exact relationship between the increased circulatory activity and the improvement in mental and physical activity has not been determined.

Children with deficient mental and physical development show pathologically developed capillaries,⁷ but those with delayed physical development, but of normal or superior intelligence, show normal capillaries.⁸

In patients afflicted with hemiplegias from infancy, the capillaries on the affected side maintain the archiform state, while those of the unaffected side develop

other diseases should not lead to the deduction that the stasis of the blood in the major blood vessels is responsible for clubbing, but only that they are coincidental manifestations.

2. Since greatly congested, stagnant capillaries may be present in nailfolds of patients for years without the development of clubbing of the fingers, and since the nailfold capillaries of many patients with advanced clubbing of the fingers appear normal in all respects, serious doubt may be entertained as to any definite relationship between these two conditions.

3. Other possible explanations for clubbing of the fingers, such as disturbance in the lymph drainage, changes in local or general metabolism, or the presence of toxic products, are thus far also without proof.

Of interest in this regard are the unpublished studies of Loeb and Richards¹⁴ of the Presbyterian Hospital of New York. These workers made comparative studies of the chemistry of the blood taken from the two arms in a small series of cases of unilateral clubbing of the fingers, in each instance associated with aortic aneurysm. The following determinations were made from an artery and a vein of each arm; oxygen content, oxygen capacity, oxygen per cent saturation; difference between oxygen readings in the corresponding artery and vein, carbon dioxide content volume per cent, carbon dioxide at 40 mm. pressure of carbon dioxide, difference between carbon dioxide readings in corresponding artery and vein; respiratory quotient, lactic acid, sugar, nonprotein nitrogen, phosphorus, calcium, p_{H} , and hematocrit readings. The results were such that no difference could be determined between the blood chemistry of the affected and of the unaffected extremity.

ARTHRITIS

Recent work by Kovacs, Wright and Duryee¹⁵ has again opened the problem of the relationship of circulation to arthritis. In more than 100 cases of arthritis of all types, the only consistent changes in the capillaries in the nailfold were found in fingers with joint swellings or Heberden's nodes. The decrease in capillary number and activity here noted could well be explained on the basis of mechanical pressure. I doubt the accuracy of a pathologic estimate based on the examination of nonvital material as to the activity of the capillaries within a joint and maintain that drawing conclusions of the condition and activity of the joint capillaries from observations of the capillaries of the skin should be a matter of great caution.

Further changes, such as lowered surface temperature, slowed capillary flow, and constrictions in the capillaries, were found in varying percentages, but in no instance did these exceed 55 per cent occurrence. Because of this lack of consistency, I cannot consider as proved that changes in the circulation, as indicated by present methods, are uniformly responsible for the pathologic changes found in arthritis.

THE EFFECT OF TOBACCO SMOKING ON THE VESSELS OF THE SKIN

Maddock and Coller¹⁶ reported in 1932 a series of twenty-one subjects in whom smoking tobacco produced a drop in temperature, as observed from the skin of

the fingers and toes. Cessation of smoking resulted in a gradual rise in temperature. Johnson,¹⁷ one of my co-workers, has confirmed these observations in a series of thirty-five subjects with the following exceptions: Six subjects showed no change after ten or more minutes of smoking. Two subjects showed an increase in temperature. In each of his subjects the room temperature was lower than the surface temperature taken at the finger tips. The extent of the drop varied from 2 to 11 degrees F. Barker¹⁸ has recently reported similar results. I have observed four patients in whom the surface temperature at the finger tips was equal to the room temperature. In none of these was there any drop on smoking. In two, there was a rise of 2 degrees F.

In certain individuals I have been able to note a marked slowing and often stasis in the capillary circulation at the nailfold during the smoking of a single cigaret. This phenomenon, when present, can be seen after the first few deep inhalations. The temperature drop¹⁷ and the slowing of the capillary flow seem appreciable only when the smoker inhales. The flow apparently is especially affected in subjects who complain of systemic symptoms from the use of tobacco. In some cases the normal circulatory activity returned during the smoking of several cigarets, while in others marked slowing and stasis remained until the completion of the smoking. The slowing could often be observed to follow a timal relationship to deep inhalations; i. e., about ten seconds following the inhalation the flow would slow perceptibly and often stop for varying lengths of time up to fifteen seconds or occasionally longer. It would then regain its former rate, but another puff would cause a repetition of the cycle. Deep breathing of room atmosphere did not in any instance produce this result.

Krogh and Lewis¹⁹ have shown that local temperature is affected by the rate of the arteriocapillary circulation; if the circulation slows up, local temperature falls.

This seems a logical correlation of the temperature and capillary conditions during smoking. The fact that one cannot always succeed in observing the capillary changes with the temperature drop may well be due to the inadequacies of present-day technic. The fact that individuals do not all react with either of these changes may be attributed to different degrees of absorption and sensitivity.

The relationship of this phenomenon to the frequent symptoms complained of by smokers presents an interesting field for speculation. One may ask whether by local action similar spasm, producing ischemia of areas of the brain or heart muscle, may not result in dizziness, nausea, unexplained anginoid pains and other phenomena. However, these symptoms may be produced by stimulation of the various parts of the sympathetic nervous system. In several patients, with complaints of tingling of the fingers from various causes, the smoking of a single cigaret would result in an increase in symptoms, accompanied by the phenomena in the capillary bed. Whether the spastic reaction takes place in the arterioles or capillaries cannot at present be determined, but it constitutes a contraindication to smoking with any condition of impaired circulation to the extremities.

These reactions in the blood vessels may be productive of end-results of two distinct types: (1) changes in the blood vessels themselves, and (2) changes based on irregularities in the distribution of blood in the organs which they supply.

The cause of these phenomena has yet to be determined. Carbon monoxide,²⁰ nicotine, the nicotine-free fraction of tobacco, and various products resulting from the chemistry of burning tobacco must be considered as possible offenders. Barker¹⁸ has presented strong evidence against the smoke from the cigaret paper being a causative factor. In our tests, various standard brands of cigarets were used with similar results.

ARGYRIA

I have recently seen several patients suffering from the bluish-gray discoloration of the skin due to the deposit of insoluble silver albuminate following the long continued administration of a soluble silver salt. In each instance the first visible evidence of this discoloration was noted along the distal margin of the lunulae of the nails in the nail beds and was believed to be cyanosis due to circulatory stasis. The bluish gray then gradually spread under the rest of the nails accompanying its appearance elsewhere in the skin.

Examination of the nailfold capillaries showed a normal appearance with normal to rapid rate of flow. Such a picture will rule out cyanosis due to stasis, which might otherwise be difficult to eliminate during the earliest stage.

The appearance of a bluish-gray zone just distal to the lunula of the nail should be an indication for the immediate discontinuance of any preparation containing a silver salt, at least until the possibility of very early argyria has been ruled out. In my patients, negligence of such precaution seems to have been followed by steady progression of this unpleasant condition.

Whether careful observation and questioning will show that this early sign is present in a large percentage of these patients in time to permit the prevention of generalized bluish discoloration remains to be determined. Evidence in favor of argyria would be lack of any indication of congestion of the nailfold capillary circulation, or of any insufficiency in the pulmonary or major circulation; lack of history of intake of acetanilid or allied substances; absence of spectroscopic bands of sulphemoglobin or methemoglobin in the blood, and, finally, biopsy if desired.

525 Park Avenue.

ABSTRACT OF DISCUSSION

DR. SOMA WEISS, Boston: In the understanding of a number of fundamental clinical problems, knowledge of the state of the capillaries and of the dynamics of the capillary circulation is essential. It is between the capillaries and the tissue cells proper that the most vital functions of the body take place. These functions have remained obscure because of the lack of available methods for their study. Recently, methods have been devised which make possible the estimation of the capillary pressure of the skin, the visualization of the capillary blood flow of the skin and of other bodily surfaces, the estimation of the capillary resistance and, to a certain extent, the capillary permeability. Complicated and inexact some of these methods may be; nevertheless they serve to enter an opening wedge in the clarification of such fundamental problems as peripheral and pulmonary edema, purpuric and other skin lesions, and conditions discussed by Dr. Wright. Physicians still cherish

a reserved respect for the physiologic approach to clinical symptoms and problems. They consider physiologic methods complicated and difficult, and often of only academic interest. It is therefore particularly fortunate that Dr. Wright has brought these problems before this gathering. It serves to impress on us that in one problem the naked eye, in another the microscope, in one morphology, and in another physiology brings understanding.

DR. NELSON W. BARKER, Rochester, Minn.: The question of morphology of the capillaries alone has not been sufficiently emphasized. At present there are no satisfactory observations on capillaries which will give definite data concerning what may be departures from the normal. Part of this has been due to the fact that it was extremely difficult adequately to record these morphologic changes. With the advent of the newer photographic methods, as has been shown by Dr. Wright, these records will now be made available. Capillaries have been studied by Brown and Roth for the last eight years, and their observations agree to a great extent with many of the observations made by Dr. Wright, so far as peripheral vascular diseases are concerned. I should like to ask Dr. Wright whether he has observed any specific changes in the morphology of the capillaries in thrombo-angiitis obliterans and, if so, just what these changes are.

DR. IRVING S. WRIGHT, New York: I realize that this work is in a very early stage and that my conclusions may be subject to change in general conception. It is not necessary to have elaborate apparatus to observe the capillaries. In the last twenty-four hours I have put up a simple microscope with a simple lighting arrangement which would enable any physician to observe capillaries in his office. The actual procedure is not difficult. However, one must look at a great many patients before one can draw conclusions, first in normal individuals and then in various disease conditions. One should not feel that this procedure does not offer great possibilities just because he is unable to recognize variations immediately. It takes practice. I would stress the similarity in usefulness between capillary microscopy and the ophthalmoscopic examination of the fundus. In itself it is not a complete diagnostic procedure. It merely helps one to obtain a better conception of the disease processes and their variations. The subject of thrombo-angiitis obliterans presents one of the more difficult problems because, in the first place, the best part of the body surface in which to observe capillaries is the nail fold. Often in cases of thrombo-angiitis obliterans, in the instances in which early gangrene or marked changes have taken place, the nail fold has been involved and the vessels are hard to see. In thrombo-angiitis obliterans, various degrees of spastic and organic factors are present, in some cases the changes that Miss Roth has shown in the exhibit, not unlike those of Raynaud's disease but to a lesser degree. One may safely assume that in the advanced cases the capillary flow has been markedly affected and that the actual structure of the capillaries is difficult to observe. Finally, I would say that my object in the exhibit and in my paper has been to make the medical profession capillary conscious.

Pernicious and Macrocytic Anemias.—It is now possible to explain why certain cases of macrocytic anemia will respond to both liver extract and autolyzed yeast and others only to liver extract. The difference appears to depend on the presence or absence of the intrinsic factor. In the light of this evidence it is clear that the common factor for producing macrocytic anemia is the failure of the specific reaction between the extrinsic and the intrinsic factors. These anemias should, then, occur both where, on the one hand, the diet is deficient in vitamin B₁₂, and on the other hand, where, although the diet is not grossly deficient, lack of the intrinsic factor is found. Thus, sprue and the macrocytic anemias of the tropics occur in communities or in individuals partaking of defective diets and show gastric anacidity less commonly than is found in patients with Addisonian pernicious anemia, who usually have more normal diet habits. In many cases a combination of gastric defect and dietary deficiency may exist, which would have the same result upon the specific hematopoietic reaction as a total absence of either of its components.—Castle, W. B.: The Etiology of Pernicious Anemia and Related Macrocytic Anemias, *Ann. Int. Med.* 7:2 (July) 1933.

CARCINOMA OF THE JEJUNUM

REPORT OF A CASE

S. E. BARNHART, M.D.

BATTLE CREEK, MICH.

Carcinoma of the jejunum is encountered so seldom that I feel justified in reporting a case recently seen in the Battle Creek Sanitarium clinic.

As the anatomy and physiology of the intestinal tract is well known, I will merely mention that the theory of carcinoma appearing more frequently in the stomach and lower bowel is based on the fact that they deal with the more solid material, while the jejunal section has to do more with the liquid state and hence is less liable to irritation.

In reviewing the literature, I find that carcinoma of the jejunum is comparatively rare. A report from the Vienna General Hospital by Johnson¹ shows that in a series of 41,883 autopsies not a single carcinoma of the jejunum was found, although in the series there were 343 cases of carcinoma in other parts of the intestinal tract. In 1904, Nothnagel² found 9 cases in 3,585 deaths from cancer. In 1927, a study of the literature was made by Hellström³ from which he collected only seventy cases of carcinoma proved by operation, including both jejunum and ileum, himself reporting three. Since 1927, Morrison,⁴ Roblee,⁵ d'Allaines⁶ and Harris⁷ have each reported one case, making in all, up to the beginning of 1931, seventy-seven cases. Since then, some additional cases have been reported.

From the cases reported, it would appear that carcinoma is liable to occur earlier in life in the jejunum than elsewhere in the intestinal tract, in men twice as often as in women, generally growing in a circular

The symptoms, which depend largely on the amount of stenosis found in the majority of cases, are diarrhea, constipation, gastric distress and vomiting. There may or may not be visible peristalsis; in this case none was observed. The nonstenotic type is more rare and the symptoms not so well marked.

With a colicky pain in the middle of the upper part of the abdomen, associated with vomiting, especially if the vomitus contains duodenal content with bile, carcinoma of the jejunum should be considered possible.

Fig. 2.—Adenocarcinoma with proliferation of epithelium.

Careful fractional gastric analysis should be made and stools studied for the presence of blood. The stomach may or may not show delay in emptying time. Our case showed a marked gastric delay with ordinary food, but the stomach emptied readily when the barium meal study was made. Gastric acidity may be subnormal, owing to the regurgitation of duodenal content.

Only one line of treatment presents itself in these cases, and that is surgical, either radical or palliative. According to Hellström, the mortality was 36 per cent in seventy cases. The radical operation, according to Harris, offers a 16 per cent chance of cure. The growth usually develops slowly.

Since the prognosis is poor, an early diagnosis is desirable.

REPORT OF CASE

J. D., a man, aged 58, American, a merchant, married, entered the Battle Creek Sanitarium clinic, May 18, 1927, with a history of chronic obstinate constipation, dating back ten years, and gastric digestive disturbance for the past two or three years, manifested by a burning sensation in the region of the stomach, occurring both forenoon and afternoon and occasionally at night, and always relieved by sodium bicarbonate and food. The symptoms did not occur every day, were more pronounced when the patient smoked excessively, were not seasonal, and did not come in attacks. The patient had never vomited; some regurgitation had occurred, but the regurgitated matter was not mixed with blood. He never noticed any black tarry stools. The family history was negative as to constitutional diseases.

The patient had had typhoid, and he had a syphilitic infection at the age of 25. Three years later he was given anti-syphilitic treatment. There was nothing else of importance in the previous history.

Repeated blood counts and chemical examinations of the blood, including a Wassermann test, examination of the urine and stool, and a fractional gastric test were made, all being practically negative except that there was a very weak Kolmer and a four plus Kahn reaction.

From May, 1927, to March, 1931, he passed through the clinic yearly with no evidence of serious trouble, but on May 15, 1932, he complained of exhaustion, obstinate constipation

Fig. 1.—Adenocarcinoma with involvement of glandular tubules.

manner and constricting in character, involving but a small cross section of the intestine. These neoplasms are usually adenomatous and metastasize late.

and daily vomiting for the previous three or four weeks. He had lost 10 pounds (4.5 Kg.) during this time.

On physical examination, no tenderness was elicited over the abdomen and no tumor mass was palpable. A neurologic examination was negative. A tentative diagnosis of pyloric obstruction was made.

The fractional gastric test was made with difficulty, owing to the clogging of the tube with spinach eaten twenty hours before, but it showed a slightly subnormal free hydrochloric acid at first with a slight increase during the later periods. With the barium roentgen study, the result was different, the emptying time being slightly more than three and a half hours. In addition to some dilatation of the duodenum, there was a marked dilatation and a greatly delayed motility in a loop of the jejunum. The barium still in the loop at eight and a half hours had disappeared at the twenty-four hour observation.

A recheck of the stomach and small intestine was made under tincture of belladonna, and a third under atropine hypodermically. At the last examination the jejunal loop appeared more dilated than before. The result of the studies indicated quite conclusively that we were dealing not with a spasm but probably with a neoplasm of the jejunum. It was quite evident that surgical assistance was imperative, so a laparotomy was advised and performed.

When the abdomen was opened, all of the ileum was contracted. The upper 18 inches of the jejunum was greatly dilated, about the size of the forearm. The dilated intestine was followed down, and approximately 2 feet from the duodenal-jejunal junction a stenosing neoplasm, which grossly resembled a carcinoma, was encountered. The jejunum was greatly dilated above this band and markedly contracted below. On palpation, no lumen could be made out. There was a group of eight or ten enlarged glands in the mesentery beneath the neoplasm. Three feet of the small intestine was resected, and a cross section of the growth revealed the presence of an adenocarcinoma with metastasis to the mesentery lymph glands.

The patient made a good and uneventful recovery. In February, 1933, he returned to the clinic in fine physical condition, having gained 30 pounds (13.6 Kg.).

ATOPY TO ACACIA (GUM ARABIC)

AARON D. SPIELMAN, M.D.

AND

HORACE S. BALDWIN, M.D.

NEW YORK

The widespread use of acacia (gum arabic) in medicine and commerce makes it of interest from the standpoint of allergy. In the present paper is reported a case of atopy to acacia which we believe is the first one to be so proved. At the same time, a general review is made of the subject of acacia from the point of view of its chemical and therapeutic interest, and its importance allergically is stressed.

T. P. C., a white man, aged 53, a plaster molder in a large candy factory, admitted to the New York Hospital Allergy Clinic, Oct. 20, 1932, complained of bronchial asthma. His asthma started in July, 1931, six months after he started to work in the factory. Since that time it has been perennial, with increased severity in June and September. There has been no definite history of hay fever. The patient noticed, however, that on coming in contact with the dust of the factory he was likely to sneeze and have a burning sensation in his eyes. It is of incidental interest that eleven months after the onset of asthma he was seized with a typical attack of coronary thrombosis which necessitated his remaining away from work for seven weeks; i. e., from June 10 to about Sept. 1, 1932. During this period he was relatively free from asthma, but on resuming work it returned.

Physical examination, on admission to the clinic, showed the typical râles of asthma and, at the base of the lungs, smaller râles more typical of cardiac decompensation. The liver was not enlarged. There was no dependent edema. The heart sounds were distant. No enlargement was made out. The blood pressure was 140 systolic, 80 diastolic. A special nose and throat examination was essentially negative. An electrocardiogram showed evidence of a previous attack of coronary occlusion. The sedimentation test was within normal limits. The blood showed 8 per cent eosinophils. A Wassermann test was negative.

Skin tests were done with the usual inhalants, and food tests were made by the intradermal method. Mild reactions were obtained to timothy grass and ragweed pollen. The patient was next directed to bring in dust collected from his factory environment, and a scratch test to this sample gave a marked reaction. The dust consisted principally of acacia, cocoa bean, corn-starch, dextrose and plaster. When the separate components were tested, the crude acacia was found to give a markedly positive reaction. Purified acacia was next used for testing and was found to be even more reactive than the crude acacia used at the factory, giving markedly positive reactions, both by scratch and intradermally in as low as 1:5,000 dilution. Blood was taken for passive transfer, and again very definitely positive reactions were obtained. Control sites were negative.

The patient was advised to arrange his work bench so that it would be enclosed, with a view to limiting his contact with the factory dust. A series of desensitizing injections was also proposed. By carrying out the first suggestion, his asthmatic state was considerably alleviated, but the series of hyposensitizing inoculations has not been possible in view of the patient's inability to attend the clinic regularly.

In order to see if other routine allergic patients reacted to acacia, thirty cases were tested to this substance by the scratch and intradermal methods. No positive reactions were obtained.

Atopy to acacia is of interest because of its widespread use in commerce and medicine. Botanists define acacia as an exudate of the tree *Acacia Senegal*. This tree is a member of the large botanical family called Mimosoidae, related members of which are widely distributed as herbs, shrubs, vines or trees. There is evidence interpreted by Beijerinck¹ as pointing to the elaboration of acacia as a result of the activities of molds, and by Greig Smith² as showing that it is a product of the metabolism of certain bacteria. As neither of these workers has proved, however, that contamination of acacia with the appropriate organism does not take place after its formation, the hypothesis that acacia originates through the activities of microorganisms, though attractive from the standpoint of bacterial specificity, must be considered as unproved.

Acacia as it is collected has a mucilaginous appearance. This and similar exudates from other trees comprise the so-called gums of commerce.

Chemically, acacia is classed as an inert colloid and is a member of the polysaccharide subdivision of the carbohydrates. Related polysaccharides are the dextrans, glycogen, cellulose and starch. All these substances are amorphous, odorless and translucent and yield on hydrolysis one or more sugars, generally pentoses and hexoses.

Commercially, acacia is used frequently in the preparation of pharmaceuticals as an emulsifying agent. Its demulcent properties are utilized in the manufacture of large quantities of lozenges, troches and gummy candies.

As a medical therapeutic agent, acacia has been increasingly used in cases of shock, especially in those

From the New York Hospital and the Department of Medicine of Cornell University Medical College.

Read before the Meeting of the Society of Asthma and Allied Conditions, Washington, D. C., May 6, 1933.

1. Beijerinck, M. W.: Arch. néerl. d. sc. exactes 19:43, 1884.
2. Greig Smith, R.: J. Soc. Chem. Indust., London 23:105 and 972, 1904.

caused by loss of blood. In a number of clinics, infusion of acacia has replaced transfusions of blood; at the Mayo Clinic, 3,000 such infusions have been given in the last few years. Recently, infusions of acacia have been reported by Hartmann and his colleagues³ as of benefit in reducing nephritic edema.

Workers at the Mayo Clinic have lately become interested in the possibility of sensitivity to acacia because of its general use there. Maytum and Magath,⁴ in their analysis of patients who had received infusions of acacia, have found only one case that gave an untoward reaction. Skin tests to acacia on this patient were negative. In this case, during a second infusion of acacia, after an interval of seven months, the patient developed nasal obstruction, lacrimation and laryngeal stridor, all of which were at once relieved by the administration of epinephrine. This was the only reaction that occurred in the 3,000 cases mentioned. It should be noted that in most of these cases only one infusion needed to be given. These same workers have attempted to sensitize animals to acacia. In the case of rabbits they were unsuccessful, but of nineteen guinea-pigs sensitized to acacia, seven showed no results; in four, anaphylaxis was mild; in three, it was fairly severe; in two, it was very severe, and three of the guinea-pigs died. From this experiment it was concluded that acacia has mild antigenic properties.

At our request, Dr. Lillian K. P. Farrar, of the Women's Hospital, where infusions of acacia have been frequently used, kindly made skin tests on twelve patients, at intervals of from ten to twenty-five days following infusion. No positive reactions were obtained.

The fact that acacia is listed as a carbohydrate prompted us to have acacia powder analyzed for its nitrogen content by Mr. Vincent Toscani, chemist of the Russell Sage Laboratory at Cornell University Medical College. In this analysis, 0.5 per cent of total nitrogen was obtained. A positive biuret test indicated the presence of protein nitrogen. A sample of the "soluble specific substance" derived from acacia by Heidelberger, Avery and Goebel,⁵ which is interesting because of its precipitating activity for types II and III antipneumococcus serum, was obtained through the kindness of Dr. Heidelberger. This failed to give a positive skin reaction either in the patient herein described or by passive transfer. Whether this finding has any bearing on the problem of whether the specific excitant in acacia is of carbohydrate or of protein nature is doubtful, as evidence is given by Heidelberger and his associates that "the specifically reacting substance for the pneumococcus type II and III immune serum is formed from the original gum arabic, probably by removal of a pentose grouping in glucosidic union, since the specific fraction contains less than one half of the pentose of the gum arabic itself."

SUMMARY

1. In a case of bronchial asthma due to sensitivity to acacia, the sensitivity was confirmed by clinical history, direct skin testing and passive transfer.

2. Efforts to find positive reactions to skin tests on patients following infusions of acacia have been unsuc-

cessful. Nevertheless, since the possibility of sensitivity to acacia exists, it is deemed advisable that patients should receive skin tests, previous to the administration of acacia parenterally, in order that a detrimental reaction may be avoided in case the skin test should indicate sensitivity.

Clinical Notes, Suggestions and New Instruments

MODIFICATION OF HANK'S CERVICAL DILATOR

RAYMOND L. BRADLEY, M.D., HOUSTON, TEXAS
Consultant in Obstetrics, Jefferson Davis Hospital

Probably few physicians who practice gynecology do not have a set of Hank's dilators in their instrument case. These dilators are very handy to use as a preliminary dilator before using a double bladed instrument and they give sufficient dilatation in many cases. Cervical tears can hardly result from the use of this dilator. There has always been one serious objection to the Hank dilator, however, this being the back pressure induced by the pumping action when the instrument is inserted into the canal, the dilator acting as a piston (shown at A in the illustration).

Several years ago, I was especially impressed with this objection when Sampson brought out the possibility of endometrial tissue being spilled from the ends of the tubes into the pelvis. Whether or not one is inclined to accept Sampson's theory as regards endometrial tissues and transplants, it remains a fact that infectious material may easily be forced out the end of an infected tube. Considerable force is established when a solid sound is forced into the cervical canal, which can very easily be overcome by using a modified Hank

A, diagrammatic cross-section of solid Hegar sound being inserted into cervix, showing piston action of sound; B, cross section of modified dilator, showing continuous canal through which pressure is released as generated.

dilator, the old set being satisfactory for alteration provided they are of the hollow type. If they are of the solid type, they cannot be drilled in a satisfactory manner.

In order to overcome the piston action, it is necessary that a continuous canal extend from end to end of the dilator as shown at B, thus releasing the pressure as it is generated. If the instrument is hollow, it is only necessary to have holes drilled in the ends and the edges smoothed. The set I have was made through a dealer in New Orleans, before the sets were made hollow.

While this alteration was made for use as a dilator, I have found the smaller sizes to be of use in office work as a urethral dilator and catheter, and as an electrode in diathermy to the cervix. The drainage feature here is an advantage over the solid electrode.

Should the instrument manufacturers feel that this alteration is justifiable, I am sure that it will be accepted by the medical profession as a safeguard against the only objection to an otherwise most useful instrument.

twenty times its volume of water containing about 0.1 per cent of hydrochloric acid. The claim for absence or prevention of "leakage" has not been accepted by the Council for any similar emulsion, though it has been frequently made.

Later the firm submitted revised circulars in which the objectionable statement regarding constipation has been deleted, but the word "constipation" was not deleted from the revised trade package circular. The product is still marketed under the name Kondremul. The firm also submitted a report of trials made under the direction of a physician to show that the product in comparison with others causes or is accompanied by no measurable "leakage." The Council's referee reported that this work does not afford evidence of the superiority of Kondremul over other emulsions of liquid petrolatum. The firm's report states that in each instance the daily dose given was 15 cc., but the directions for the use of Kondremul call for twice that amount, one tablespoonful in the morning and one on retiring. It is misleading to compare one tablespoonful of liquid petrolatum with that dose of the emulsion which contains only about half the volume of liquid petrolatum. The report shows variation in the diameter of droplets in Kondremul of from 6 to 40 microns; in another commercial product of from 6 to 80 microns. No essential difference is apparent. The fact that Kondremul emulsion separates on standing causes the referee to suspect that a fresher specimen of Kondremul than of the compared preparation was used. This would be of no importance even though there was always an average difference of 11 microns in the diameter of the oil droplets. In the report the "leakage" appears to have been measured as the amount of oil that separated from the stool. That is not the commonly accepted meaning of the term; it refers to the escape of oil in amounts that soil the clothing or render the parts about the anus oily.

The Council voted to confirm its decision that Kondremul (Plain) and Kondremul with Phenolphthalein are unacceptable for New and Nonofficial Remedies because the amount of potent ingredient is not stated on the labels because the claims for absence of "leakage" is unwarranted, and because the products have not sufficient originality to justify the use of the proprietary and uninforming name Kondremul.

Committee on Foods

GENERAL COMMITTEE DECISIONS

THE COMMITTEE ON FOODS AUTHORIZES THE PUBLICATION OF THE FOLLOWING GENERAL COMMITTEE DECISIONS ADOPTED FOR ITS OWN GUIDANCE AND FOR THAT OF FOOD MANUFACTURERS AND ADVERTISING AGENCIES ON FOOD COMPOSITION AND FOOD ADVERTISING.

RAYMOND HERTWIG, Secretary.

FORTIFICATION OF FOODS OTHER THAN TABLE SALT WITH IODINE OR IODINE COMPOUNDS

The fortification of foods other than table salt with iodine or iodine compounds for dispensing additional food iodine to the public and supplementing that naturally present in foods is unnecessary and may lead to excessive iodine intake and endanger public health. Foods so fortified, other than table salt, will not be eligible for acceptance.

"HEALTH FOOD" CLAIMS AND THE TERM "HEALTHFUL"

The term "health food" and equivalent claims or statements to the effect that a food gives or assures "health" are vague, misinformative and misleading. An adequate or complete diet and the recognized nutritional essentials established by the science of nutrition are necessary for "health," but "health" depends on many other factors than those provided by such diet or nutritional essentials. No one food is essential for "health"; there are no "health foods." Statements of well established nutritional or physiologic values of foods are permissible.

The term "healthful" is frequently encountered in food advertising. As used, it commonly means that the food described

corrects a possible nutritive deficiency or some abnormal condition in such a manner as actively to improve health. It incorrectly implies that the food possesses unique (or unusual) health-giving properties. The term has a popular specific "health food" significance which makes its use in advertising misinformative and misleading.

"Healthful" and "wholesome" by dictionary definition have almost identical meanings; the former, however, intimates an active significance, whereas the latter signifies quality or condition. "Wholesome" indicates that a food so described is sound, clean, fit for consumption and free of any objectionable qualities; it is appropriate for characterizing foods fulfilling these qualifications and should replace "healthful" as used in food advertising.

REPORTS OF THE COMMITTEE

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION, AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

RAYMOND HERTWIG, Secretary.

JELKE GOOD LUCK MAYONNAISE

Manufacturer.—John F. Jelke Company, Chicago.

Description.—Mayonnaise containing cottonseed (or corn) oil, eggs, water, sucrose, distilled vinegar, salt and mustard.

Manufacture.—The frozen eggs are beaten; the water and then the cane sugar, salt, mustard, vinegar and salad oil are beaten in consecutively to produce an emulsion which is homogenized and automatically filled into glass jars.

Analysis (submitted by manufacturer).—

| | per cent |
|---|----------|
| Moisture | 23.4 |
| Ash (salt free) | 0.3 |
| Sodium chloride (NaCl) | 1.8 |
| Fat (ether extract) | 65.4 |
| Protein (N \times 6.25) | 2.9 |
| Reducing sugars as invert | 0.0 |
| Sucrose | 5.0 |
| Lipoid phosphoric acid (P ₂ O ₅) | 0.107 |
| Total phosphoric acid (P ₂ O ₅) | 0.111 |
| Carbohydrates (by difference) | 5.6 |
| Titrate acidity as acetic acid | 0.4 |

Calories.—6.2 per gram; 176 per ounce.

Claims of Manufacturer.—Conforms with the respective United States Department of Agriculture definition and standard.

SPINTRATE

Manufacturer.—Spinach Products Company of South Carolina, Columbia, S. C.

Description.—A dried powdered spinach; an abundant source of vitamins A, B and G, iron and iodine.

Manufacture.—Fresh, selected, hand picked spinach is trimmed of the butts and bruised or discolored leaves, washed in water, rinsed and centrifugated to remove adhering surface water. It is dried in a specially constructed apparatus in a recirculating current of practically inert gas, largely carbon dioxide, the temperature of which does not exceed 66 C. The dried product is pulverized and screened; the powder of desired fineness is mechanically packed in glass jars.

Analysis (submitted by manufacturer).—

| | per cent |
|--|----------|
| Moisture | 7.9 |
| Ash | 13.6 |
| Fat (ether extract) | 4.5 |
| Protein (N \times 6.25) | 31.5 |
| Crude fiber | 8.4 |
| Carbohydrates other than crude fiber (by difference) | 34.1 |
| Average (parts per million) | |
| Iron (Fe) | 530 |
| Calcium (Ca) | 10,700 |
| Phosphorus (P) | 6,400 |
| Copper (Cu) | 10 |
| Manganese (Mn) | 140 |
| parts per billion | |
| Iodine | 700 |

Calories.—3.0 per gram; 85 per ounce.

Vitamins.—Biologic report shows that vitamins C and D are practically absent; the product contains 6,000 units

(Sherman) of vitamin A per ounce (nearly half the A potency of cod liver oil and four times that of butter) and 60 units (Sherman) of vitamin B complex per ounce (approximately that of dried brewers' yeast). The vitamin B content is about twice and the G content about equal to that of dried brewers' yeast.

Claims of Manufacturer.—Especially adapted for use in the diet of infants and the sick in accordance with the physician's directions. It is an excellent source of utilizable iron for counteracting nutritional anemia and an abundant source of food iodine.

HAWAIIAN FINEST QUALITY PINEAPPLE

VACUUM PACKED (CRUSHED, SLICED AND TIDBITS)

- (1) BURKE'S, (2) CAMEL, (3) DEXTER'S, (4) FAIRWAY,
(5) HALE'S LEADER, (6) HALE'S PRIDE, (7) HAPPY
HOUR, (8) HOMESPUN, (9) ROUNDY'S,
(10) S AND F, AND (11) TABLE

QUEEN BRANDS

Packer.—Hawaiian Pineapple Company, Ltd., San Francisco.

Distributors.—1. The Burke Grocery Company, Cincinnati.
2 and 7: Campbell Holton and Company, Bloomington, Ill.
3 and 9: Roundy, Peckham and Dexter Company, Milwaukee.
4: Twin City Wholesale Grocery Company, St. Paul and Minneapolis.

5 and 6: Hale-Halsell Company, McAlester, Okla.

8: Phillips-Lewis Co., Inc., Richmond, Va.

10 and 11: Smart and Final Company, Ltd., Pasadena, San Bernadino, Santa Ana, Wilmington and Los Angeles, Calif.

Description.—Canned pineapple (sliced, crushed and tidbits) packed in concentrated pineapple juice syrup with added sucrose. The same as Doles 1, 2 and 3 Hawaiian canned pineapple products (THE JOURNAL, April 8, 1933, p. 1106, and April 29, 1933, p. 1338).

HOMOGENIZED PASTEURIZED MILK

ADVERTISING OF McDONALD

DAIRY COMPANY

Manufacturer.—McDonald Dairy Company, Flint, Mich.

Description.—Advertising of bottled, pasteurized, homogenized milk.

Preparation.—Milk delivered cold from producers under city department of health inspection is tested for milk fat, acidity and sediment and its reaction to methylene blue; unsatisfactory milk is rejected. Acceptable milk is pasteurized by the holding method (68 C. for thirty minutes), cooled to 52 C., homogenized under 3,000 pounds pressure, cooled to 4 C. and automatically filled in bottles which have been washed in 3 per cent sodium hydroxide solution.

Analysis (submitted by manufacturer).—

| | per cent |
|---------------------------------|----------|
| Moisture | 87.4 |
| Total solids | 12.6 |
| Ash | 0.7 |
| Fat | 3.8 |
| Protein (N \times 6.38) | 3.2 |
| Lactose (by difference) | 4.9 |

The butter fat varies between 3.8 and 4.0 per cent.

Calories.—0.7 per gram; 20 per ounce.

Claims of Manufacturer.—The cream does not separate. The curd formed in the stomach is softer than that from unhomogenized milk.

ROTH'S RYE BREAD

Manufacturer.—The A. Roth Baking Company, Newport, Ky.

Description.—Rye bread prepared by the sponge dough method (method described in THE JOURNAL, March 5, 1932, p. 817) from wheat "clear" flour and medium dark rye flour, water, powdered buttermilk, salt, caraway seed, yeast, lard and malt syrup.

Analysis (submitted by manufacturer).—

| | per cent |
|---|----------|
| Moisture (entire loaf) | 35.6 |
| Ash | 1.0 |
| Fat | 1.9 |
| Protein (N \times 6.25) | 10.4 |
| Crude fiber | 0.9 |
| Carbohydrates other than crude fiber (by difference) .. | 50.2 |

Calories.—2.6 per gram; 74 per ounce.

GLADIOLA PATENT FLOUR-PHOSPHATE

ADDED (MATURED, BLEACHED)

FANT'S FAIRY PATENT FLOUR-PHOSPHATE

ADDED (MATURED, BLEACHED)

Manufacturer.—Fant Milling Company, Sherman, Texas.

Description.—Patent flours milled from a blend of soft and hard wheats containing 0.5 per cent of added calcium acid phosphate; bleached.

Manufacturer.—Selected wheat is cleaned, scoured, tempered and milled by essentially the same procedures as described in THE JOURNAL, June 18, 1932, page 2210. Chosen flour streams are blended and bleached with a mixture of benzoyl peroxide and calcium phosphate (1 part to 50,000 parts of flour) and with nitrogen trichloride (one-ninth ounce per 196 pounds), and admixed with calcium acid phosphate (1 part to 195 parts of flour).

Analysis (submitted by manufacturer).—

| | per cent |
|---|-------------|
| Moisture | 13.0 -14.0 |
| Ash | 0.76 - 0.80 |
| Fat (ether extraction method) | 0.8 - 1.2 |
| Protein (N \times 5.7) | 9.0 -11.0 |
| Crude fiber | 0.3 - 0.5 |
| Carbohydrates other than crude fiber (by difference) .. | 76.1 -72.5 |

Calories.—3.5 per gram; 99 per ounce.

Claims of Manufacturer.—Phosphated patent flours intended especially for biscuit baking.

CLAPP'S ORIGINAL PUREE OF ASPARAGUS

Manufacturer.—Harold H. Clapp, Inc., Rochester, N. Y.

Description.—Strained cooked asparagus. The method of preparation is efficient for retention in high degree of the natural vitamins and minerals.

Manufacturer.—Purchased canned asparagus is strained in an atmosphere of water vapor and subsequently treated as described for Clapp's Original Baby Soup (THE JOURNAL, June 24, 1933, p. 2011).

The canned asparagus is prepared from young, tender asparagus, which is washed, inspected to remove unsuitable material, again washed, cut into small pieces and packed into tins; hot water is added; the cans are passed through an exhaustor to remove absorbed air, sealed, cooked under pressure and immediately cooled.

Analysis (submitted by manufacturer).—

| | per cent |
|---|----------|
| Moisture | 94.1 |
| Total solids | 5.9 |
| Ash | 1.2 |
| Fat (ether extract) | 0.2 |
| Protein (N \times 6.25) | 1.4 |
| Crude fiber | 0.5 |
| Carbohydrates other than crude fiber (by difference) .. | 2.6 |

Calories.—0.2 per gram; 6 per ounce.

Vitamins and Claims of Manufacturer.—See Clapp's Original Baby Soup (THE JOURNAL, June 24, 1933, p. 2011).

HOSTESS MAYONNAISE

Manufacturer.—Hostess Products Corporation, Long Island City, N. Y.

Description.—Mayonnaise in glass jars containing refined cottonseed oil, fresh egg yolk, water, cider vinegar, salt, sucrose, mustard and white pepper.

Manufacturer.—Egg yolk, salt, sugar and spices in definite proportions are beaten at high speed in a mixing machine; the oil is beaten in and then the water and vinegar. The emulsion of mayonnaise is automatically filled into glass jars. Only enough mayonnaise is manufactured from day to day to care for immediate orders.

Analysis (submitted by manufacturer).—

| | per cent |
|---|----------|
| Moisture | 10.9 |
| Ash | 1.2 |
| Sodium chloride (NaCl) | 1.1 |
| Fat (ether extract) | 84.5 |
| Protein (N \times 6.25) | 0.9 |
| Carbohydrates (by difference) | 2.2 |
| Titratable acidity as acetic acid | 0.3 |
| Lecithin-phosphoric acid (P ₂ O ₅) | 0.058 |
| Unsaponifiable matter | 0.3 |
| Estimated egg yolk solids | 3.7 |

Calories.—7.7 per gram; 219 per ounce.

Claims of Manufacturer.—Conforms to the U. S. Department of Agriculture definition and standard for mayonnaise.

SATURDAY, AUGUST 5, 1933

ETIOLOGY OF HEAT CRAMPS

Talbot and Michelson¹ have recently reported studies bearing on the etiology of heat cramps. The subjects were men employed in the construction of the Hoover dam in Nevada, who, in the course of their work, were exposed to the extreme summer heat of the Colorado River basin desert. The symptoms varied from vomiting and dizziness to mild and severe cramps in the muscles of the legs, arms and abdomen and were associated in all cases with profuse sweating. Similar observations have been made by others on miners, iron workers and stokers laboring under much the same working conditions.

In the present instance, the subjects were seen soon after entering the hospital and a sample of venous blood was obtained before any treatment had been instituted. Both chemical analysis and morphologic examination of the blood were carried out and certain analyses of the urine also were made. The most striking change in the composition of the blood during heat cramp is a diminution in both the total base and the acid ions; the change is more pronounced in the latter and is accounted for largely by the drop in content of chloride. There is also a concomitant loss of water from the circulation. Treatment consisted of physiologic solution of sodium chloride either subcutaneously or intravenously and milk in quantity as the only food. After the salt and liquid had been given, both the total base and the acid ions approached the normal level of concentration in the blood; at the same time the urinalysis showed a retention of sodium chloride and of water for several days. These observations indicate that the profuse sweating incident to vigorous exertion in extreme heat results in a loss of water and sodium chloride through the skin severe enough to be reflected in the acid-base and water balance of the body.

The pathogenesis of heat cramps thus appears to be defined rather succinctly by these recent chemical studies. The loss of salt and water and the replacement

of fluid alone through intake of water diminish the osmotic pressure of the interstitial fluid. The tissues tend to lose chloride in an attempt at adjustment to the hypotonic surrounding medium, and at some level characteristic of the individual there occur the neuromuscular disturbances typical of heat cramps. Other suggestions have been made to explain the origin of this syndrome. Thus it was at various times said to result from acute muscular degeneration, from water poisoning and from temporary cessation of kidney function. However, it appears that the evidence based on studies of the water and salt balance before treatment and the resulting chemical changes provide a more tenable theory for the etiology of heat cramps. Supporting evidence is afforded in the records of prevention of this disturbance through the free use of milk and of saline drinks of various kinds. No doubt practical preventive therapy will be developed for the occupations concerned when the data on the critical level of base and chloride in the blood, the approximate extent of sweating and the salt in the food are equated on the basis of clinical statistical experience.

RECENT STUDIES OF VITAMIN C

It was to be expected that biochemists would devote themselves assiduously to the intriguing problems of the isolation and identification of the vitamins. Recent years have witnessed considerable progress in this field of research. The purification of vitamin D, for example, has proceeded to a point at which well crystallized active antirachitic substances of surprising potency have been secured. Both German and English investigators have reported the production of purified products of which 1 mg. is equivalent to 40,000 international (rat) units. From yeast, workers¹ in the department of biochemistry at Oxford have separated "crystals" that act antineuritically in the conventional pigeon test in daily doses of less than 2 gammas; that is, 0.000002 Gm. This is greater than the activity of other crystalline preparations previously described. The identification of the potent principle in these instances remains to be established.

Even more satisfactory has been the progress in the investigation of vitamin C, the antiscorbutic principle. The false hopes raised by the alleged association of this vitamin with the alkaloid narcotine have been shattered. On the other hand the evidence now seems clear that vitamin C is a hexuronic acid, more recently designated as ascorbic acid.² The distribution of vitamin C in fruits and vegetables is now generally recognized. One of the citrus fruits is commonly used to supply, through its juices, a standard solution for the estimation of antiscorbutic potency. In a quest for suitable source material for the preparation of ascorbic acid, Svirbely

1. Talbot, J. H., and Michelson, J.: *J. Clin. Investigation* 12: 533 (June) 1933.

1. Kinnersley, H. W.; O'Brien, J. R., and Peters, R. A.: *Crystalline Preparations of Vitamin B from Baker's Yeast*, *Biochem. J.* 27: 232, 1933.

2. Szent-Györgyi and Haworth: *Nature* 131: 24, 1933.

and Szent-Györgyi³ of the University of Szeged in Hungary have discovered the strong antiscorbutic properties of paprika, the Hungarian red pepper (*Capsicum annuum*). Out of its juices large quantities of ascorbic acid have been prepared and purified in a variety of chemical ways, with a yield of more than 0.5 Gm. from each liter of paprika juice. In animal experiments, 0.5 mg. of the crystalline product protected guinea-pigs—the conventional test animals—from scurvy. This affords another illustration of the remarkable physiologic potency of vitamins.

It has been known for some time that the suprarenal cortex normally contains considerable amounts of the hexuronic acid now identified as vitamin C. Recent studies⁴ have demonstrated that the content of ascorbic acid in the glands is greatly decreased under conditions that give rise to scurvy. For example, in animals fed liberal amounts of spinach, nearly a milligram of ascorbic acid per gram of the suprarenal was estimated to be present. With lowered intake of antiscorbutic foods, the content of vitamin C in the glands decreased. On a vitamin C-free diet it gradually dropped as low as 0.03 mg. per gram. The same striking phenomenon of parallelism was observed with varying intakes of ascorbic acid. These investigations suggest that there is a wide limit between health and scurvy and that animals fed on restricted amounts of the vitamin, though showing no sign of scurvy, are greatly depleted of their vitamin store. Herein probably lies the chemical explanation of so-called latent scurvy in man. It is an interesting fact that in species such as the dog and the rat, which are not susceptible to scurvy, the suprarenals are not readily depleted of vitamin C.¹

GLOMERULAR FUNCTION

The various theories proposed to account for the production of urine by the kidney involve combinations of the following factors: glomerular filtration, glomerular secretion, absorption in the tubules and secretion by the tubular epithelium. Efforts to obtain experimental evidence in support of one or the other of the theories have been limited by the extremely small size of the unit of structure involved, the glomerulus and the associated tubule. It is obvious that a simultaneous comparison of the chemical composition of the blood in the renal vessels and of bladder urine will yield little cogent information concerning glomerular function and hence the process whereby the urine is actually formed. Of particular interest, therefore, are the recent reports of Richards and his co-workers¹ in which the earlier

studies of the collection and chemical analysis of glomerular urine have been confirmed and extended. This further series of investigations seemed necessary, because the principle of glomerular filtration indicated by the earlier experiments was not unanimously supported by the studies of others.

The minute quantity of fluid that it is possible to obtain by direct puncture of the glomerulus with a capillary cannula² required the development of special adaptations of standard analytic methods. The procedures thus employed were colorimetric; the reactions are carried out in fine capillary tubes of 0.35 mm. bore. It is thus possible to make certain analyses on volumes of glomerular fluid and protein-free filtrate from blood ranging from 0.03 to 0.5 cubic millimeter containing dissolved substances in quantity from a millionth to a few hundred thousandths milligram with degrees of accuracy of the order of magnitude ordinarily attained with samples of the usual size.

Simultaneous analyses of blood and of glomerular fluid for uric acid indicate that this substance passes through the glomerulus of frogs and snakes by simple filtration. This is especially significant in the reptile, as concentration of uric acid by the glomeruli would facilitate the excretion of waste nitrogen in this species. Reducing substances were present in the same concentration in the plasma of frogs as in glomerular fluid, even after administration of phlorhizin. Likewise a determination of inorganic phosphate in the plasma and glomerular urine of frogs and salamanders showed no difference in concentration in the two fluids. After the injection of a solution of pure creatinine into frogs, the plasma and the glomerular urine contained the same amounts of this metabolite. These recent data, affirming the earlier observations on urea and chlorides, constitute impressive evidence that the elaboration of the characteristic fluid in the glomeruli from the blood consists of simple filtration or of a biologic process yielding essentially the same results as does filtration.

That not all of the vital membranes behave as does the glomerular epithelium is evident from further studies by Walker.³ He observed that in the cerebrospinal fluid of frogs and of depancreatized dogs there were 30 per cent less reducing substances and 60 per cent less inorganic phosphate than occurred in plasma. In the frog, man, fowl, dog and cat the aqueous humor likewise contains less reducing substance, urea, uric acid and phosphate than does the plasma. Lymph, on the other hand, contains inorganic phosphate and reducing substance in the same concentration as does the plasma. These observations have a significant bearing on physiologic theory and clinical practice and present another triumph of chemical methodology.

Current Comment

SPONTANEOUS RUPTURE OF THE AORTA

A not infrequent cause of sudden and often instantaneous death is rupture of the aorta, a form of death too sudden to present appreciable symptoms or with symptoms so vague and of such short duration that death is explained only by postmortem examination. The exact frequency of rupture of the aorta, independent of aneurysmal sacs, is not known. While by no means frequent, it is probably more frequent than is commonly supposed. Whether under certain circumstances the normal aorta ruptures through inability to withstand the ordinary pressure within it has been the cause of much controversy. Some maintain that the undamaged aortic wall may at times be placed under such stress as to give way in sudden and fatal hemorrhage; others are equally convinced that no spontaneous rupture is possible without antecedent damage or degeneration of vascular tissue. The consensus seems to be that the rupture in most cases, though primarily due to some pathologic condition of the aorta, is immediately caused in nearly all cases, except those due to traumatic accident, by something that increases the arterial pressure. The most frequent causes are strains, sudden muscular effort, as during confinement, hypertrophy of the heart, passions, and similar incidents. Rupture occurs in the greatest percentage of cases near the heart somewhere below the arch and is intrapericardial in most instances. It is next most frequent in the curved portion of the vessel and is least frequently found in the abdominal aorta. In character the lesion falls into three groups. In the first there is complete rupture of all the coats at once, the tear in the outer coat corresponding to that in the inner coat. The interior may be smooth, and the lesion is usually rather sharp, as if cut with a knife. In the second group the inner coat ruptures sometimes before the outer, which usually gives way at one end or the other of the inner tear or at a little distance from it, there being no infiltration between the coats. The tear in the outer coat is usually at right angles to that in the inner coat. In the third group the rupture occurs as in the second but there is infiltration of blood, sometimes extensive, between the coats. In this group fall all cases of dissecting aneurysm of the aorta. To the first group belong about 65 per cent of all cases, to the second about 20 per cent and to the third about 15 per cent. The symptoms are indefinite. In the first group death is usually instantaneous and without recognizable symptoms. Pain is the most constant symptom and usually is severe, tearing and intrathoracic, radiating to the shoulder, back, neck or abdomen. Of other symptoms, dyspnea, collapse, feeble irregular pulse, vomiting, coughing and hemoptysis are occasionally noted. Death does not always take place with the initial tear, as the rupture may penetrate only the inner coat of the arterial wall and not lead to complete rupture. Then within a short time, frequently three or four days, external rupture occurs with sudden death. In some cases the interval may be longer, one of the longest

recorded intervals being thirty-nine days. Rarely, recovery may take place with the formation of a healed dissecting aneurysm. Death in the majority of such cases is due to hemorrhage into the pericardium or into the pleura or abdomen, especially when the dissecting aneurysm is extensive. There is no doubt that among the cases of sudden death attributed to heart failure a considerable number are due to spontaneous rupture of the aorta.

THE STRUCTURAL CHANGES IN HUMAN PSITTACOSIS

Knowledge of human disease is based to a large degree on the results of the study by many observers of cases as they occur here and there from time to time. This may be a slow and gradual process. It is now more than fifty years since three necropsies by Eberth on patients who had died from parrot fever, or psittacosis, were published. These three necropsies mark the beginning of the study of the structural changes in this disease. Since then reports of forty-four additional necropsies have been published. On the basis of these widely-scattered reports and of the study of five new cases from the 1929-1930 pandemic, Lillie¹ writes an instructive unified account of the pathologic anatomy and histology of parrot fever in man. The characteristic feature is an inflammatory process in the lungs, which is primarily focal or lobular in extent and apparently not closely related to the bronchioles. Even when the lesion is grossly more or less lobar, its primarily lobular nature is evident microscopically. There is nothing really distinctive in the distribution of the lesion in the lungs, which has been noted most frequently in the left lung and least frequently in the lower and middle lobes of the right lung. Usually each case presents various stages in the process. Early the exudate contains fibrin, red cells, leukocytes and alveolar cells; then the fibrin disappears, the red cells become fewer, and the leukocytes are replaced by mononuclear phagocytes and alveolar cells, which undergo degeneration and may appear to become invaded by rickettsia. In the tissue of the septums may be serous exudate and later infiltration with lymphocytes and large mononuclear cells. The bronchioles may remain clear or they may contain the same kind of exudate as the alveoli near by. There may be inflammatory changes in the pleura. In the lymph glands and the spleen, which usually is large and soft, the macrophages are increased. In the liver the Kupffer cells show increase in phagocytic activity; there may be small foci of necrosis, and in one case Lillie noted granulomatous formations like those seen in psittacotic parrots. Punctate hemorrhages may occur in the brain, serous membranes and elsewhere. In the five new cases reported by Lillie, rickettsia—minute, coccobacillary bodies (*Rickettsia psittaci*)—were demonstrated in large round cells in the exudate in the lungs. In parrots with psittacosis these bodies are found in epithelial cells (intestine, ureter, renal tubules, bile ducts), macro-

1. Lillie, R. D.: I. The Pathology of Psittacosis in Man, and II. The Pathology of Psittacosis in Animals and the Distribution of Rickettsia Psittaci in the Tissues of Man and Animals, Bull. 161, National Institute of Health, Washington, D. C. Government Printing Office, 1933.

phages and reticulo-endothelial cells. These observations naturally suggest that *Rickettsia psittaci* may be the cause of psittacosis, but no final proof of such a relationship can be offered at this time. This account by Lillie of the structural changes in human parrot fever shows how knowledge of the nature of the disease advances as opportunities to study human material with newer methods present themselves. The solution of the etiologic problem, however, requires experiments on animals.

Association News

MEDICAL BROADCAST FOR THE WEEK

American Medical Association Health Talks

The American Medical Association broadcasts on Tuesday and Thursday from 9:15 to 9:20 a. m., Chicago daylight saving time, which is one hour faster than central standard time, over Station WBBM (770 kilocycles, or 389.4 meters).

The subjects for the week are as follows:

August 8. Grape Juice.
August 10. The Problem of Adoption.

There is also a fifteen minute talk sponsored by the Association on Saturday morning from 9:45 to 10 o'clock over Station WBBM.

The subject for the week is as follows:

August 12. Analysis of Urine.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ALABAMA

Portrait of Dr. Mabry.—A painting of Dr. Albert Gallatin Mabry, one of the first trustees of the Alabama Insane Hospitals, was recently presented to the Bryce Hospital by Mr. W. S. and Miss Virginia Mabry, son and daughter of the late physician. Dr. Mabry was associated with the early history of the hospital, having suggested the establishment of a hospital for the insane of Alabama at a meeting of the state medical association in Mobile in 1847, according to a newspaper account. At this time he was appointed to investigate the old state capitol building at Tuscaloosa, which had been vacated when the capitol was moved to Montgomery, to determine the suitability of the building for a hospital. Dr. Mabry was appointed a trustee by the governor in 1857 and served continuously until his death in 1874 at Selma. The portrait was placed in a "Hall of Fame" made up of a group of portraits of other persons distinguished in the history of the Alabama hospitals for the insane, assembled through the efforts of Dr. William D. Partlow, superintendent of the hospitals.

ARIZONA

State Department Establishes Sanitary Division.—In the reorganization of the state department of health, a division of sanitary engineering has been established with the aid of the Rockefeller Foundation, newspapers report. F. Carlyle Roberts, Jr., Tucson, who has been named state sanitary engineer with offices in the state board of health's headquarters, has already begun a survey of water supplies in the state.

ARKANSAS

Personal.—Dr. Allen B. Jemison has been appointed in charge of the departments of epidemiology, milk control and malaria control of the state department of health, effective July 1. He was recently appointed health officer in Jefferson County, succeeding Dr. George A. Hays. Dr. Herbert H. Howze, Little Rock, will replace Dr. Jemison in Jefferson County.

Medical Board Election.—Dr. William W. York, Ashdown, was elected president of the State Medical Board of the Arkansas Medical Society at its meeting in Little Rock, June 19. Dr. William T. Lowe, Pine Bluff, was named vice president and Dr. Albert S. Buchanan, Prescott, secretary-treasurer. Offices of the board have been transferred from Searcy to Prescott.

COLORADO

Dr. Meader Resigns at University.—Dr. Charles N. Meader, dean emeritus, University of Colorado School of Medicine, Denver, has resigned as head of the department of medicine, effective July 1. Dr. Meader has been connected with the school since 1912. In 1914 he was appointed instructor and in 1916, dean and professor of medicine. He resigned as dean in 1925 and was made dean emeritus. Dr. James J. Waring has been appointed professor and head of the department of medicine to succeed Dr. Meader. Other changes at the school include the appointments of Drs. Roy Parsons Forbes and Emanuel Friedman as assistant professors of pediatrics and Roderick J. McDonald, Jr., and Wilford W. Barber, instructors in pediatrics.

CONNECTICUT

Statewide Tuberculosis Campaign.—A resolution authorizing a statewide campaign against tuberculosis was adopted by the house of delegates of the Connecticut State Medical Society, May 25. Emphasis will be placed on the finding of persons with tuberculosis by a new low cost method of making roentgenograms. The plan developed from a project in New Haven in which roentgenograms were made of about 6,400 high school students in an effort to detect tuberculosis (THE JOURNAL, March 11, p. 746). In carrying out the campaign, the state department of health will furnish information to medical societies, physicians and health officers and handle information for the public, and the state tuberculosis commission will interpret the roentgenograms. Persons availing themselves of the reduced prices offered in the campaign will be expected to pay for their own roentgenograms. The interpretation of the films will be reported to local authorities, who will report in turn to the patients or patients' families. The family physician will complete the diagnosis when further study is required and a member of the state commission will be available for additional consultation. The responsibility of the follow-up work will devolve on the health officer. The program will be carried out only in those communities that request it. It is planned to begin the campaign early in the fall.

DISTRICT OF COLUMBIA

Society News.—Dr. Maude E. S. Abbott, assistant professor of medical research and curator of the medical museum, McGill University Faculty of Medicine, Montreal, Que., addressed the Washington Heart Association, April 28, on "Congenital Heart Disease." Dr. Thomas A. Claytor was elected president of the society, May 26, and Dr. James Esler, secretary.

Dr. Hickling Retires as Alienist.—Dr. Daniel Percy Hickling, for many years alienist for the district government, will be retired, September 30, and the work attached to his position will be transferred to the chief psychiatrist of the Gallinger Municipal Hospital, under an order of the district commissioners, July 21. Dr. Hickling, who has been connected with the district government more than thirty years, will reach the retirement age about two weeks before the order becomes effective. He is professor of medical jurisprudence at the National University Law School and professor of clinical psychiatry at Georgetown University Medical School.

FLORIDA

Society News.—Dr. George S. McKnight, Avon Park, addressed the De Soto-Hardee-Highlands Counties Medical Society in Arcadia, June 13, on pellagra.—The Suwanee River Medical Society heard Dr. John D. Gable, Lake City, discuss mental diseases at its meeting in Live Oak, June 9.

Financing Health Units.—The Rockefeller Foundation has given \$4,000 to the Florida State Health Department to defray in part operating expenses of health units in the state, it is reported. Since the creation of the three units in Taylor, Leon and Escambia counties, they have been operated with funds supplied on an equal basis by the federal, state and county governments. However, no provision for these funds was made in the economy program of the federal government. It was stated that the Rockefeller Foundation gift would assure the continuance of two of the units, and every effort will be made to continue the three on a full time basis.

GEORGIA

Typhoid in Atlanta.—About twenty-one cases of typhoid occurred in Atlanta recently, the *Bulletin* of the Fulton County Medical Society states. Investigation disclosed a local dairy to be the source of the outbreak and the dairyman to be a typhoid carrier. His license was revoked.

Society News.—Mr. Robert Hudgens of Emory University was elected president of the Georgia Hospital Association at its annual meeting, held in Atlanta, June 29.—Dr. William W. Anderson gave a paper on "Anemias in Infancy," before the Fulton County Medical Society, Atlanta, July 20, and Dr. Richard B. Wilson a clinical talk on "Air Encephalography and Diseases of the Nervous System." Dr. John D. Martin, Jr., presented a case report on reconstruction of the lower lip. Dr. William W. Young addressed the society, July 6, on "Recent Advances in Psychiatric Education," and Dr. Henry R. Donaldson gave a clinical talk on "Vaccine Therapy Treatment of Typhoid Fever."

ILLINOIS

Free Examinations at State Fair.—The Sangamon County Medical Society and the state department of health will make free tuberculin tests and roentgen examinations on a limited number of children at the Illinois State Fair in Springfield, August 19-26. According to the state department of health, this project is undertaken as a demonstration of the use and value of the Mantoux skin test and the x-rays in the early diagnosis of tuberculosis. Children between 5 and 16 years old, whose parents or guardian request it, will be accepted for the test and examination. Children brought to the fair for the test will be provided with admission tickets to the grounds and asked to return two days later for a reading of the test. It is planned to roentgenograph immediately those with positive tests. It is to be emphasized particularly, the announcement states, that a positive test does not necessarily mean active tuberculosis. Physicians of the state are invited to send to the fair any of their patients whom they wish to have tested and examined.

INDIANA

Personal.—Dr. Richard Schillinger, Richmond, has replaced Dr. Louis F. Ross as medical superintendent of the Richmond State Hospital, it is reported.

Child Health Conferences.—Two hundred and seventy-six children were examined by members of the Shelby County Medical Society in a series of conferences conducted throughout the county, recently. The conferences revealed that less than 9 per cent of the children had been immunized against diphtheria and a smaller percentage had been vaccinated against smallpox. As a result, an active immunization campaign is planned in the county by committees of the medical society, the county tuberculosis association and the Red Cross, which were the cooperating agencies in the fourteen conferences. Lay committees handled the clerical work and graduate nurses donated their services at the conferences.

Program for Child Health.—In a news item concerning the work of the department of child health and maternal welfare of the Indiana State Board of Health published in *THE JOURNAL*, July 29, page 372, it should have been stated that this work is to be done through the organization of the Indiana State Medical Society, with approval and participation of the county medical societies. District chairmen appointed by Dr. Oscar N. Torian, chairman of child health, are to be key men in obtaining cooperation of the county societies in their districts. It is the purpose of the plan that each county society shall educate its own citizens in child health. According to officials of the state medical society, the plan goes into effect in any locality only on the request and with the approval of the local county medical society.

IOWA

Society News.—Dr. Walter C. Alvarez, Rochester, Minn., addressed the Black Hawk County Medical Society, June 8, on "The Doctor and His Family."—At a meeting of the Clinton County Medical Society, June 1, Dr. Franklin R. Peterson, Iowa City, spoke on "Diseases of the Spleen."—Dr. Andrew B. Rivers, Rochester, Minn., discussed "Causes of the Vomiting of Blood" before the Floyd County Medical Society in Charles City, recently.—The Johnson County Medical Society was addressed, June 7, by Drs. William F. Boiler, Iowa City, and Granville A. Bennett, Boston, on "Treatment of Acute Otitis Media" and "Degenerative Changes in Joints Resulting from Continued Trauma and Increasing Age, and Their Relationship to Hypertrophic Arthritis," respectively.

—Veterinarians of the county presented a symposium on diseases transmitted by animals to man before the Mills County Medical Society in Glenwood, June 22.—Dr. Joseph B. Vanderveer, Philadelphia, talked on "The Electrocardiogram as an Aid to the Diagnosis and Treatment of Heart Affections" before the Scott County Medical Society in Davenport, June 6.—Dr. Andrew J. Smith, St. Joseph, Mo., conducted a skin clinic before the Taylor County Medical Society, recently, and Dr. Willard C. Proud, St. Joseph, spoke on "Conditions Affecting the Eye, Ear, Nose and Throat."—The sixtieth annual meeting of the Des Moines Valley Medical Society was held in Ottumwa, June 20. Speakers included Drs. Harry C. Willett, Des Moines, on "Lesions of the Lips," and George B. Crow, Burlington, "Heart Diseases."—The Southwest Iowa Postgraduate Medical Society was addressed in Red Oak, June 1, by Drs. Edwin Davis, Omaha, on "Advantages and Disadvantages of Transurethral Prostatic Resection as Compared with Prostatectomy," and Aldis A. Johnson, Council Bluffs, on "Mistakes in Diagnosis and Why We Make Them."—Dr. Frederick A. Willius, Rochester, Minn., was among the speakers at the summer meeting of the Upper Des Moines Medical Society at Lake Okoboji, June 29; his subject was "Carcinoma of the Urinary Bladder."

MICHIGAN

State Stops Distributing Some Products.—The state department of health, July 1, discontinued the distribution of bacteriophage as well as scarlet fever toxin for active immunization and the Dick test. The Kahn test will be available for state institutions and charitable organizations only. The restriction was necessary because of a marked reduction in the budget of the department. Other services and preparations will be continued as usual.

Dr. Peterson Retires from Active Practice.—Dr. Reuben Peterson, emeritus professor of obstetrics and gynecology, University of Michigan Medical School, Ann Arbor, retired from active practice on his seventy-first birthday, June 29. Dr. Peterson became associated with the medical school in 1901 as professor of obstetrics and gynecology, a position he filled until 1931, when he retired with the title of emeritus professor. He was medical director of the University of Michigan Hospital from 1911 to 1918. Early in his career he was connected with the Post-Graduate Medical School of Chicago, 1898-1901, as professor of gynecology, carrying a concurrent appointment as assistant professor of obstetrics and gynecology at Rush Medical College. He was medical adviser to the governor of Michigan from 1917 to 1919 and president of the Michigan State Medical Society in 1915 and of the Washtenaw County Medical Society in 1902. Dr. Peterson is the author of many articles on his specialty. At the recent annual session of the American Medical Association in Milwaukee, Dr. Peterson was made an honorary Fellow.

MINNESOTA

Court Vacates Charter of Medical Corporation.—Judge John W. Boerner filed an order, June 2, vacating the charter of the Pioneer Mutual Health and Benefit Insurance Company of Minnesota, which had been organized in St. Paul apparently for "maintaining a health service or insurance." So-called policies of insurance were issued whereby the holder and others would get medical, surgical and dental services for \$1.50 a month by consulting physicians, surgeons and dentists employed by the company. The Minnesota State Board of Medical Examiners, believing the plan to be in violation of the law so far as the furnishing of medical and surgical services is concerned, instituted court proceedings.

MISSOURI

Personal.—Dr. Lawrence T. Post has been appointed head of the department of ophthalmology of Washington University School of Medicine, St. Louis, on a part time basis.—Dr. Benjamin A. Wilkes has resigned as superintendent of the Southeast Missouri Hospital, Cape Girardeau; he will be succeeded by Mr. T. J. McGinty.

Health Department Reorganized.—The St. Louis Health Department was recently reorganized to centralize and coordinate more closely the various services. All activities of the department, with the exception of secretarial service and popular health education, will be grouped under four sections: medical, dental and nursing; laboratory; food control, and sanitary sections. The medical, dental and nursing section includes services in communicable disease, tuberculosis, venereal disease, child hygiene, prenatal care, public health nursing, dentistry and health center clinics. Dr. Paul J. Zentay, St.

Louis, instructor in clinical pediatrics, Washington University School of Medicine, has been appointed in charge of this division. Other appointments include the following:

J. S. Koen, D.V.S., formerly chief meat inspector, to chief of food control section.

Mr. W. Scott Johnson, Jefferson City, chief sanitary engineer.

Dr. Alfred L. Kavanagh, chief of venereal clinic.

Ernest C. McCulloch, D.V.M., supervisor of milk control.

In addition to the coordination within the department, a closer cooperation with physicians in private practice and with the medical schools and health organizations is planned.

MONTANA

State Medical Election.—Dr. Byron L. Pampel, Livingston, was installed as president of the Medical Association of Montana at its annual meeting, July 11-13. Dr. Charles E. K. Vidal, Deer Lodge, was chosen president-elect, and Dr. William E. Long, Anaconda, named vice president. Dr. Elmer G. Balsam, Billings, was reelected secretary. The next annual session will be held in Helena, July 11-12, 1934.

NEW YORK

Society News.—Dr. Morris Fishbein, Chicago, editor of THE JOURNAL, addressed the summer meeting of the Medical Society of the County of Chautauqua, August 2, at Chautauqua Institution, on "Follies of Socialized Medicine." Dr. Marshall Clinton, Buffalo, addressed the society, June 21, on abdominal emergencies.—Drs. James R. Goodall, Montreal, and Edward K. Cravener, Schenectady, addressed the Medical Society of the County of Franklin, Saranac Lake, June 9, on "Ovarian Dysfunction" and "Lumbar and Sacral Pain," respectively.

Health at Schenectady.—Telegraphic reports to the U. S. Department of Commerce from eighty-five cities with a population of 37 million, for the week ended July 22, indicated that the highest mortality rate (17.8) appeared for Schenectady and the rate for the group of cities as a whole, 9.5. The mortality rate for Schenectady for the corresponding period last year was 7 and for the group of cities, 10.8. The annual rate for eighty-five cities for the twenty-nine weeks of 1933 was 11.3, as against a rate of 11.8 for the corresponding period of the previous year. Caution should be used in the interpretation of weekly figures, as they fluctuate widely. The fact that some cities are hospital centers for large areas or have large Negro populations may tend to increase the death rate.

Begin Work on Saratoga Spa.—The ceremony of laying the cornerstone of the Hall of Springs, the first building in the program of development of Saratoga Springs as a state-owned spa, was held, July 12. Bernard M. Baruch, New York, who was chairman of the Saratoga Springs Commission which planned the present development, laid the cornerstone and Gov. Herbert H. Lehman made the principal address. The Hall of Springs will be 160 feet long and 70 feet wide, with a high arched roof enclosing three of the principal medicinal springs. Marble counters will surround the fountains, from which attendants will serve the water at prescribed temperatures. The group of buildings will finally include a sanatorium, bath houses, a bottling plant for the waters, a gymnasium and a new unit of the laboratory and administration building, all of which are to be finished by Jan. 1, 1936. Beginning of the work was made possible by a loan of \$3,200,000 from the Reconstruction Finance Corporation in June.

New York City

Society News.—Bronx physicians whose names appeared in the list of approved radiologists published by the Council on Medical Education and Hospitals of the American Medical Association recently organized the Society of Approved Roentgenologists of Bronx County. The purposes of the organization were announced to be: to remove abuses connected with practice of the specialty, to strive for high scientific standards and to promote mutual cordiality among members and between them and the medical profession in general. Dr. Samuel F. Weitzner is president and Dr. Jacob Fierstein, secretary.

NORTH CAROLINA

Johnson Medical Building Completed at Wake Forest.—The William A. Johnson Memorial Medical Building at Wake Forest College School of Medicine, a gift of the family of Dr. Johnson, who was killed in an automobile accident in 1927, has been completed and turned over to the school. The new \$60,000 structure is three stories high and contains adequate teaching and research facilities. Dr. Johnson received his academic degree at Wake Forest and after graduating from the University of Pennsylvania School of Medicine in 1925 returned to his alma mater as professor of anatomy, which position he occupied at the time of his death.

OKLAHOMA

Extension Course.—The extension division of the University of Oklahoma sponsored a course of weekly lectures at El Reno recently. Instructors and their subjects were:

Dr. Thomas P. Sprunt, Baltimore, Arterial Hypertension and Arteriosclerosis.

Dr. William S. Middleton, Madison, Wis., Diagnosis and Treatment of Lobar Pneumonia.

Dr. Newton S. Stern, Memphis, Coronary Disease: Its Recognition and Management.

Dr. Paul L. Schroeder, Chicago, Mental Hygiene of Infancy and Childhood.

Dr. Henry F. Helmholz, Rochester, Minn., Diseases of the Urinary Tract in Childhood.

Dr. Peter T. Bohan, Kansas City, Use of Drugs in Heart Failure.

Dr. Horton R. Casparis, Nashville, Tenn., Infant Feeding.

PENNSYLVANIA

Society News.—Drs. Edward Weiss and Temple S. Fay, Philadelphia, addressed the Clearfield County Medical Society at a meeting at the Crystal Springs Rod and Gun Club, near Clearfield, July 13, on "Cardiac Neuroses" and "Surgical Treatment of Brain Injuries," respectively.—Dr. Ralph M. Tyson, Philadelphia, addressed the Luzerne County Medical Society's Hazleton branch, in June, on acute anterior poliomyelitis.—Dr. Truman G. Schnabel, Philadelphia, discussed treatment of anemias before the Northampton County Medical Society, Easton, June 16.

Philadelphia

Alvarenga Prize Awarded.—The College of Physicians of Philadelphia announces that the Alvarenga Prize, amounting to about \$300, has been awarded to Drs. Harry Shay and Jacob Gershon-Cohen, Philadelphia, for their essay entitled "Experimental Studies in Gastric Physiology in Man." The authors of the winning essay are graduates of the University of Pennsylvania School of Medicine, Dr. Shay in the class of 1921 and Dr. Gershon-Cohen, the class of 1924. The former is a specialist in internal medicine and the latter in roentgenology. The Alvarenga Prize essay may be on any subject in medicine and must represent an addition to the knowledge and understanding of the subject based on either original or literary research. It was not awarded in 1932.

SOUTH DAKOTA

Cancer Campaign Planned.—At the recent annual meeting of the South Dakota State Medical Association the cancer committee of the association was authorized to engage in an educational campaign to further the diagnosis and treatment of cancer in cooperation with the American Society for the Control of Cancer. It was recommended that the facilities of all available educational agencies be concentrated for an initial period of one year on the subject of cancer of the breast. Members of the cancer committee are Drs. William R. Ball, Mitchell; Jesse D. Whiteside, Aberdeen, and Nelius J. Nessa, Sioux Falls.

TEXAS

Personal.—Dr. John H. Foster, Houston, president of the State Medical Association of Texas for 1932-1933, received the honorary degree of doctor of science at the June commencement of Southwestern University, Georgetown, his alma mater.

Society News.—At a meeting of the Brooks-Duval-Jim Wells Counties Medical Society in Alice, June 21, Dr. Carroll F. Crain discussed roentgen diagnosis of diseases of the chest and Dr. Charles W. Skipper, Corpus Christi, syphilis.—Drs. Wilson D. Anderson, Sanatorium, and Clifford T. Womack, San Angelo, among others, addressed the Mason-Monard-McCulloch Counties Medical Society in Brady, June 7, on "Phrenic Resection in Treatment of Pulmonary Tuberculosis" and "Spinal Anesthesia," respectively.—Speakers at the June meeting of the Dallas County Medical Society were Drs. Paul H. Duff, on treatment of empyema; Richard L. Nelson, lead poisoning in children, and Elza M. Perry, Dallas, polyneuritis and vitamin deficiency.—Drs. Milford O. Rouse and Thomas H. Cheavens, Dallas, addressed the Henderson County Medical Society, June 5, on treatment of peptic ulcers and syphilis of the nervous system, respectively.—Dr. Newton H. Bowman, Mercedes, among others, addressed the Hidalgo County Medical Society, Edinburg, June 8, on diagnosis of ocular paralysis.—Dr. Cleve C. Nash, Dallas, presented a paper on "Injuries of the Head and Their Treatment" before the Denton County Medical Society, Denton, June 8.—Dr. Wilmer L. Allison, Fort Worth, was among the speakers at a meeting of Tarrant County Medical Society, Fort Worth, June 5, on "Newer Theories Regarding the Cause and Treatment of Epilepsy."

WASHINGTON

Personal.—Dr. Albert E. Stuhlt, director of the State Department of Health, Seattle, for the past eight years, has been appointed surgeon of the American Mail Line.—Dr. Marinus W. Conway, Cheney, has been appointed superintendent of Eastern State Hospital for the Insane at Medical Lake.—Dr. Leslie A. White, Seattle, has recently gone to Metlakatla, Alaska, to take charge of the medical service of an Indian station.—Dr. Roger L. Hickman has resigned from the Yakima Indian Sanatorium, Toppenish, to become associated with the Western Oklahoma Tuberculosis Sanatorium, Clinton.—Dr. Paul L. West, Wenatchee, has resigned as health officer of Chelan County after nine years' service.

WEST VIRGINIA

Child Health Conference.—Dr. Moritz F. Petersen, Charleston, was appointed chairman of a continuation committee following the state conference on child health and protection held in Charleston in May. West Virginia was the twenty-eighth state to hold such a conference along the lines of the White House Conference held in Washington in 1930. The continuation committee will seek a plan whereby the work of child welfare organizations in the state can be coordinated. Dr. George M. Lyon, Huntington, organized the conference. Among physicians who took part were Drs. Delivan A. MacGregor, Wheeling, president of the West Virginia State Medical Association; David Littlejohn, Charleston, then acting state health officer; Robert C. Hood, Clarksburg; John T. Thornton, Wheeling, and William Byrd Hunter, Huntington.

GENERAL

Change in Status of Licensure.—The Rhode Island Public Health Commission has reported the following revocation:

Dr. John B. Coffey, Providence, license revoked in February under the state narcotic law. He is at present serving a term in the Providence County jail on conviction of failure to keep records of drugs dispensed. This license had previously been revoked, but an appeal to the supreme court which had never been heard prevented the revocation from becoming effective.

Woman's Journal Enlarges Scope.—With its June issue the *Medical Woman's Journal* broadened its activities to include the work of women in allied scientific fields and adopted the name *Medical and Professional Woman's Journal*. Interests of dietitians, dentists and women in public health work are presented in special departments. There will also be a department of medical jurisprudence.

Prizes for Research on Mental Disease.—The Eugenics Research Association, Cold Spring Harbor, N. Y., is offering a prize of \$3,000 and another of \$1,000 for original research on the inheritance of mental disorders. Only white persons are to be studied, and family history of about 100 years should be considered. Two years will be allowed for the research; typewritten reports are to be submitted to the association on or before July 1, 1935. The announcement emphasizes that the probability of commitment to an institution is the criterion on which the research must hinge.

Study Public Health Problems in Europe.—Two health officers are members of a party of municipal executives from various American cities who will spend six weeks in Germany and Austria studying public health conditions and problems, it is reported. The physicians are Drs. John L. Rice, health officer of New Haven, Conn., and George C. Ruhland, health officer of Syracuse, N. Y. The party includes a mayor, a city manager, a police chief, a city engineer, a park executive and other municipal executives. The trip has been made possible by the Carl Schurz Foundation of the Oberlaender Trust, a Philadelphia organization established for the promotion of cultural relations between the United States and German speaking countries.

Society News.—Dr. Agnew H. Hilsman, Albany, Ga., was elected president of the Chattahoochee Valley Medical and Surgical Association at its annual meeting in Albany, July 12, succeeding Dr. Seale Harris, Birmingham, Ala. Dr. William J. Love, Opelika, Ala., was reelected secretary.—A resolution requesting the U. S. Public Health Service to take measures to prevent introduction of psittacine birds into the United States was adopted by the western branch of the American Public Health Association at its annual meeting in Pasadena recently. The resolution declared that the appearance of psittacosis in California and other Western states had established a distinct menace to public health and urged continuance of the investigations of the disease which have been under way in California for the past year.—Dr. Jean P. Pratt, Detroit, was elected president of the Association for the Study of Internal Secretion at its annual meeting, June 13, and Dr. Francis M. Pottenger,

Los Angeles, reelected secretary. The next annual session will be held in Cleveland.—At the annual meeting of the Medical Library Association, June 19, Miss Marcia C. Noyes, Baltimore, was elected president, and Miss Marjorie J. Darrach, Detroit, reelected secretary. The next annual session will be held in Baltimore.—The annual meeting of the Association of Military Surgeons will be held in Chicago, September 25-27, under the presidency of Dr. Ralph C. Williams, Washington, D. C.—Dr. George A. Dowling, Seattle, was named president-elect of the Pacific Northwest Medical Association at the annual meeting in Vancouver, B. C., in July. The 1934 session will be held in Salt Lake City.

Funds Needed—Anatomy of Lung.—Dr. Lawrason Brown, Saranac Lake, N. Y., is sending to interested physicians a letter asking for contributions to a fund to finance the publication of the work of Dr. William Snow Miller, Madison, Wis., on the anatomy of the lung. Dr. Miller has much of the material, including a number of plates, Dr. Brown's letter says, but he requires about \$3,000 to enable him to get the manuscript ready for the publishers by Jan. 1, 1934. This sum would be spent as follows: \$2,500 for the services of a secretary and an artist and \$500 for Dr. Miller's living expenses. Because of financial reverses Dr. Miller, now 76 years old, is unable to do this work without outside aid. Dr. Brown's letter concludes:

I was impressed with the opportunity which presented itself to American medicine, for here almost within our grasp lay what we might consider to be a classic. It is for this reason that I am writing to ask your immediate aid in the form of a small contribution and possibly a few others from some of your friends and acquaintances. The appeal is urgent. Father Time is no laggard. I shall be glad to act as treasurer of the fund.

Dr. Brown's address is 24 Church Street, Saranac Lake, N. Y.

FOREIGN

New Medical Buildings.—Kings College Hospital Medical School, London, recently opened several new buildings, completing a program interrupted by the World War. They include a teaching museum, a dental museum, a biochemical research laboratory, and a refectory hall provided with a stage which will make it adaptable for meetings and school ceremonies.

Society News.—The Medical Association of South Africa will hold its annual meeting at the University of Capetown, Groote Schuur, September 25-30. Dr. Edward Barnard Fuller is president. Three morning plenary sessions will be held at which discussions will be held on "Diet in Relation to Health in South Africa," "Maternal Mortality in Urban and Rural Areas" and "Medicolegal Problems of General Practice." Alternate mornings will be given over to section meetings and the afternoons to business meetings, a golf tournament and special excursions. The president's garden party will follow the annual business meeting the third day of the meeting.—The directorate of the German Physiologic Society has decided to cancel the session that was to have been held in Innsbruck in September.

International Congress on Cancer.—An International Congress for the Scientific and Social Fight Against Cancer will be held in Madrid, October 25-30. Subjects to be discussed by the scientific section are: biology of the cancer cell, early diagnosis, treatment of cancer and tumors of the nervous system. Subjects for the social section are: occupational cancer, statistics of cancer, organization of a permanent international bureau and public education against cancer. Official languages of the congress are English, French, Spanish, German and Italian. Further information may be obtained from Dr. Julio Bejarano, general secretary, Atocha 104, Madrid. Newspapers report that Drs. James Ewing, New York, and Francis C. Grant, Philadelphia, have been appointed delegates to represent the United States.

Memorial to William Harvey.—The tower of Hempstead Church, Essex, where William Harvey and members of his family are buried, is to be partially restored after lying in ruins for fifty years, the *British Medical Journal* reports. Lord Dawson of Penn, president of the Royal College of Physicians, laid the foundation stone, July 7, for the new tower, which will be known as Harvey Tower. In 1882 the church tower fell suddenly and the damage has never been repaired. The College of Physicians in 1883, feeling that the remains of Harvey should be more fittingly cared for, removed the leaden shell containing his body from the Harvey vault, which had fallen into disrepair, and placed it in a marble sarcophagus in the Harvey chapel, a part of the church originally built by members of the family. Within the last few years a committee of representatives of the medical profession and the parishioners of Hempstead has raised sufficient funds to finance rebuilding of part of the tower. It remains to find funds for the restoration of the ringing room and the belfry.

Cancer Research

Years ago it was discovered that shale workers in the Scottish coal fields developed warts on their hands, which tended to become cancerous. In the research department of the Cancer Hospital, London, the cancer-producing substances of shale, tar and paraffin were investigated and the work has now been brought to a successful conclusion. Mr. Hieger, a member of the staff, has succeeded in isolating from coal tar a cancer-producing body of great virulence and, moreover, has prepared this body synthetically. It is a hitherto unknown hydrocarbon; namely, 1:2 benzopyrene. Five benzene rings are united in the molecule in a particular manner. This substance is to be distinguished from another cancer-producing substance prepared synthetically at the Cancer Hospital some time ago (1:2:5:6 dibenzanthracene). Work is now proceeding on the possible relation of these substances to compounds that occur in the tissues of the body. Light on the subject is being sought by means of x-ray crystallography. Working at the Royal Institution, Dr. J. M. Robertson has shown that dibenzanthracene differs from anthracene, which is not cancer producing, in ways that were not otherwise apparent.

At the Cancer Research Laboratory of the London Hospital, Dr. Lumsden, the honorary director, has made therapeutic researches. In 1925 it was first shown that antisera capable of destroying cancer cells could be produced. The first attempts to cure an animal by injecting antiserum failed, but by 1932 it could be reported that mice were cured in a large percentage of cases. These mice were in future immune to experimental cancer. Some of them are now living and have been free from recurrences for nearly a year; i. e., a period equivalent to something like thirty or forty years in the life of a man. The results, gradually but progressively attained, all confirming the hypothesis on which ten years ago the research was based, have led at last to the final test on man. Twenty-five patients suffering from cancer in a hopeless form have voluntarily placed themselves under antiserum treatment. It is not considered expedient at this early stage to publish even the provisional conclusions. But the results are considered to justify further and intensive investigation along these lines, and the Cancer Campaign has provided the necessary funds. The annual report of the British Empire Cancer Campaign describes this research.

The Profession's Control in a State Medical Service

Mr. Somerville Hastings, a laryngologist, delivered his presidential address to the Socialist Medical Association on the extent to which physicians should be heard in the administration of a state medical service. He referred to the fact that for many years the state and the local authorities had been undertaking to supply the medical needs of part of the population. To what extent ought the physicians, who were whole or part time government servants, to have a controlling voice in the services they were administering? Mr. Hastings referred to the recent dispute between the London County Council and the British Medical Association concerning the conditions of service of the consultants about to be employed. The association claimed that it should have been consulted about the condition and have some voice in the selection. Much of the medical work of the Council was carried out by committees composed of medical officers of their hospitals and other ser-

vices who issued reports to the health officer of the council. He transmitted these, with any modification he thought necessary, to the public health committee. The system seemed to work well in practice, but it was open to the theoretical objection that the only official communication was through the very narrow bottle-neck of the health officer. In the voluntary hospitals the most diverse conditions were found. Some of the smaller voluntary hospitals were completely controlled by the medical staff. On the other hand, in some of the larger hospitals the staff had no control whatever. In some they had representatives on the committee of management.

Mr. Hastings enunciated principles as to the amount of control to be given to workers in a state medical service: 1. They must have the sole voice in determining the type of treatment for each patient. 2. The public authority employing a medical officer must have the sole voice in his appointment. But a physicians' union should keep careful watch on salaries, hours and other conditions of employment and consult with the public body responsible. 3. The physicians employed or their representatives must have direct access to those administering the medical service. 4. They must have power to tender advice as to the development of the service.

Scottish Vital Statistics

Like England, Scotland continues to record a constantly falling birth rate. The report for 1932, just published, shows that the birth rate was 18.6 per thousand, again the lowest on record. The death rate was 13.5, compared with 13.26 in 1931. Infant mortality was 86 per thousand births, compared with 82 in 1931 and an average of 85 for the previous five years. But the tuberculosis death rate reached a record low figure of 84 per hundred thousand of population, compared with 87 in 1931. The birth rate now is only approximately half the maximum recorded (35.62 in 1876). In a discussion of the causes of the decline, it is pointed out that it cannot be explained by diminution of the marriage rate or increase of the average age on marriage. The average age on marriage from 1861 to 1901 shows little variation—from 27.2 to 27.5 years. Since 1901 there has been a slight tendency to increase, the average age in 1930 being 27.8 years. The decline in the birth rate started in 1876, while the tendency to increase in age at marriage is much more recent. Moreover, the married population at the censuses of 1901, 1911 and 1921 were, as regards age, more favorably constituted for a high birth rate than in 1885.

Lack of Milk a Cause of Tuberculosis

The Tyneside towns of Jarrow and Blaydon have each a working class population of about 32,000 and show an equal amount of overcrowding, but the tuberculosis death rate for the former is about 2 per thousand and for the latter about 1 per thousand. The National Association for the Prevention of Tuberculosis therefore investigated the matter. It was found that there were more poor families in Jarrow than in Blaydon. In the latter there are many married miners living in houses provided by the colliery owners, which are rent free—a great advantage during unemployment. The association of poverty with tuberculosis was thus manifested. In keeping with this, it was found that undernutrition was greatest in the tuberculous families. They consumed more bread but less meat, butter and milk than nontuberculous families. The shortage of milk in the diet was even greater than that of meat. It was suggested that the shortage of milk was possibly more important than undernourishment and that vitamins, enzymes or some unknown constituents of fresh milk played a part in the body's defense against tuberculosis. A racial factor entered into the etiology, for the incidence of tuberculosis was higher among the large Irish population in Jarrow. This higher rate could not be

entirely explained by inferior conditions of life. It was estimated that they made the death rate 31 per cent higher than it would have been in their absence. The practical conclusion was that the use of fresh milk, especially for children, should be regarded as a daily necessity in poor families. The neglect of milk was not simply a matter of poverty, for its use was more neglected than that of meat, though that is more expensive.

Council of the British Medical Association Condemns Dichotomy

At a meeting of the council of the British Medical Association, the following resolution was proposed, for the Central Ethical Committee, as a recommendation for the representative body: "That in the opinion of the representative body the practice of fee splitting, commonly called dichotomy, an arrangement between two practitioners whereby, unknown to the patient, one practitioner receives part of the fee due to the other, is really a secret commission, unlawful and highly detrimental to the honor of the medical profession." The subject originated in an anonymous letter to the *Lancet*, in which a consultant complained that he was forced by physicians to submit to the practice of dichotomy. An editorial followed in the *British Medical Journal* dissociating the profession from any countenance of the practice. Then the president of the General Medical Council condemned it as a contravention of an act of parliament which made secret commissions illegal. The council of the British Medical Association agreed to the recommendation, with omission of the reference to the illegality of a secret commission.

PARIS

(From Our Regular Correspondent)

June 14, 1933.

The Treatment of Accidental Asphyxiation

The city of Paris has a well organized fire department. Calls may be turned in from private telephones or from any one of the many special boxes located in the streets. These street boxes are now to be used also in summoning aid from a new service created to aid persons who have become accidentally asphyxiated by carbon monoxide, electrical shock, hanging and submersion; that is, persons discovered apparently dead, except cases resulting from disease or traumatism. In response to such calls, an ambulance is sent out with special equipment and one or two members of the special service of the prefecture of police, trained in the treatment of asphyxiation: artificial respiration by the Schäfer method; use of the inhalator mask, with a pouch containing oxygen and a 5 per cent admixture of carbon dioxide; and, finally, the vehicle to transport the victim to a hospital in case first aid should not prove sufficient.

The organization of this service is due to Lieutenant-Colonel Cot, M.D., who resigned from the army to become the director of this municipal service. His military career had brought him to Paris as chief physician of the fire department. The firemen are often exposed to asphyxiation in the basements of burning buildings. Dr. Cot improved the masks with which the firemen were equipped and studied the developments in the technic of resuscitation, visiting institutions in France and foreign countries. He introduced the use of the Henderson gas mixture and the mask, replacing the pure oxygen administered with the aid of a balloon and a rubber tube. He formed classes in the technic of resuscitation for the benefit of the firemen and policemen. The work of the pupils of Dr. Cot, confined to first aid, has led to saving the lives of more than 500 victims in the past two years. The municipalities near Paris are beginning to imitate this example, and twenty of them have organized for their police force a course of instruction. If, however, the case is grave, the intervention of the

physician becomes necessary. Dr. Cot has published, for the use of physicians, a number of important brochures in which he discusses the best forms of technic.

The Effect of Tobacco on the Heart

Laubry, Deglaude and Walser have taken up again experimentally the old question of the effects of tobacco on the heart, studying them on an isolated heart of a rabbit. This research shows that the output of the heart varies directly with the output of the coronary arterial system. An infusion of tobacco and a solution of nicotine, if they contain the same amount of nicotine, exert the same effects on the coronary output. Small doses of nicotine provoke constantly an increase of the coronary output (from 30 to 60 per cent of the initial figure). Moderate doses of nicotine provoke a constant augmentation of the coronary output (from 5 to 20 per cent of the initial figure). Strong doses of nicotine provoke in a constant manner a diminution of the coronary output (from 10 to 20 per cent of the initial figure). Nicotine exerts, therefore, experimentally a strong vasodilative action in weak doses and a weak vasoconstrictive action in strong doses. An approximate calculation showed the authors that the probable concentrations of nicotine in the blood of ordinary smokers (from ten to twenty cigarettes a day) correspond to the weak and moderate doses of their experiments. If it is permissible to apply these experimental data to the clinical aspects, it would seem that, in the mechanism of the attacks of angina associated with tobacco intoxication, the influence of the coronary vasoconstrictive factor is nil or negligible, whereas the toxic action on the nerve elements of the cardiac plexus is paramount. The evils of tobaccoism must therefore be associated with chronic intoxication of the autonomic cardiac motor system. The vascular spasms are plainly evident; their influence on the retinal circulation is likewise observed. But their effect on arterial pressure and on the myocardium is slight. The physician can therefore assume a tolerant attitude toward the moderate use of tobacco in persons who experience no inconvenience from it.

Erythemas Due to Medicines

Mr. Milian, of the dermatologic services in the Hôpital St. Louis in Paris, has reported his comprehensive research on erythemas due to medicines. These erythemas should not be attributed, as they usually are, to an intoxication, because they do not produce phenomena characteristic of intoxications (vasomotor disorders, edemas and the like); these are infectious erythemas brought out by the medicament. They are scarlatiniform, morbilliform or rubeoliform, and in each variety, from the ninth day on, there develop febrile and functional symptoms analogous to the eruptive disease of which it is the type. Thus, in scarlatiniform erythema one observes sore throat, headache, vomiting and a temperature of 40 C. (104 F.); in morbilliform erythema one notes conjunctivitis and the like. On the ninth day, independent of the erythemas, there may appear other infectious manifestations: sore throat, coryza, acute articular rheumatism and the like. These erythemas are therefore only attenuated eruptive fevers, developing in persons with latent micro-organisms, half, or at least partially, immunized. When they appear in the immediate vicinity of persons who are not immune—infants, for example—they may infect them with measles or scarlet fever.

Refusal of Students to Take a New Examination

A ministerial decree issued eighteen months ago, on the advice of the superior council of public instruction, provided for a new examination at the end of the second year in medical school, the examination to comprise a written composition on anatomy and physiology. The superior council had acted in response to a desire of the medical syndicates to see the studies for the degree of doctor of medicine made more

difficult, in order to diminish the number of physicians. A written composition would make it possible to avoid favoritism on the part of examiners. The ministry did not announce the introduction of the new examination until two months before the date set for the test. The delayed notice caused excitement among the students of Paris, and they decided to refuse to present themselves for examination. The students of Montpellier, Nancy, Strasbourg and other universities imitated their example. Their principal complaint was that the new rules should be applied only to the new students and not to those who had begun their studies under previous requirements. The minister would not relent and a number of deputies intervened before the tribunal of parliament in order to question the minister and to ask his indulgence for the culprits. The minister finally consented to postpone the examination until next October. The excitement among the students has not been allayed. They are convinced that the project contemplates adding a sixth year to their studies. The minister finds himself in an embarrassing position.

BERLIN

(From Our Regular Correspondent)

June 26, 1933.

Changes in Management of Medical Profession

The Aertzvereinsbund, a syndicate of the medical profession which controlled the professional policies, and the Hartmannbund, a syndicate which dictated the economic policies, were until recently under the sole direction of Geheimrat Sanitätsrat Dr. Stauder in Nuremberg. After the Aertzvereinsbund had opposed, a few months previously, bringing the medical profession under political influence, and after stormy altercations between the syndicates and the physicians associated with the national-socialist party, the latter and these two syndicates finally divided the administrative offices between them. The duties of chairman were then performed jointly by the chairman of the national-socialist physicians, Dr. Wagner of Munich, and by Dr. Stauder. Physicians who had become dissatisfied with Stauder's attitude have been desiring his resignation, but nothing happened until recently, when suddenly he announced his determination to resign. The new political developments, Stauder states, have prepared the way for a unified organization. He said it was a mistake to continue longer the duumvirate—on the one hand the interjected commissar Dr. Wagner, who enjoys the confidence of the federal government, and, on the other hand, the regular chairman, who is bound by law and the constitutions of the leagues and is responsible for all transactions of a legal or financial nature. Dr. Wagner will now be the sole occupant of the office of chairman until the new election is held. His position has been approved by the government. Whether the Aertztag, the annual convention of these two leagues, which was postponed a few months ago, will be held at all, this year, is doubtful.

Eugenic Sterilization

In a recent letter it was mentioned that the attitude of representatives of the medical profession toward eugenic sterilization has undergone a change. In the meantime, the new government has issued a public statement. The Prussian minister of the interior has announced that the council on health has drawn up a bill as the basis for deliberations throughout the reich. Sterilization for medical reasons is already permitted. The new bill concerns sterilization for eugenic reasons but not for social reasons. According to statements issued by the ministry, it is possible that this law will go beyond voluntary sterilization. It is a question whether a physician can be required to sterilize a human being who is opposed to such a procedure. Some contend that the eugenic purification of the body politic through sterilization is the work of generations.

Professor Muckermann, director of the department of eugenics at the Kaiser Wilhelm-Institut für Anthropologie in Berlin-Dahlem, has issued a warning against pursuing too radical a course. In promoting differentiated propagation, one must distinguish the families with sound hereditary qualities from those with unsound qualities. If one should try to eliminate every German family with hereditary taints, one would sound the death knell of the German people. Therefore, experts must be called to make most thorough research in order that only such elements may be excluded from propagation as are unable to propagate other than degenerate progeny. Furthermore, it is important that families with sound hereditary qualities be given financial aid to support large families of children (for example, by remission of taxes and a special tax on bachelors, which has already been introduced in Germany). Muckermann warned against the illusion that all measures proposed would bring rapid results. It is too much to expect that eugenic bureaus will function ideally in a few months.

Professor Fetscher of Dresden, director of a marriage consultation center, found that, during the period 1929-1933, sterilization was indicated in eighty-eight cases; but in only sixty-five cases was he able to bring it about. He cited a family in which five out of eight children were idiots. They have cost the community thus far more than 58,000 marks (\$13,804). In contrast, there have been men or women who have requested sterilization for unjustified reasons. They have been refused.

Vital Statistics of German Cities

The disturbances caused by the economic condition showed signs of subsidence in 1932. The cataclysmic decrease in the marriage rate was checked. The decline in the birth rate underwent a 50 per cent reduction during the second half of the year. The migratory movement continued to subside, the number of removals decreasing more rapidly than the immigrations. In the large cities as a whole, the number of marriages was somewhat smaller than the previous year, but in the cities with from 15,000 to 100,000 inhabitants, marriages showed an increase. Also the birth rate declined only in the large cities. The greatest decline in the birth rate was shown, in recent years, by the industrial cities of Upper Silesia and of Rhineland and Westphalia; after them came Berlin and the Saxon cities Dresden and Plauen. The mortality kept along the low level of the two previous years, the effects of the doubtless often inadequate diet being evidently compensated for by other favorable factors. The increase in population showed a considerable decline as a result of the reduced birth rate. The communes with more than 15,000 inhabitants had an excess of births over deaths amounting to 48,000, or 1.6 per thousand, as against 2.1 and 3.7, respectively, for the previous two years. The greatest losses were recorded of course in the large cities, eleven of which registered more deaths than births. Net losses from emigration exceeding those of the previous year were recorded only by Berlin and Hamburg.

It is evident from the report in the *Reichs-Gesundheitsblatt* that the number of suicides increased. There was a decrease in fatal accidents; also in the number of deaths due to infectious diseases, to childhood fever and to infant mortality from convulsions and syphilis. The diseases of advanced age—cancer, heart disease, cerebral hemorrhage and senile weakness—came more to the front and accounted for more than 42 per cent of all deaths.

Outbreak of Scabies

According to an announcement of the Prussian ministry of the interior, scabies shows a greatly increased incidence, in some parts of the country, among ramblers and persons without permanent abode. A vigorous campaign to combat the spread of the disease should be undertaken. The campaign of enlightenment in the shelters is imperative. To avoid the cost of hospitalization, treatment, so far as possible, should be given

in the shelters after a diagnosis has been made by the local physician of the poor.

Hans Prinzhorn's Death

The unexpected death of Hans Prinzhorn, in Munich, at the age of 47, has been announced. His death marks the passing of one of the most interesting figures of this generation. He devoted himself to the history of art and later turned his attention to psychology and psychiatry. His chief work, "Bildneri der Geisteskranken" (sculptures of psychopaths), was followed by a second, "Bildneri der Gefangenen" (sculptures of prisoners). Prinzhorn taught for a time as a "guest instructor" at a university in southern California.

TURKEY

(From Our Regular Correspondent)

Ankara, June 15, 1933.

The Government Monopoly of Narcotics

The narcotic law, promulgated June 6, makes the manufacture of preparations from crude opium, opium salts, ethers and extracts, morphine and its salts and crude cocaine and its salts, and the import and export of specialties containing such constituents a government monopoly. The monopoly of drugs and narcotics has been established as a part of the ministry of national economy. The new law has twenty articles, the most important of which are as follows:

The monopoly is to attend to all affairs pertaining to the purchase and sale of opium and to engage in all enterprises in connection therewith, to analyze all prospective purchases, to combine the different grades, reclassify them, insure the standardization of opium, organize an administrative center and establish a laboratory, and fix prices. The administration is to indicate the areas set aside for opium cultivation and by advertisements in the press bring to the attention of the public the areas where the cultivation is unlawful. To make sure that aldermen have this information, they are to sign a statement to that effect. Supervision of the opium areas is the responsibility of the civil authorities. The manufacture of preparations under this law is to be carried out at the one laboratory the monopoly will establish and administer in Ankara. Laboratories now manufacturing such preparations are to function no longer. The ministry of national economy, in cooperation with the ministry of health, fixes the regulations on the administration of the laboratory, the kinds of preparations made, their amounts, and the supervision of the sales. Exportation of these preparations is to take place from the Istanbul and Izmir customs. The monopoly will have a board of five trustees, who will serve a term of two years and may be reelected. The monopoly headquarters are located in Istanbul. The ministry of national economy may decide to establish branches in other parts of the country or abroad. Persons growing opium in an unlawful area are to be fined from 5 to 100 pounds and their plantations are to be destroyed or the harvest confiscated. Persons who smuggle crude opium into another country are imprisoned from one to three years and besides are fined three times the value of the opium smuggled. Persons who at the date of the promulgation of this law have a stock of crude opium of the former harvest must within fifteen days make a declaration to the civil authority.

The Reorganization of Istanbul University

The long contemplated reorganization of the Istanbul university is being set in motion by the new minister of education, Dr. Reshid Galib. A temporary faculty is to be appointed for one year. The appointment of the permanent faculty is to take place, May 31, 1934. The recommendations of Professor Malche of Geneva University, who at the invitation of the government made a survey of the situation last year, will be

carried out. The most revolutionary are those in connection with the medical school. With the establishment of the university twenty-five years ago, the medical school established by Sultan Mahmoud II in 1827 became a part of it. Originally the medical school was located in old Istanbul on the European side, but thirty years ago the sultan removed the medical school to Haidar Pasha on the Asiatic shore of the Marmora, then an isolated location. Among the most important of Professor Malche's recommendations was that the medical school be transferred to Istanbul, because of the limited number of hospital beds at the Haidar Pasha clinics. In Istanbul, the psychopathic hospital has 1,480 beds. At the Haidar Pasha clinic, the maximum number is 350. It is possible also to put aside for teaching 800 beds at the Istanbul hospitals. The dormitories are located in Istanbul and the 370 students lose much valuable time in commuting, not to speak of the expense involved. This transfer marks the beginning of the Istanbul university center. Professors who have reached the age limit are going to be retired. Faculty members who have no publications to their credit or those who have no wide knowledge of two modern languages have no chance for reappointment. It is probable that Professor Malche will be offered the presidency of the university and that a number of authorities from abroad will be invited to accept chairs. A committee on publications and translations from among former members of the faculty who are not given a position in the new organization is to be appointed. Professor Malche considers that the publications hitherto in use, either original or translations, have been insufficient.

BUCHAREST

(From Our Regular Correspondent)

June 18, 1933.

Iodized Eggs

One of the latest dietetic fads is the consumption of iodized eggs in cases of secondary and tertiary syphilis, arteriosclerosis, exophthalmic goiter and other maladies in which iodine is indicated. The eggs are produced in special poultry farms under scrupulous hygienic conditions, the animals being periodically subjected to blood tests and other examinations. The hens are given foods that contain a great quantity of iodine, and their drinking water amounts to a weak iodine solution. An analysis of these eggs made at the chemical analytic laboratories in Bucharest revealed that they contain about 6.75 mg. of iodine per hundred grams, while ordinary eggs contain only 0.012 mg. The iodine in the eggs is in the organic form. A disadvantage of the eggs is their repulsive taste, and patients tire of them. There are in Austria two, in Hungary three and in Rumania two special poultry farms where iodized eggs are produced.

The Prevention of Uterine Cancer

Dr. Crainicianu, gynecologist to the Bucharest university clinic, states that 156 cases of uterine cancer were under treatment from 1921 to 1931 and that 68 per cent of these were found on the borderline of operability. The majority of the patients were between 30 and 40 years of age. Uterine cancer represented 7.25 per cent of the total number of gynecologic patients at the clinic. Crainicianu believes that the cause of this situation, in part, is the slow evolution of the disease, as well as the incompetence of midwives, who in the rural parts of Rumania first see these women. However, the chief cause of the frightful spread of cancer is the utter ignorance of this disease among the general public.

As regards prophylaxis, Crainicianu suggests systematic biopsies; also the treatment of precancerous diseases. Much more important is public education by means of lectures, moving pictures and newspaper articles. Women should subject themselves to thorough gynecologic examination twice yearly.

To this end he is going to make an appeal to the government to erect gynecologic advisory centers under the leadership of competent gynecologists. He also urges government regulation of the midwives, most of whom carry on quackery and do abortions.

Marriage and Syphilis

Dr. Aurel Voina of the University of Bucharest lectured at a recent meeting of the Rumanian Medical Society on the necessity of changing the time limit within which syphilitic patients are forbidden to marry. He argued that the unjustified length of time during which they must remain single is harmful to the individual and to the state. Fournier, whose centenary will be celebrated next year, favored the unduly long term of five or six years. Gaucher, late professor of syphilology at the Faculté de médecine de Paris, asserted that a syphilitic man can never be considered completely cured from the point of view of procreation. It must be remembered that the energetic antisyphilitic treatment administered in recent years has shortened the duration of infectivity. The drugs administered at present are much more efficacious than those administered a score of years ago. For this reason, it is unjust to demand abstinence from marriage for five or six years. A bachelor, in comparison with a married syphilitic man, is a disease carrier and therefore a social menace. These circumstances point to the fact that in the interest of social hygiene the point of view of the medical profession regarding permission for persons with syphilis to marry should be revised.

Cutaneous Mycoses in School Children

Cutaneous mycoses form, at present, between 15 and 20 per cent of all skin diseases encountered in the school children of Rumania. The great extension of the trichophyton epidemics in the schools is mainly due to the regrettable fact that the school physicians have no microscopes and that they do not send the children to well equipped laboratories for a microscopic analysis in all early cases. In Rumania, Dr. Theodorescu said that the first microsporia epidemic was in 1925, in a Bucharest children's asylum. In all cases of cutaneous mycosis it is necessary to isolate the patients. To save the children from missing school too long because of the protracted treatment, some authorities suggest establishing special school classes for the sick children. Roentgen treatment is best for mycoses if done by competent radiologists.

The New Law Concerning Venereal Disease

Up to the present there has been no compulsory medical examination before marriage, except when either the bride or bridegroom requested it. Brothels existed also in nearly every town in the country. A new law has been drafted in parliament forbidding brothels and imposing a compulsory medical examination for venereal diseases before marriage. The main points of this new law are as follows:

Veneral diseases are considered to be syphilis, gonorrheal infections and soft chancre in any part of the human body. Persons suffering from venereal disease must undergo treatment; they are examined and treated free of charge in state hospitals and ambulances, and also in university medical clinics and similar institutions.

Every physician treating a patient with venereal disease is required to inform him of its infectious character and that he is obliged to undergo treatment, and to warn him that the law will hold him responsible if he communicates his disease to a healthy person. The physician must warn him not to marry as long as he is not cured. The physician must inquire as to the source of the infection and communicate this information

to the authorities, who will verify it and undertake adequate measures. The physician must keep records of the patients he treats and give all necessary information to authorities if requested to do so officially. If the patient stops treatment before he is cured, the treating physician is obliged to notify the authorities. If there is danger of the patient communicating his venereal disease to another person, he must be discreetly sent to a hospital and there treated until cured.

The Ministry of Public Health must widely propagandize venereal disease, especially among schoolchildren, students, and in the military forces. The heads of hospitals and ambulances for venereal diseases must be active in instructing the population. The keeping of brothels is against the law.

Every person about to be married must produce a medical certificate issued by a state physician that he is free from venereal disease. Priests and other officials who conduct a marriage cannot do so if either the bride or the bridegroom does not have an official medical certificate. If they permit the marriage without such a certificate, they will be punished.

It is forbidden to give any treatment for venereal disease without an examination of the patient; it is also forbidden to give advice by correspondence, to send medicaments or to advertise medicaments for the treatment of venereal disease verbally, through the press, or in any similar manner.

Anybody communicating a venereal disease to another person in any way will be punished by law. If a syphilitic woman undertakes to nurse a healthy baby and communicates the disease to it, she will be punished; equally parents who, knowing that their baby is syphilitic, infect in such manner a healthy nurse will be punished.

The Ministry of Public Health shall open special institutions—aided especially by the women's organizations for girls whose morals are threatened, and for those who have been punished for prostitution, in order to enable them to earn an honest living. Special institutions will be opened for women and girls who come to cities in search of work or who are unemployed. If the morals of a girl under the age of 20 are threatened either in her own family or in the house where she is living, the authorities have the power to remove the girl and hand her over to an institution or to an honest family.

All administrative or other measures which heretofore have been in force for the control of prostitutes are abolished.

The new law solves an important social problem by protecting all young persons, especially girls, against venereal disease.

Death of Professor Joannovic

In the death of Prof. Dr. Georges Joannovic, the faculty of Medicine of Belgrade lost not only one of its leading professors but also its founder. Dr. Joannovic was born in 1871 of Serbian parents who were living in Vienna, where he studied medicine and as a young practitioner was chosen to be the assistant of Professor Paltauf. He worked for twenty-five years at the Institute of Pathology, Histology and Bacteriology in Vienna and was for many years head of the Institute of Pathology and Anatomy of the Vienna Polyclinic. In 1920, after the formation of the kingdom of Yugoslavia, Dr. Joannovic was invited by the government to found the first Yugoslav Faculty of Medicine, and with Dr. Batut and the late Professor Subbotic he founded the faculty. In 1926 the imposing building of the Institute of Pathology in Belgrade, projected according to the ideas of Professor Joannovic, was completed. His work on cancer research is known in all scientific institutions of Europe. After the death of Professor Paltauf Dr. Joannovic was invited to take the chair of his former teacher, in Vienna, but he refused the offer. He was dean of the Faculty of Medicine in Belgrade and a permanent member of the International Office for Public Hygiene in Paris, where he represented his country for many years.

Marriages

JESSE NEWMAN McLANE, Pensacola, Fla., to Miss Marguerite Brittain Thompson of Tallahassee, May 4.

REX T. HENSON, Coeur d'Alene, Idaho, to Miss Edna Stoner of Spokane, Wash., June 2.

RUFUS CARTER ALLEY, Lexington, Ky., to Mrs. Frances Head Hudson, June 10.

CARNOT H. SHERMAN, Oakes, N. D., to Miss Hila Smith of Anoka, Minn., June 8.

RAYMOND R. RICHARDS, Blair, Wis., to Miss Alice Thwing of Augusta, June 10.

GLENN HALL RICKS, Brady, Texas, to Miss Mary Boyd Fleming, June 3.

Deaths

Henry Cottrell Rowland, Washington, D. C.; Yale University School of Medicine, New Haven, Conn., 1898; veteran of the Spanish-American War; war correspondent for *Collier's Weekly* and accredited special agent of the intelligence department, U. S. Navy, in France in 1918; author of several novels and short stories; aged 59; died, June 6, of asphyxia due to lymphosarcoma.

William Ellery McDuffie, Olean, N. Y.; University of Buffalo School of Medicine, 1888; member of the Medical Society of the State of New York; formerly health officer of Olean; past president of the board of education; on the staff of the Olean General Hospital; aged 74; died, June 12, at the Buffalo (N. Y.) General Hospital, of acute agranulocytic angina.

William M. Robertson, St. Louis; University of Virginia Department of Medicine, Charlottesville, 1889; member of the American Urological Association; fellow of the American College of Surgeons; on the staffs of the Jewish and St. Louis City hospitals; aged 67; died, June 6, of chronic myocarditis, uremia and chronic nephritis.

John Eddy Luckey, Vinton, Iowa; Rush Medical College, Chicago, 1897; for many years president of the board of education; fellow of the American College of Surgeons; on the staff of the Virginia Gay Hospital; aged 66; died, June 29, in the University Hospital, Iowa City, of thrombosis and pneumonia.

Clarence Wyman Fipphen, Shrewsbury, Mass.; Harvard University Medical School, Boston, 1919; member of the Massachusetts Medical Society; served during the World War; formerly member of the school committee and local board of health; aged 39; died, May 7, of heart disease.

William Sinn Gardner, Elkton, Md.; College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1889; for many years medical examiner for the Mutual Life Insurance Company, New York; aged 67; died, June 5, in Towson, of cerebral hemorrhage.

Charles W. Shaff, Lewiston, Idaho; State University of Iowa College of Medicine, Iowa City, 1881; member of the Idaho State Medical Association; fellow of the American College of Surgeons; on the staff of St. Joseph's Hospital; aged 77; died, June 22, of cerebral hemorrhage.

Thomas Edward Walton Grover, Huntington, W. Va.; University of Michigan Medical School, Ann Arbor, 1877; University of Louisville (Ky.) School of Medicine, 1883; formerly city and county health officer; aged 76; died, May 28, of pernicious anemia.

Moe Lenkowsky, Brooklyn; St. Louis University School of Medicine, 1928; member of the Medical Society of the State of New York; on the staffs of the Jewish and United Israel-Zion hospitals; aged 30; died, June 20, of acute myocarditis and leukemia.

Henry William Rice, Columbia, S. C.; Medical College of the State of South Carolina, Charleston, 1896; member of the South Carolina Medical Association; aged 64; on the staff of the Columbia Hospital, where he died, June 24, of heart disease.

William Joseph Egan, Chicago; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1905; on the staff of St. Bernard's Hospital; aged 58; died, July 7, of cerebral hemorrhage.

Katherine Berry Richardson, Kansas City, Mo.; Woman's Medical College of Pennsylvania, Philadelphia, 1887; aged 75; founder of the Mercy Hospital, where she died, June 3, of a ruptured gallbladder and peritonitis.

James Franklin Donnelly, Portland, Ore.; University of Pennsylvania School of Medicine, Philadelphia, 1908; on the staff of the Good Samaritan Hospital; aged 49; was found dead in bed, June 28, of heart disease.

Percy A. Scollick, Kansas City, Kan.; Western University Faculty of Medicine, London, Ont., Canada, 1912; on the staff of the Providence Hospital; aged 44; was found dead, June 27, of coronary infarction.

Charles U. Davis, Fredericktown, Mo.; Beaumont Hospital Medical College, St. Louis, 1898; member of the Missouri State Medical Association; aged 61; died, May 4, of coronary occlusion and arteriosclerosis.

Ernest E. MacLeod, Los Angeles; University of Oregon Medical School, Portland, 1906; aged 62; died, May 9, in the Los Angeles County General Hospital, of inguinal hernia and arteriosclerotic heart disease.

Tracy George Russell, San Francisco; Columbia University College of Physicians and Surgeons, New York, 1899; on the staff of the Southern Pacific Hospital; aged 60; died, June 18, of heart disease.

Winifred Mason Dowlin, Claremont, N. H.; University of Vermont College of Medicine, Burlington, 1892; member of the New Hampshire Medical Society; aged 67; died, April 12, of arteriosclerosis.

John Leonard Smith, Pittsburgh; Temple University School of Medicine, Philadelphia, 1915; aged 42; on the staff of the Allegheny General Hospital, where he died, June 21, of acute appendicitis.

Frederic John Patton, New York; University of Minnesota Medical School, Minneapolis, 1899; served during the World War; aged 63; died, June 8, in the New York Polyclinic Hospital, of leukemia.

Sol Spainhour Flynt, Rural Hall, N. C.; College of Physicians and Surgeons, Baltimore, 1889; bank president; member of the school board; aged 72; died, June 15, of chronic myocarditis.

William Joseph Langan, St. Louis; Missouri Medical College, St. Louis, 1875; member of the Missouri State Medical Association; aged 82; died, May 22, of chronic myocarditis.

William John Shields, Sarasota, Fla.; Long Island College Hospital, Brooklyn, 1897; aged 61; died, June 24, in the Cleveland (Ohio) Clinic Hospital, of cerebral hemorrhage.

George M. Haywood, Minneapolis; Homeopathic Medical College of Missouri, St. Louis, 1881; aged 76; died, June 18, of coronary sclerosis and myocarditis.

William F. Waters, Flat Rock, Tenn.; Meharry Medical College, Nashville, 1910; aged 50; died, June 17, in Nashville, of cerebral edema and pneumonia.

Shandy Z. Holland, Daytona Beach, Fla.; Missouri Medical College, St. Louis, 1890; formerly mayor; aged 72; died, May 21, of hypostatic pneumonia.

Susan Fairfield Laird, Blytheville, Ark.; Hahnemann Medical College and Hospital, Chicago, 1905; aged 75; died, May 25, of cerebral hemorrhage.

William Price Scott, Stockton, Calif.; California Medical College, San Francisco, 1899; aged 67; died, May 10, of arteriosclerosis and coronary occlusion.

Horace Tennent Dodge, Long Beach, Calif.; Hahnemann Medical College, San Francisco, 1887; aged 76; died, June 13, of acute dilatation of the heart.

William Lincoln Barnes, Atlanta, Ga.; University of Louisville (Ky.) School of Medicine, 1884; aged 70; died, June 24, of diabetes mellitus.

Charles Eugene Bryant, Blackfoot, Idaho; Minnesota Hospital College, Minneapolis, 1885; aged 84; died, April 2, at Pocatello, of nephritis.

Henry Nathaniel Scholl, Green Lane, Pa.; Jefferson Medical College of Philadelphia, 1907; aged 49; died, April 5, of cerebral hemorrhage.

John Benjamin Adams, Honea Path, S. C.; University of Georgia Medical Department, Augusta, 1905; aged 51; died, June 1, of pneumonia.

John Crittenden Jordan, Detroit; University of Tennessee Medical Department, Nashville, 1894; aged 73; died, June 18, of chronic nephritis.

John M. Christian, Hamilton, Ga.; University of Georgia Medical Department, Augusta, 1892; aged 59; died, May 2, of chronic myocarditis.

W. M. Weatherall, Star City, Ark.; Physio-Medical College of Texas, Dallas, 1906; aged 64; died, June 12, in Pine Bluff, of gastritis.

Bureau of Investigation

THE WESTERN MEDICAL CORPORATION

Selling Phenobarbital (Luminal) as a Mail-Order Treatment for Epilepsy

The Western Medical Corporation is a later name for what was earlier known as the Western Medical Association. The concern sells on the mail-order plan what the public is led to believe is a cure for epilepsy. For some years it did business from 137-143 W. 62nd St., Chicago; recently (June, 1933) it moved to 415-423 W. 39th St., Chicago.

The Western Medical Association was the subject of an article in this department of *THE JOURNAL*, Jan. 28, 1922. It was brought out in this article that J. B. Creevy and W. W. Lister, M.D., were the two men mainly concerned in operating this piece of mail-order quackery. The public had no means of knowing that Dr. Lister was in any way connected with the Western Medical Association, and part of the advertising "come-on" sent out by the concern was a photographic facsimile of what was described as an "unsolicited letter" from Dr. Lister on his professional stationery, puffing the Western Medical Association's alleged treatment.

J. B. Creevy has also been connected with other mail-order quackeries, the Van Ard Sanatorium and the so-called Cass Treatment, both of them alleged cures for rheumatism.

In 1928 the Western Medical Association changed its name to the Western Medical Corporation. According to information furnished by the Secretary of State of Illinois, the Western Medical Corporation was incorporated in the State of Delaware and licensed to transact business in the State of Illinois as a foreign corporation in April, 1933. According to the same source of information, J. B. Creevy is its president.

Creevy's name appears nowhere in the advertising. The name that is played up is that of Harry L. James, M.D., who is described as the vice-president of the corporation and as the "directing physician." Harry L. James was born in Springfield, Ill., in 1885 and holds a diploma from Northwestern University Medical School, 1911, and an Illinois license granted in 1912. Needless to say, the man is not a member of his local medical society or of the American Medical Association. An important part of the advertising ballyhoo of the Western Medical Corporation is a six-page puff of Harry L. James, M.D., written by Harry L. James, M.D. In this Dr. James capitalizes his dead father's work and even his grandfather's work as physicians, although, so far as our records show, neither of these older men was even remotely connected with mail-order quackery. No small amount of space in this autobiography of Harry L. James is given to his exploits during the World War and how he came to be awarded an engraved "Roll of Honor" certificate. The sum and substance of this autobiography is, however, to emphasize that Harry L. James is one of three generations of physicians and that he specializes in the "treatment of epilepsy attacks."

In the advertising Dr. James would have the public believe that he is peculiarly well qualified to treat cases of epilepsy. A most careful search of medical literature from the time of Dr. James' graduation until June, 1933, fails to show that he has contributed a single article on any medical subject in any reputable medical journal.

In the autobiography already referred to, Dr. James says to the prospective victim that he is sending the advertising matter to him "with the thought that perhaps there is no physician near you who is thoroughly acquainted with the most up-to-date methods of treating epilepsy attacks."

In the first article published on this concern, a detailed report was given of the findings of the A. M. A. Chemical Laboratory of the so-called "Western Medical Association Treatment." The tablets that were furnished at that time came in three boxes labeled, respectively, A, B and C. Box A was found to contain what were essentially one-grain tablets of phenobarbital (luminal). Box B contained tablets that had the general characteristics of those unscientific mixtures of pepsin, pancreatin, etc., vaguely described as "digestive tablets." Box C contained a laxative—tablets that responded to tests for emodin-bearing drugs and aloin.

In other words, this treatment is essentially the administration of phenobarbital to persons Dr. James never sees and sent out in a secret mixture on the mail-order plan for the self-treatment of a serious condition—epilepsy. To even an intelligent layman it should be obvious that there is neither moral nor scientific excuse for business of this kind.

THE GLOW OF LIFE FRAUD

Another Aphrodisiac Fake Debarred from the Mails

"Glow of Life" is a nostrum that was put out by the Glow of Life Laboratories Company of Columbus, Ohio. The company was owned and operated by Frank J. Albert and his brother, Ray J. Albert. Frank J. had no medical training or experience; Ray J. was a registered pharmacist. In March of this year, the Post Office Department sent the company a copy of a memorandum of charges calling upon the company to show cause why a fraud order should not be issued against it. At the time set for the hearing, no one appeared at Washington, but the lawyer for the company filed a written reply to the memorandum of charges. Judge Horace J. Donnelly, Solicitor for the Post Office Department, in his memorandum to the Postmaster General recommending the issuance of a fraud order, stated that the Glow of Life Laboratories Company advertised "in various publications of a kind which are not particular as to the character of the advertisements which

GLOW OF LIFE

**Helps You Overcome
Your Sexual Weaknesses**

Newest, greatest, most effective and safest sexual rejuvenator, stimulant and tonic known for weak, deficient, starved and abused conditions of the sex glands caused by impotence, advanced age, sexual excesses, fast living, late hours, nervousness, over-work, worry, disease, etc. Used by men and women everywhere. Easy to take. Results will more than surprise you. Don't take chances or waste your money on other worthless and harmful preparations, when only Glow of Life can help you. Satisfaction guaranteed or money refunded. All correspondence confidential. Correspondence with physicians invited. Mailed to you in plain sealed package, postpaid 24 tablets for \$1.00; 100 for \$3.00; 200 for \$5.00. Druggists and agents write us for our special proposition.

GLOW OF LIFE LABORATORIES CO.
Dept. C-2, P. O. Box 744, Columbus, O.

Typical advertisement of "Glow of Life." This appeared in *Cloverleaf American Review*, May, 1932.

they print, including magazines whose principal contents are pictures of nude females and stories of a salacious character."

Those who answered the advertisements were sent a circular entitled, "Glow of Life, The Fountain of Youth, A Remedy That Will Help You To Overcome Your Sexual Weaknesses." With the circular came an order blank which contained the statement: "Our reputation and standing as manufacturing pharmacists and chemists is back of every order we send out."

The postal authorities in their investigation discovered that the Glow of Life Tablets were actually manufactured for the promoters by another concern. The tablets sold for \$1 a package of twenty-four, or about 4 cents a tablet. They consisted, according to the government's report, essentially of nuxvomica and zinc phosphide, together with chalk and gum. The promoters had claimed that they also contained arsenic, gold, cantharides (Spanish fly) and laxatives. None of these were found.

The government presented expert medical evidence to prove that these tablets would not restore "lost manhood" or cure sexual impotence or frigidity. It also brought out the fact that the ingredients of Glow of Life Tablets have been incorporated in other preparations sold under similarly fraudulent claims in cases wherein fraud orders have been issued against the promoters of such schemes; yet, the Glow of Life concern claimed that their product was an original discovery!

In view of the findings, Judge Donnelly recommended the issuance of a fraud order and on April 26, 1933, the Hon. James A. Farley, Postmaster General, issued such an order, closing the mails to the Glow of Life Laboratories Company.

Correspondence

ALIMENTARY ANAPHYLAXIS AND FEVER OF UNKNOWN ORIGIN

To the Editor:—On page 1958 of *THE JOURNAL*, June 17, the answer to a question concerning fever of unknown origin makes no mention of the possibility of alimentary anaphylaxis as a cause of fever.

To test this possibility, all food should be omitted for a period of forty-eight hours, the patient being given nothing by mouth except water. Disappearance of the fever during this time will indicate that its origin was due to alimentary anaphylaxis. The particular food responsible can then be determined by adding articles of diet one by one.

A. Haritantis (*Presse méd.* 41:119 [Jan. 21] 1933; abstr. *THE JOURNAL*, April 1, p. 1072) describes such a case of alimentary anaphylaxis with prompt disappearance of fever on omission of food. There are many points in common between the case of Haritantis and the patient of your correspondent, such as daily exacerbations of fever, absence of leukocytosis and negative general examination except for enlargement and tenderness of the liver.

This hypothesis of alimentary anaphylaxis is so easy to establish or to refute by the simple omission of food that it should be considered in all cases presenting frequently occurring chills or fever without obvious cause.

JOHN E. WALKER, M.D., Opelika, Ala.

VENOUS PRESSURE

To the Editor:—Concerning "A Clinical Method of Venous Pressure Determination" by H. F. Robertson (*THE JOURNAL*, July 15, p. 206), several important facts must be noted. It has been shown that the level of collapse is altered by the speed at which the arm is raised—very slowly, slowly, or rapidly. The tonus and irritability of the vessel wall and exercise of the part must be considered. The Gärtner and Frey methods of estimation of venous pressure have not come into general use because these simple methods of estimation are not sufficiently accurate.

Variations of venous pressure in conditions other than cardiac decompensation occur, obesity, pregnancy, the menopause, pneumothorax (tuberculosis), mediastinal disease, and emphysema and dyspnea resulting from it. Kroetz, in 1922, showed a rise in venous pressure in pneumothorax. "Essential venous hypertension" might be mentioned.

Engorged jugular veins, passive congestion in the lungs and elsewhere, cyanosis or subcyanosis, and enlarged tender liver are usually present when the venous pressure is increased in the arm. However, the clinical determination of the venous pressure in the arm may give earlier indications of beginning myocardial failure. In such cases decholin (intravenous) injections will give a delayed bitterish taste in the tongue and mouth and indicate early circulatory failure.

While visiting (1929 and 1931) in the Rudolph Schmidt medical clinic of the German University of Prague, I saw Winternitz and others use intravenous decholin injections as a useful means of rating cardiovascular insufficiency. The exact time interval from the moment of intravenous injection to the first appreciable bitterish taste in the tongue is used as the guide. This is increased in early myocardial failure.

Vaquez of Paris stated in 1924 that Frey's method and Gärtner's method are both unreliable. He concludes that "it appears that at present the study of venous pressure can scarcely instruct us in the normal or deficient resistance of the heart. It must be left for the future to decide whether, by perfecting the methods, these interesting but still limited ideas are suscep-

tible of development, and of opening to the clinician new paths in cardiac or venous pathology."

William Evans of Detroit said, in 1932, "the estimation of venous pressure has not come into general clinical practice apparently because simple methods of estimations are not sufficiently accurate or because the more exact methods are not sufficiently simple."

HYMAN I. GOLDSTEIN, M.D., Camden, N. J.

"THE RESIDUAL EFFECTS OF WAR GASES"

To the Editor:—In *THE JOURNAL*, May 13, appears an editorial review of Gilchrist and Matz's article on this subject. In this editorial the statement is made that "mustard gas as used in the World War caused untold misery." It is believed that this statement may possibly create an impression that you do not wish to convey, for when the general effect of the use of mustard and other chemical agents in war is considered, exactly the opposite is found to be true. Mustard and other chemicals reduce the misery that is incident to warfare.

This point is best illustrated by a study conducted by Col. Albert G. Love of the Medical Corps of the United States Army. This study on war casualties was printed as Army Medical Bulletin 24. We in the service consider this work the outstanding statistical contribution pertaining to war data.

The following figures taken from Colonel Love's work show how much in the way of death and misery chemical weapons have avoided, and it should be remembered that mustard gas was the most effective of all chemical weapons. On page 111:

"The percentage of killed to wounded would then be:

"(a) 16 per cent when there are both gas and gunshot wounded;

"(b) 20 per cent when there are only gunshot wounded."

An analysis of these figures shows that when gas is added to other implements of warfare fewer men will be killed; the exact saving in life is 20 per cent. This does not mean that gas kills 20 per cent less than other weapons. Gas kills few, but when gas is used along with other weapons the death rate is reduced as quoted. This means that 20 per cent fewer families will lose loved ones during war. Is this not a misery-reducing factor?

I wish also to call your attention to pages 49 and 50 of the study mentioned. On page 49 you will see that almost 90 per cent (to be exact, 89.18 per cent) of the individuals whose battle injuries are caused by poisonous gas make a complete recovery and are able to return to full military duty, while you will notice that over one third of all of the casualties that are caused by gunshot injuries are rendered unfit for any further military service. Please notice that here we have war gases or chemical weapons avoiding over two thirds of the wartime misery. It is also worthy of note in connection with these two tables that on page 49 one finds that less than 2 per cent (1.73 per cent, to be exact) died in hospital from chemical injuries, while 8.12 per cent of those whose injury was caused by gunshot wounds died in hospital. Here again it is found that chemical weapons effect a reduction of the death rate of almost 80 per cent, and the consequent reduction in the misery that the families suffer is certainly equally great.

Please do not think that I am one of that group who make themselves ridiculous by referring to any weapon as "a humane weapon." I do not believe there is anything humane about war. But I do think that war is a very human eventuality that the world will always be confronted with, and I also think that a weapon can be a highly efficient agent for the production of casualties and still help to reduce the misery that is an incident of war.

LEON A. FOX, M.D., Washington, D. C.
Major, Medical Corps, U. S. Army.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

TONSILLECTOMY IN SMALL CHILDREN

To the Editor:—What is the present attitude toward tonsillectomy in small children? I have advised this operation for a child aged 2½ years, who is suffering from bronchial asthma. The attacks recur approximately at intervals of six weeks. Skin tests are negative and elimination diets have given no results. Roentgenograms show infected antrums. The tonsils are moderately enlarged and chronically inflamed. The parents have been advised elsewhere against tonsillectomy. Please omit name.

M.D., Michigan.

ANSWER.—The attitude toward tonsillectomy in young children should be conservative. Occasional attacks of tonsillitis running a mild course unassociated with cervical adenitis and, of course, such other things as involvement of the endocardium should not make operation imperative. There is no set age limit, but many men like to wait until 3 or 4 years of age. As far as bronchial asthma is concerned, it is the consensus of most authorities in the field of allergic diseases that tonsillectomy neither prevents nor cures bronchial asthma. Of course, a child with asthma may have badly infected tonsils, like any other child. In this event the question should be settled on its own merits and without regard to the lung condition, unless this is so severe as to be a positive contraindication. Roentgenographic evidence does not make the diagnosis of infected sinuses. The shadow so frequently seen in allergic individuals may just as easily be due to an edematous polypoidal nonsuppurative involvement of the sinus mucosa as to a purulent condition. The roentgenographic evidence should be coupled with a search in the nose for the presence of pus; if this is present and does not yield to conservative measures such as suction and astringents, one should carry out lavage or at least diagnostic puncture, in this case preferably under gas anesthesia. An asthmatic child with a suppurative sinusitis of any degree does better when this condition is removed.

CARITOL AND CAROTENE

To the Editor:—I have seen statements that Carotene as sold by the S. M. A. Corporation in the form of Caritol is recommended for treatment of cataract. Is there any justification for this statement? Has Caritol been accepted by the Council on Pharmacy and Chemistry? In an advertisement of the S. M. A. Corporation there appears the following statement: "Cod Liver Oil, halibut liver oil and other fish oils do not contain carotene (primary vitamin A), and the secondary form, which they do contain, cannot be converted into primary vitamin A. Carotene should be prescribed either alone or with other vitamin products." This implies that Carotene should be added to fish liver oils. Is there any justification for this belief? Is Carotene any better than vitamin A? Please omit name.

M.D., Ohio.

ANSWER.—The claim for the value of carotene in the treatment of cataract is apparently based on the reprint of an article by Dr. T. H. Shastid (Carotene and Cataract, *American Medicine*, January, 1933). This report has been circulated widely among physicians. The only part of Dr. Shastid's paper dealing with the announced subject is a short paragraph in which he reports that in "three fairly advanced cases" of cataract he had "excellent results with Caritol." In the three succeeding paragraphs the increase of visual acuity in patients is given and the author urges "other oculists to try out caritol thoroughly," remarking that "whenever it does no good, it will do at least no harm." This may be true; but if it "does no good" the patient loses time and money to gain the increased visual acuity which, today, operative procedure can certainly give. The remainder of Dr. Shastid's article deals with quite other matters. The statement elsewhere in the article that Caritol had apparently desensitized to "house-dust" allergy and had given a "decided increase in her hearing power" to a patient is hardly scientific.

It is, of course, misleading for the firm to base claims of the value of "Caritol" in the treatment of cataract on the casual report of three cases. The Council on Pharmacy and Chemistry has recognized no such claims for Carotene or for vitamin A as contained in fish liver oils or concentrates. It is surprising, to say the least, that the firm should be advancing such claims.

The statement quoted by our correspondent is found in an advertisement appearing on page 2, *Medical Economics*, April, 1933. It is a masterpiece of misrepresentation. The fact that fish oils do not contain carotene has nothing whatever to do with their therapeutic value and the fact that the vitamin A

which they do contain cannot be converted into carotene is also entirely beside the point, since it would be ridiculous to desire to have the "finished vitamin" converted into an inert precursor. Interpreted strictly, the statement in the last sentence of the quotation implies that carotene *should* be prescribed in order to bring about desired therapeutic results; at most, one might be justified in saying that "carotene" may be so prescribed, which is an obvious platitude. In this quotation, as in other advertising propaganda, the firm stresses "primary" vitamin A as if it had some superior virtue. As a matter of fact its value apparently depends on its being converted into true vitamin A, which the firm attempts to belittle by the designation "secondary form." There is evidence that carotene is by no means always converted quantitatively into vitamin A or its equivalent; so that the relative importance would seem to be in favor of the fully formed or "secondary" form as of foremost significance. Furthermore, it is debatable whether one ought in fairness to refer to carotene as "primary vitamin A." The false implication is that carotene actually is a kind of vitamin A, whereas it is merely a mother substance or possible forerunner of the vitamin itself.

CREOSOTE BURNS OF THE EYE

To the Editor:—During the past year I have had several cases of burns of the conjunctiva caused by creosote getting in the eye. These burns have been rather persistent (from ten to twelve months), manifesting themselves with severe conjunctivitis with no evidence of adhesions between the bulbar and palpebral conjunctiva. I should like to know whether there is anything in creosote that would cause this condition to persist. It might be some other chemical than creosote causing this condition. If you have any idea what this chemical is, please let me know. I have also noticed that, following traumatic eye conditions and foreign bodies in the eye, these cases have had a great deal of meibomian gland infection. When pressure is exerted on these lids, pus can be seen exuding from the ducts of the glands and in some cases this infection is rather difficult to clear up. I should like to know whether this type of infection is common following traumatic injuries and foreign bodies of the eye. Please omit name.

M.D., Texas.

ANSWER.—Creosote is a name applied to a complex mixture of phenols and their ethers produced in the fractional distillation of wood tar. It is also applied to a similar product obtained from coal tar. Both products are usually brownish, because of impurities; pure creosote is colorless. It is impossible to say whether the irritative effect on the conjunctiva is due to one of the phenols or to one of the ethers or to some impurity. In all probability the compound causes a chemical irritation due to a low degree of superficial burn of the conjunctival epithelium which destroys the integrity of the tissues. It is not probable that any of the creosote remains on or in the tissues to produce continued burning. The persistent conjunctivitis is due to secondary infection that is difficult to control owing to the altered character of the epithelium in which the infection is found. Mechanical lavage with non-irritating solutions will prove more efficacious in the long run than bactericidal agents.

Infection of the meibomian glands of the eyelids is common following trauma to the eye and is best treated by frequent and repeated massage of the eyelids.

LEAD POINTS IN ELECTROCARDIOGRAPHY

To the Editor:—In THE JOURNAL, Oct. 1, 1932, in Carter's article on electrocardiography, page 1171, it is stated "that the three lead points, when connected, form a triangle, which can be considered to be essentially equilateral (fig. 7). Electrically and geometrically lead 2 is equal to the sum of lead 1 and 3 and therefore . . ." I cannot see the application. Will you please set me right. Please omit name.

M.D., Pennsylvania.

ANSWER.—The three lead points universally used in electrocardiography, as Einthoven has indicated, constitute the vertices of a triangle which can be considered to be essentially equilateral. The projections of the total resultant heart potential in the plane of the chest on the sides of this imaginary triangle represent the potential differences at any given period in the cardiac cycle recorded by the electrocardiograph for the various leads. The projection on the side connecting the right arm and the left arm represents the potential of lead 1; on the side connecting the right arm and the left leg, potential of lead 2, and that on the remaining side the potential of lead 3. These potentials may be likened to the drops in voltage over three resistances connected to form a triangle. In such a closed network it is known by Kirchhoff's Law that the algebraic sum of the potential drops is equal to zero. Hence the potential in lead 2 at any instant equals the sum of the potentials in leads 1 and 3 at the same instant. From an inspection of figure 7 (page 1172) it is evident that, if potentials in leads 1 and 3 are considered

positive, the potential in lead 2 must be considered negative. Further discussion may be found in "The Mechanism and Graphic Registration of the Heart Beat," by Thomas Lewis, London, Shaw and Son, 1925, page 107.

DIET IN GOUT

To the Editor:—Please designate the articles of food in the following list which may be permitted to a patient with chronic gout (medical textbooks are either indefinite on the subject or do not mention this group):

| | | |
|---------------|------------------|------------------|
| Cranberries | Tomatoes, juice | Turnips |
| Clam chowder | Tomatoes, stewed | Cabbage |
| Oyster soup | Bananas | Corned beef |
| Corn bread | Strawberries | Malted milk |
| Rye bread | Cherries | Bacon |
| Stewed corn | Rhubarb | Ham |
| Sauerkraut | Lentils | Avocado |
| Salmon | Dried prunes | Peanut butter |
| Lamb, roast | Sweet potatoes | Cherries (fresh) |
| Tomatoes, raw | Beets | |

Is there a book that contains a complete and detailed list of foods which may be given patients in various diseases and which should be prohibited?

EMIL KRULSH, M.D., Portland, Ore.

ANSWER.—Usually in a case of gout the foods containing purines are restricted. The amount of purine in the various foods can be determined from the quantitative tables compiled by J. Walker Hall. Unfortunately not all foods are listed, but as far as we can determine in the list submitted in the question we are able to give the following:

Foods allowed: corn bread, rye bread, stewed corn, raw tomatoes, tomato juice, stewed tomatoes, bananas, strawberries, fresh cherries, canned cherries, rhubarb, sweet potatoes, beets, turnips, cabbage, malted milk, avocado pear, peanut butter, prunes.

Foods restricted: cranberries, clam chowder, oyster soup, salmon, lamb roast, lentils, corned beef, bacon, ham, sauerkraut (because of heavy seasoning).

Detailed diet lists may be found in the following books:

- McLester, J. S.: Nutrition and Diet in Health and Disease, Philadelphia, W. B. Saunders Company.
Baer, Oscar: Diet Prescriptions, Niagara Falls, N. Y., Aronson's Service and Supplies.
Friedenwald, Julius, and Rubrah, John: Diet in Health and Disease, Philadelphia, W. B. Saunders Company.
Hall, J. W.: Purine Bodies in Foodstuffs, London, 1903, quoted by Carter, Howe and Mason: Nutrition and Clinical Dietetics, 1923.

USE OF SPECTRUM ANALYSIS IN LIVING HUMAN BODY

To the Editor:—Is it possible by means of the x-rays or other instrumentality to determine intra vitam the organic constituents of bone and other tissues of the body by spectrum analysis and, if so, quantitatively?

THOMAS I. O'DRAIN, M.D., Philadelphia.

ANSWER.—The conditions under which spectrum analysis of organic materials must be carried on preclude its application to the living human body. Such methods could be applied only to tissues removed at biopsies or to samples of blood, urine or the like. While hemoglobin, and possibly some other substances, might be uncertainly recognized in an analysis of light that had passed through the ear or the hand, the opacity of human tissues is too great to permit the obtaining of any definite results; certainly, no quantitative results are possible.

Some inorganic constituents may be identified by x-ray spectrum analysis, such as CaCO_3 , $\text{Ca}_3(\text{PO}_4)_2$ in bone (n being not less than 2 nor greater than 3). Or they may be excluded, as CaHPO_4 or CaC_2O_4 (Roscherry, H. H.; Hastings, A. B., and Morse, J. K.: X-Ray Analysis of Bone and Teeth, *J. Biol. Chem.* 90:395 [Feb.] 1931). Some approximate quantitative estimates by x-ray spectrum analysis have been made on material removed from bodies.

OPTIMUM ATMOSPHERIC CONDITIONS IN HOSPITALS

To the Editor:—Inquiry has been made of me regarding the optimum atmospheric conditions for hospital operating and convalescing rooms. I should like to have your opinion regarding conditions of temperature, humidity and air motion which should be maintained in such places. I should also appreciate your opinion as to whether or not conditions should be varied for different types of operations. Any data will also be appreciated which you may have on convalescing rooms. Several of the hospitals in town are interested in air conditioning and I should like to assist them in the selection of equipment but do not wish to make any recommendations until I have additional information from some authority as to what conditions should be maintained. I am therefore requesting that you give me the benefit of your experience in this matter.

OTIS L. TURNER, Engineer, Washington, D. C.

ANSWER.—The optimum atmospheric conditions for an operating room in a hospital are a temperature of from 74 to 76 F. and a relative humidity of from 50 to 55, with a ventilation circulation of four or five air changes an hour. There is

no reason why these optimum conditions should vary with the type of operation performed.

In convalescing rooms a comfortable temperature is of more importance than the relative humidity, although a desirable humidity has admitted value. For convalescent wards the optimum temperature is from 68 to 70 F. in the daytime and somewhat lower than this at night, with a relative humidity of from 50 to 60 and a ventilation circulation of four or five air changes an hour.

The relative humidity most suitable often depends on the disease. Pneumonia patients and those suffering from bronchial conditions will often find relief in a low relative humidity (from 20 to 25), while in another section of the same hospital, in the nursery department, a high humidity, approximating 60 to 65, is most satisfactory.

CHRONIC NONSPECIFIC PROSTATITIS

To the Editor:—Will you please outline the treatment for chronic nonspecific prostatitis? My patient has had massages for more than a year by a urologist but still he has recurrences with fever and violent headaches. Smears and cultures have shown *B. coli* as the predominating organism. No history of gonorrhea has been given and repeated Wassermann tests are negative. He is able to go about his business most of the time and otherwise appears good except for a spastic colon. Roentgenograms of the chest are negative also. Any recent advances or suggestions would be especially appreciated. Please omit name and address.

M.D., Illinois.

ANSWER.—A recurrent nonspecific prostatitis is rarely primary. This patient should be studied for other foci of infection which may be responsible for the recurrence of the prostatitis. The fact that he has a spastic colon is rather suspicious. Calculi in the follicles of the prostate gland are at times the cause of persistence or recurrence of infection. A roentgenogram should reveal such calculi. An autogenous vaccine, although rarely helpful, might be tried.

METABOLIC DISORDER WITH GLYCOSURIA AND DISTURBANCE OF WATER BALANCE

To the Editor:—A woman, aged 46, came under my care a year ago when she had an acute infection of the upper respiratory tract. Diabetes had been diagnosed several years before, when, according to the history, a bowel resection was done, but the diabetic condition had never been treated. She has one grown child. When she went to bed with the respiratory condition, she weighed 215 pounds (97.5 Kg.); on recovery, she weighed 195 pounds (88.5 Kg.). Though when I first saw her one drop of urine reduced 5 cc. of Fehling's solution, sugar has at most times been eliminated from the urine by dieting alone. A few recurrences have lasted less than a week. Cooperation has been so good that it has never been necessary to resort to the use of insulin. However, attempts to bring her down to approximately normal weight have failed. The basal metabolic rate on two occasions has been -5 and -15; the systolic blood pressure runs from 160 to 170 mm. An electrocardiogram was typical of hypertension but otherwise negative. Thyroid has been given up to 12 grains (0.78 Gm.) a day and diet has been reduced to 900 calories or less, but the weight remains between 185 and 190 pounds (84 and 86 Kg.). When thyroid is discontinued, she gains rapidly. Calcium has been given almost continuously and pituitary and ovarian extracts have been combined with the thyroid for short periods. The pulse rate has not gone above 106, but after a few days, on large doses of thyroid, edema of the legs becomes marked with increase of weight. Please omit name, M.D., Illinois.

ANSWER.—There are two problems in this case. The mild glycosuria described in association with obesity and hypertension probably belongs to the type of mild diabetes often seen with this combination. Usually it is not only unnecessary but unwise to use insulin, for when the weight is reduced to normal the glycosuria is apt to disappear.

In considering the question of the patient's obesity, attention should be called to the fact that during the infection of the upper respiratory tract she lost 20 pounds (9 Kg.). This fact in itself shows that the patient can lose weight. Also, the interesting observation regarding the appearance of edema of the legs brings up the question as to how much of her weight increase is due to a disturbance of water balance. It may be that in addition to a marked restriction of calories attention should be paid to the salt and water intake, both of which should be definitely limited. The total sodium chloride intake should be restricted to the amount natural in foods, and the patient should add no salt to any of her food. The fluid intake might well be restricted to 1,000 cc. or, at the most, 1,500 cc. daily. In addition, some type of diuretic drug, such as ammonium chloride, by mouth, or one of the mercurials, such as salyrgan intravenously, might be given a trial.

Until efforts to correct the possible error in water balance are tried, it would seem unwise to attempt other forms of therapy. Naturally, however, a low caloric diet must be maintained.

USE OF MERCUROCHROME INTRAVENOUSLY
IN GONORRHEA.

To the Editor:—Please give your opinion on the use of 1 per cent mercurochrome used intravenously in the treatment of active gonorrhea. the use of mercurochrome in certain high concentration applied locally as an antiseptic, and the use of merthiolate, 1:1,000, used as a local antiseptic as tincture of iodine is used.

RICHARDS A. IRONS, M.D., Thomasville, Ala.

ANSWER.—This question was referred to the Brady Urologic Clinic of Johns Hopkins University Medical School, which replies:

Injections of 1 per cent mercurochrome intravenously should, of course, be combined with appropriate local treatment. Even when the infection has become well established and has resisted various types of local treatment, the eradication of the infection can be hastened by intravenous injections of mercurochrome in many cases, according to published reports. Also, if used soon after the onset of complications, such as acute epididymitis and acute prostatitis, the duration and severity of these complications are appreciably shortened. The intravenous injections of mercurochrome are an important adjunct to the therapy of gonorrheal rheumatism in the acute, subacute and chronic forms. In the acute, extremely painful joints, this form of treatment, it is reported, is often followed by marked relief of discomfort and inhibition of the destructive process.

As with other forms of specific or nonspecific therapy, intravenous mercurochrome should not be used unless one has been assured by physical examination that there is no preexistent cardiorenal disease. The patient should be warned that in about one hour's time a reaction is to be expected, manifested by malaise, chill, fever, nausea and, perhaps, vomiting. The best results are usually obtained in cases presenting such a reaction. In some cases, some vague abdominal discomfort may occur, accompanied by slight diarrhea. It is, therefore, customary to instruct these patients to go home to bed immediately following the injection, but the reports do not indicate a reaction of sufficient severity to require hospitalization. In adults, a dosage of 12 cc. of a 1 per cent solution is used and, at the same time, local treatment. After an interval of two or three days, an injection of 14 cc. is given, and, four days later, an injection of 16 cc. If organisms are still present, injections of 18, 20 and 22 cc. of a 1 per cent solution may be given at intervals of four or five days. However, as a general rule, definite results have been obtained usually after the first three doses. It is extremely important that only the crystals prepared for intravenous use be used. After the 1 per cent solution has been made in freshly distilled, boiled, cooled water, it must not be boiled or autoclaved.

In urologic work, mercurochrome is rarely used in stronger than a 2 per cent solution in the urethra or bladder. Occasionally, in the treatment of ulcerative lesions about the genitalia, we have used 10 and 20 per cent solutions with satisfactory results, but it must be remembered that these solutions have certain caustic effects. Brady has used 20 per cent aqueous solution in the treatment of gonorrheal vaginitis and cervicitis, applications being made with tampons.

For skin sterilization, a solution of acetone, alcohol and aqueous 2 per cent mercurochrome is used exclusively in the Brady Clinic, as it does not produce the irritation and desquamation that so often follow the use of tincture of iodine, especially about the external genitalia.

Whereas there are many antiseptics far more powerful than mercurochrome, the chief value of this drug is emphasized to be that its antiseptic action is combined with a relative lack of irritating and toxic properties.

TREATMENT OF CHRONIC MYELOGENOUS
LEUKEMIA

To the Editor:—A friend of mine, aged 31, has chronic myelogenous leukemia. His latest white cell count is 870,000, 65 per cent of the cells being myelocytes and myeloblasts. His only complaint is occasional severe priapism. There is some question as to when to begin roentgen therapy, also the use of arsenic preparations or even benzene. I would appreciate information as to best treatment, including relief and prevention of priapism. Please omit name and address.

M.D., New York.

ANSWER.—Irradiation, by either x-rays or radium, is the most effective means for the control of chronic myelogenous leukemia. It is not to be considered a cure nor will it materially prolong life, but it will increase the period of effective life and markedly alleviate symptoms. With time its effectiveness becomes less marked, the disease process becoming more refractory with each successive treatment. Treatment by radiation should therefore be conserved; the general condition and the complaints of the patient rather than the blood count should

determine whether and when such treatment should be begun or repeated.

In the present instance, with a white blood count of 870,000, of which 65 per cent are myelocytes and myeloblasts, and with the patient suffering from attacks of priapism, it would seem wise to start treatment with radiation at once.

If irradiation by x-rays is selected (as indicated by the question), a total dose of from 300 to 350 roentgens over the spleen for each series of treatments should be effective, from 100 to 116 roentgens being given each over the anterior, posterior and lateral surfaces of the spleen, at a distance of 20 inches, with 180 or preferably 200 kilowatts, with 1 mm. of copper and 1 mm. of aluminum filters, at intervals of three days. Beneficial results will probably be in inverse proportion to the number of immature or blast cells present.

Arsenic has long been used with benefit in the treatment of chronic leukemia, but with the advent of irradiation its use had all but gone out of fashion. There appears to be no good reason why arsenic should not be administered in the intervals between periods of irradiation, and, in fact, it is again being extensively used in this manner.

The use of benzene has been almost if not entirely abandoned in the treatment of leukemia in recent years on account of the difficulty of control and the adverse effect it has on the development of red blood cells.

The exact cause of priapism in leukemia is not known; it is, however, but one of many clinical manifestations of leukemia and should recede, if not disappear, as a manifestation of the disease with the benefits to be anticipated by the use of irradiation and arsenic. Other means for the control of priapism, such as the use of large doses of potassium bromide or monobromated camphor by mouth, the surgical aspiration or ligation of the corpora cavernosa, or the use of diathermy by rectum have been recommended but are of questionable effect.

USE OF IODIZED PROTEINS IN ARTERIOSCLEROSIS

To the Editor:—May I ask you to be good enough to advise me whether enough scientific data have been established between the protolipo and alkali iodides as to their absorption, systemic action, elimination and preference, especially in cases of arteriosclerosis. (I know that in syphilitic cases potassium iodide is preferable.) Should the calcium intake in case of arteriosclerosis be reduced or kept about the same level? Kindly omit name.

M.D., California.

ANSWER.—Thus far, clinical studies have failed to reveal any convincing evidence of differences in effect of the electrolytic alkaline salt iodides and iodized lipins or iodized proteins. Numerous claims of superior activity for one or another preparation have been advanced, but thorough clinical trial fails to substantiate these claims. The mechanism of action of the ordinary iodides is not understood. The most conspicuous effects are seen in the stimulation of absorption of some inflammatory exudates, particularly syphilitic gummas. The iodides do not show any germicidal power. The effects of iodides on arteriosclerosis are probably limited to the enhancement of absorption of syphilitic exudates in the arterial walls; it is most questionable whether they are of any appreciable benefit in nonsyphilitic arteriosclerosis. Certainly the iodides have no direct lowering effect on the arterial tension.

Iodine compounds with proteins and lipoids are somewhat less irritating to the alimentary tract than potassium iodide. The percentage of iodine in the various organic iodides, as listed in New and Nonofficial Remedies, varies from 18 to 80 per cent. Much variation in pharmacologic effect is therefore to be anticipated, based on weight for weight dosage; based on actual iodine ingested, the pharmacologic effect does not vary much. The iodized fatty acids produce similar systemic effects, but they are much more slowly absorbed and more slowly eliminated. Iodized fatty acids are saponified and absorbed in the small intestine, as are the ordinary fats. The chemical investigations of F. C. McLean (*Arch. Int. Med.* 15:92 [Jan.] 1915) and others have demonstrated that most of the iodine is in the lipid fraction on tissue extraction when iodized fatty acids are administered; when potassium iodide or iodized proteins were given to animals, more iodine was found in the water soluble fraction of the tissues. McLean concluded that iodized proteins and the metallic iodides have almost identical action but that iodized lipins are slowly absorbed and secreted as such. Histochemical identification of iodides in tissues is extremely difficult; as yet no wholly satisfactory method has been found (Gersh, E. I., and Stieglitz, E. J.: *Anat. Rec.*, May 1933).

In view of these considerations it is highly improbable that any appreciable difference in clinical effects could be anticipated from one or another of the various iodide compounds. Theoretically the iodized lipoids might offer some advantages:

slower absorption, milder and more prolonged action and increased lipid solubility (arteriosclerotic lesions are lipid in nature). Thus far these theoretical considerations have not received adequate clinical proof. There is no indication for radical restriction of calcium-containing foods in arteriosclerotic disease. Additional calcium medication is unnecessary and unwise.

USE OF SODIUM MORRHUATE IN THROMBOPHLEBITIS

To the Editor:—I am now treating a woman, aged 45, with varicose veins who gives a history of having had an indurated area at the lower end of the inner side of the right leg for the past four to five years. This area at times swells considerably and becomes painful. When I examined her, I found a red, very thick and indurated area at the site mentioned, which was not painful (6 cm. transverse, 4.5 cm. vertical diameter) and only slightly tender to the touch. The patient weighs 245 pounds (111 Kg.). The blood pressure is 150 systolic, 100 diastolic. The lungs and heart are normal. Urinalysis is negative except for poor concentration (the specific gravity is only 1.012). The Wassermann reaction of the blood is negative. I should like to treat this patient by the injection method. In the meantime I have advised elevation of the leg, with applications of warm boric acid solution. Would the presence of the red, indurated area be a contraindication to injection? Is chronic nephritis a contraindication? I have inquired at a local druggist concerning sodium morrhuate, mentioned by Smith (THE JOURNAL, Dec. 10, 1932, p. 2008), but the druggist was not familiar with the preparation. What is its nature and what company produces it? Is it necessary to use a tourniquet when injecting this chemical? Please let me know also whether you believe the indurated area will clear up following the injection treatment. I have informed the patient that if this lesion is neglected it will eventually form a chronic varicose ulcer. Was I correct? Please omit name and address.

M.D., New York.

ANSWER.—The description of the case suggests a superficial patchy thrombophlebitis with a tendency to recur. A search should be made for infected teeth and tonsils. If the deep veins are patent and provocative injections of a few drops of sodium morrhuate do not activate a latent phlebitis, a cautious obliteration of the veins above the thrombophlebitic induration may be attempted. Nephritis or the presence of degenerative kidney lesions does not contraindicate the injection treatment. Sodium morrhuate is the iodine salt of fatty acids of cod liver oil. A description of the product and tests for its purity appeared in THE JOURNAL, June 3, page 1766. It is available in 5 and 10 per cent solution. The Council on Pharmacy and Chemistry has accepted for inclusion in New and Nonofficial Remedies Ampules Sodium Morrhuate 5% with Benzyl Alcohol (Searle); another brand, we are informed, is before the Council for consideration. The use of the tourniquet is not obligatory. The indurated area may soften to some extent and the red discoloration may become lighter, but a certain amount of pigmentation will remain. The induration should also be treated with prolonged elastic support, such as the Unna's paste boot or elastic adhesive dressings, and, in rebellious cases, can be favorably influenced by small repeated doses of x-rays. The thrombophlebitic patch may break down very easily and thus form a chronic thrombophlebitic ulcer. Generally speaking, the case described requires considerable experience and an activation of a latent phlebitis with ascending thrombosis should be carefully avoided.

TROPHIC ULCER IN DIABETES

To the Editor:—I have a patient, aged 46, with true diabetes mellitus. He weighed 290 pounds (131 Kg.) four years ago and now weighs 215 pounds (97.5 Kg.). He is kept free from sugar with two doses of insulin while on a diet of 2,250 calories. The point that interests me is the treatment of an ulcer on the sole of the foot, which is punched out and from time to time develops sinuses under the skin. It becomes necessary to slit up these tracks, which heal but leave the ulcer present as usual. This condition was present on the other foot but is now healed after being present for six months. The ulcer now present has been there for six months and has a foul discharge. I have tried dressing it at different times with the following: scarlet red over a period of several weeks; dichloramine over a period of several weeks; iodox ointment over a period of several weeks; alcohol over a period of several weeks; bacteriophage ointment for several weeks. It looks like a perforating ulcer, but the Wassermann reaction has always been negative. The patient tells me that since boyhood he has had callous spots of both feet, which he has been able to care for with salicylic acid in collodion. The last few years he has not had the same success. I should appreciate any advice you may care to give. The textbooks, including Joslin, advise general care, but I do not seem to have success. Please omit name and address.

M.D., Illinois.

ANSWER.—From the description, the ulcer is a trophic disturbance. The predisposing cause of such an ulcer in a diabetic patient is usually a diabetic neuritis which has rendered the innervated area partially or wholly anesthetic. The constant pressure of a corn or a poorly fitting shoe may then act as the immediate exciting agent to produce the lesion. The development of the ulcer is, of course, favored by the poorer nutritional state of the limb due to the arteriosclerosis that is

usually present. The latter factor and the constantly open wound also account for the recurrent infections that have had to be treated.

In view of the foregoing, one would hardly expect the ulcer to respond to treatment by the application of antiseptics alone. The treatment should be directed at the cause of the lesion, which is the constant, unrelenting pressure or trauma to that particular spot on the sole of the foot. Prolonged rest and elevation of the foot are indicated. Any exuberant epithelial growth about the ulcer may be removed, and quartz light or other forms of radiant heat may be of benefit. Mild antiseptic dressings should be used only to protect the wound from extraneous infection. When the ulcer has healed, attention should be directed to the care of the feet and the padding of the shoes so as to avoid pressure at the site of the ulcer.

The local application of insulin to the ulcer has been reported to be of benefit in some such cases and may be worth trying in conjunction with the suggestions already given.

IRRIGATION AND MASSAGE IN CHRONIC GONORRHEA

To the Editor:—In the answer to the query regarding chronic gonorrhea (THE JOURNAL, April 1, p. 1058), the last three lines of the third paragraph mention "alternating massage with dilation of the prostatic urethra, followed by instillation or irrigation." An instructor advised irrigation first and massage afterward, owing to the increased danger of epididymitis with the reverse procedure. May I have the consensus on this point?

E. D. ABRAHAM, M.D., Los Angeles.

ANSWER.—There is no reasoning for the danger of producing epididymitis by reversing the procedure given in the answer. The usual methods in all well regulated places make use of irrigation following massage for the purpose especially of washing out from the urinary tract the expressed secretions resulting from this manipulation and is the method to be recommended.

ONYCHOLYSIS

To the Editor:—For more than a year a patient of mine has noted that her fingernails are loosening from their beds, at the sides of the nails. The condition is becoming progressively worse. The strips of loosened nail are about a sixteenth of an inch in width, and in some cases extend back almost to the moons. At least a third of the surface of one nail is undermined. The nail bed is not particularly tender and is not moist. There are no signs of active infection, nor has there been any infection in the past. There is no suggestion of a low metabolism, and the history is devoid of suggestion. Will you mention possible causes and appropriate treatment? Please omit name.

M.D., California.

ANSWER.—From the description, this must be one of the rare cases of true onycholysis, in which there is no manifest general or local disease to account for the loosening of the nails. Of the few cases on record, in a number there has been hyperhidrosis of the hands, sometimes associated with cyanosis and cold hands and feet. The toenails are not often involved. Others have shown no signs of acrocyanosis. In one case, the trouble existed on both third fingers from early childhood. In another, the loosening of the nails was associated with severe pain in the upper extremities, possibly an atypical case of erythromelalgia, or Raynaud's disease. The etiology is wholly dark. Therapy suggested by Julius Heller, the chief authority on this subject (*Handb. d. Haut u. Geschlechtskr.* 13:115 [No. 2] 1927) consists of washing the hands in hot water, followed by stimulating applications containing tar, resorcinol and salicylic acid in oil or in alcohol and glycerin, painted on or as a dressing. Preparations of arsenic may be given internally, with care to prevent its continued use. The prescription should be labeled "Do not repeat."

SODIUM AMYTAL IN OBSTETRICS

To the Editor:—Can you give me any information regarding the use of sodium amytal in obstetric practice? The makers recommend giving 3 grains (one capsule) as soon as the cervix is effaced or dilated to at least 2 cm. A second dose (3 grains) is given in from one to four hours if necessary. What effect have the barbiturates on the force of labor pains? Is there any danger to the fetus in their use?

W. J. COCHRANE, M.D., Westborough, Mass.

ANSWER.—Opinion is divided concerning the success obtained with sodium amytal in obstetrics. Most obstetricians who employ this drug are enthusiastic about it. Some administer it orally, others rectally and still others intravenously. In most instances, regardless of the route, complete amnesia is secured if the drug is given early and in sufficient doses. The general consensus is that labor is not retarded by the barbiturates. It is claimed that sodium amytal furnishes a satisfactory method of treating spastic cervix and retraction ring. It is generally

conceded that, when given in proper doses, no ill effects are observed on the babies. In contrast to these favorable opinions are some which maintain that administration of sodium amylal necessitates an increased frequency of forceps deliveries and results in the frequent narcotization of babies.

This drug and other sodium barbiturates have two distinct disadvantages: First, its administration, whether by mouth, by rectum or intravenously, requires skill and good judgment; therefore it must be given by a physician and not by a nurse. Second, restlessness, in some instances quite violent, is observed in a definite proportion of women. This necessitates an increased personnel to manage these women in labor, aside from the harm that may result to them, especially to those with a high blood pressure.

The Council on Pharmacy and Chemistry cautions against the intravenous use of sodium barbiturates, except under conditions of emergency.

TORSION OF THE TESTICLE

To the Editor:—A man, aged 24, gives the following history: Four years ago in a running jump, he jumped a height of three feet. While in the air, he suddenly felt a severe pain in the right testicle, which seemed to him as if the cord was being pulled on the testicle. He was doubled up with pain, which lasted from half to three quarters of an hour. Afterward, the testicle was swollen twice its normal size. He was put to bed, and the next day the other testicle was swollen and as tender as the right. He remained in bed one week, during which time the scrotum was supported with a pillow. Since being up he has worn a suspensory but has a continual burting at the site of both external rings, which are normal in size. During the past four years he has been examined repeatedly by an excellent urologist, medical man and surgeon, and no pathologic condition has been found. Kindly advise as to proper diagnosis and treatment. Please omit name. M.D., California.

ANSWER:—From the history, it is evident that the patient suffered from a rare condition variously termed "torsion of the testicle" or "torsion of the spermatic cord."

The treatment, as followed at that time, apparently relieved his condition at the time. When the torsion has been relieved, the testicle, as a rule, rapidly returns to normal. On the other hand, when the torsion persists and is not relieved within a short time, complete atrophy usually follows; therefore it would be interesting to know whether or not he has, at this time, atrophy of one or both testicles.

On the other hand, his pain at this time may be referred pain due to infection in the prostate gland, or seminal vesicles, or both. Because of this possibility, a careful rectal examination is in order and this should include stripping of the prostate and vesicles so that the fluid expressed may be examined for the presence of pus, in which event the usual treatment for chronic infection is in order, such as massage, hot sitz baths, heat by rectum, and the internal administration of potassium iodide, 0.65 Gm., three times a day, and sodium salicylate, 0.65 Gm., three times a day.

If the prostate and vesicles are free of infection and the pain persists, it might be well to suggest fixation of the testicles in the scrotum by an open operation.

EFFECTS OF PHENOLPHTHALEIN ON KIDNEY

To the Editor:—Kindly tell me whether there is any evidence to show that the normal or diseased kidney is injured by the prolonged use of phenolphthalein in various combinations. Please omit name.

M.D., Connecticut.

ANSWER:—While phenolphthalein has been generally considered a nontoxic drug, the enormous increase in its use in the form of various proprietary combinations is bringing about a modification of this attitude toward the substance. This fact was called to the attention of the readers of THE JOURNAL in an article, "Phenolphthalein as a 'Patent Medicine,'" published, April 29, in the Bureau of Investigation's department. This article stated in part: "Among its disadvantages is a degree of variability in action, small doses sometimes acting excessively, when at other times a larger dose will fail to act. It may cause, in addition to purgation, colic, rapid pulse, difficult breathing, and even collapse. Hydrick as long ago as 1914 reported a case of albuminuria lasting from one to three days following the administration of phenolphthalein in doses of from one to two grains. Fuerbringer in 1917 reported a case of poisoning following the taking of about nine grains of phenolphthalein by a woman who developed cardiac weakness, a rapid, intermittent, irregular and thread-like pulse, with irregular respiration and dyspnea and some mental confusion. Later the patient developed a trace of albuminuria and an almost total anuria. Holz has reported observing severe gastrointestinal disturbances, hematuria, chill and pain suggesting renal stone colic."

Susceptible persons occasionally have urticarial and erythematous eruptions following the use of phenolphthalein. In the latter type, peculiar polychromatic eruptions on the skin with bullous, vesicular and eroded lesions of the mucosa and genitalia are provoked. These lesions leave pigmented areas, which may persist for months or years.

BULBAR PARALYSIS

To the Editor:—A sister-in-law of mine in Iowa, aged 54, in fair health, able to do her housework, in August of 1932 consulted several physicians and a well known clinic in regard to her health and particularly because of occasional spells of difficult swallowing and attendant fear of serious trouble or possible death. After a thorough examination, general and neurologic, a diagnosis of bulbar paralysis of the chronic poliomyelitic type was made. This condition apparently has been very slowly progressive, and at present she has been enjoying a period of remission. A destructive arthritis accompanies this condition but is independent of the main complaint and preexisted some ten or more years. I am particularly interested in an opinion as to treatment, palliative or curative, if known, also as definite a prognosis as can be given. If the disease causes a fatal termination, and if treatment is of no avail, is it reasonable to suppose that the patient will eventually become bedridden and the difficulty in swallowing result in general exhaustion? A final question: Is the end peaceful or attendant with pain requiring opiates? Please omit name. M.D., Washington.

ANSWER:—A bulbar palsy cannot be treated symptomatically. If difficulties in swallowing occur, tube feeding may be resorted to. Death usually occurs from an aspiration bronchial pneumonia, although sometimes inanition may be the final cause of death. The end is often disagreeable, as consciousness persists in spite of difficulties in respiration and swallowing. Opiates usually hasten the end because of their depressing effect on respiration. It might be stated that the diagnosis of chronic poliomyelitis at the age of 54 localized in the medulla with progression has probably been made for a vascular disease affecting the medulla.

USE OF SILVER NITRATE IN URETHRA

To the Editor:—For the treatment of gonorrheal urethritis by means of topical applications through the urethroscope when there is a folliculitis, I have always used 2 per cent silver nitrate. Is this the usual strength employed? Please omit name.

M.D., Ohio.

ANSWER:—If the application to protruding follicles is confined to these prominences by controlling the procedure through a urethroscope, silver nitrate solutions of any concentration may be used. Treating extensive areas of the urethral mucosa with high per cent silver solutions is apt to lead to the formation of urethral strictures.

SO-CALLED ASEPTIC URETHRAL DISCHARGE

To the Editor:—In THE JOURNAL, May 20, in answer to a query, you state that "an aseptic purulent discharge from the urethra is as a rule secondary to chronic congestion of the prostate and seminal vesicles." While the gonococcus has been definitely excluded as the offending organism, sufficient evidence has not been adduced to prove the urethral discharge sterile in this case.

A urethral discharge of this nature is usually due to chronic infection of the prostate and seminal vesicles, and a smear showing over 20 pus cells to the high power field tends to confirm the diagnosis. A fresh specimen of prostate secretion showing from 20 to 80 per cent pus will often show only 20 pus cells or less to the high power field, when smeared, fixed and stained. For this reason it is well for the urologist to examine the fresh secretion microscopically before making a smear for the laboratory. In these infections, the colon bacillus is often the offending organism, though foci in distant parts of the body may be responsible. Old strictures and chronic infections of Cowper's glands are not infrequently found, even with a negative history. Either of these conditions may cause a chronic urethral discharge.

The treatment of chronic infection of the prostate and seminal vesicles, unless tuberculous in origin or complicated by malignancy, consists of thorough gentle massage, deep irrigations and the passage of sounds. Sounds are indicated independent of the presence of stricture so as to insure emptying the prostatic ducts, the orifices of which at times become plugged with purulent or caseous material. Hydrotherapy and diathermy are useful adjuncts. Infection tends to recur, especially if foci of infection, as in the teeth or tonsils, otitis media or cowperitis, are not removed.

I do not agree with your statement that successful evacuation of the seminal vesicles can be accomplished only by the use of a club-shaped instrument. It requires thorough training and practice to enable one to empty the seminal vesicles properly, or the prostate gland for that matter. The use of any instrument for this purpose is fraught with danger. It must be borne in mind that sterile pus from the prostate as well as from the kidney may be due to tubercle bacilli. While symptoms of tuberculosis of the prostate and genital tract are often elicited and confirmed by careful examination, the final diagnosis depends on guinea-pig inoculation or potato culture.

I read Queries and Minor Notes with interest and not without benefit.

J. GREGG SMITH, M.D., Portsmouth, Va.
Lieutenant Commander, M. C., U. S. Navy.

Council on Medical Education and Hospitals

COMING EXAMINATIONS

ALASKA: Juneau, Sept. 5. Sec., Dr. Harry C. DeVighe, Juneau.

AMERICAN BOARD OF DERMATOLOGY AND SYPHILOLOGY: *Written.* Boston, Chicago, Cleveland, New York, Philadelphia, St. Louis and San Francisco, Oct. 28. *Oral.* New York, Dec. 15-16. Application must be filed before Sept. 1. Sec., Dr. C. Guy Lane, 416 Marlboro St., Boston.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY: The examinations will be held in various cities of the United States and Canada, Dec. 9. Sec., Dr. Paul Titus, 1015 Highland Bldg., Pittsburgh.

AMERICAN BOARD OF OTOLARYNGOLOGY. Boston, Sept. 16. Sec., Dr. W. P. Wherry, 1500 Medical Arts Bldg., Omaha.

NATIONAL BOARD OF MEDICAL EXAMINERS: Parts I and II. The examinations will be held at centers where there are five or more candidates, Sept. 13-15. Ex. Sec., Mr. Everett S. Elwood, 225 S. 15th St., Philadelphia.

NEW HAMPSHIRE: Concord, Sept. 14-15. Sec., Dr. Charles Duncan, State House, Concord.

NEW YORK: Albany, Buffalo, New York and Syracuse, Sept. 25-28. Chief, Professional Examinations Bureau, Mr. Herbert J. Hamilton, Room 315 Education Bldg., Albany.

OKLAHOMA: Oklahoma City, Sept. 12-13. Sec., Dr. J. M. Byrum, Mammoth Bldg., Shawnee.

PUERTO RICO: San Juan, Sept. 5. Sec., Dr. O. Costa Mandry, Box 536, San Juan.

WISCONSIN: *Basic Science.* Madison, Sept. 23. Sec., Prof. Robert N. Bauer, 3414 W. Wisconsin Ave., Milwaukee.

California February-March Examination

Dr. Charles B. Pinkham, secretary, California Board of Medical Examiners, reports the written examination held in Los Angeles, Feb. 28-March 2, 1933. The examination covered 9 subjects and included 90 questions. An average of 75 per cent was required to pass. Sixty-four candidates were examined, 57 of whom passed and 7 failed. The following colleges were represented:

| College | PASSED | Year Grad. | Per Cent |
|--|---------|------------|----------|
| College of Medical Evangelists | (1932) | 79.2 | 83.4 |

Book Notices

Electrosurgery. By Howard A. Kelly, M.D., LL.D., F.A.C.S., and Grant E. Ward, M.D., F.A.C.S. Cloth. Price, \$7. Pp. 305, with 352 illustrations. Philadelphia & London: W. B. Saunders Company, 1932.

Electrosurgery opens up a vista, these authors believe, destined in no small measure to replace scalpel, ligature and hand contacts with wounds, as well as notably to pare down the number of cases listed as "inoperable" by skilled surgeons. Too much time is not wasted in this volume in preliminary and theoretical discussions of the various effects on tissues that can be brought about by the use of various currents. However, the tissue changes produced by electrodesiccation and "acusection" are clearly differentiated and their means of attainment and clinical indications defined. Thereafter the volume is divided into topical electrosurgery; chapters are given to the skin, oral cavity, otolaryngology, thyroid, thorax, breast, abdomen, gynecology, urology, proctology and the central nervous system. Anesthesia, preparation of the patient and postoperative care are covered. In other words, this is a manual, the most complete one in any language, covering the use of electrosurgery in the various regions. This book is convenient in teaching and invaluable as a guide to those interested in the use of electricity in surgical operations.

Intracranial Tumors. By Percival Bailey, Professor of Surgery, University of Chicago. Cloth. Price, \$6. Pp. 475, with 155 illustrations. Springfield, Illinois: Charles C. Thomas, 1933.

This interesting volume is a series of twenty clinicopathologic lectures, elaborated into book form. In the first three chapters the author discusses tumors in general, giving those anatomic and physiologic facts which he has found of value in neurologic diagnosis. Fifteen chapters are devoted to various types of tumors, beginning with acoustic neuroma, then hypophyseal adenomas and craniopharyngiomas, and so on. In all these chapters, cases are reported which were demonstrated in these lectures. The last three chapters are devoted to gen-

eral diagnosis, differential diagnosis and treatment. The book contains much valuable information. The author has devoted most of his time in recent years to a study of the pathology of brain tumors and is one of the recognized authorities on this phase of the subject. He has developed a fondness for collecting brain tumors, as he stated at the international neurologic congress in Berne in 1931, as others have a fondness for collecting butterflies. This point of view has colored his book to such an extent that it has led him into difficulties. The book, as he states in his preface, is for students; yet, by his overemphasis of the pathologic point of view it will inevitably confuse students, since the titles of his chapters from 4 to 18 are all types of tumors, while the subtitles refer to areas of the brain, and one not familiar with the subject might gain the idea that the symptoms are characteristic of certain types of tumor. At times the author realizes this fallacy, when, in chapter 13, after devoting twenty-two pages to an excellent account of oligodendrogliomas, a tumor so rare that Cushing in his 2,023 cases saw only 27 instances, he remarks, "None of the symptoms we have just described is in any way characteristic of this type of tumor." The reason for the arrangement of the chapters is not apparent. It would seem more logical if chapter 10, on encephalic tumors, in which the author gives a general survey of the modern point of view about the pathology of brain tumors, preceded chapters in which he describes the different types of tumors.

The chapters on pituitary tumors and glioblastoma multiforme are particularly valuable, since the author has incorporated in them his own studies and views on these types to which he has devoted special attention; but in these chapters, as well as in all the book, the author has seriously handicapped himself by his dislike of glazed paper (as he states in his preface), on which alone photomicrographs and roentgenograms may properly be reproduced. Certainly since the author is emphasizing pathology, it would have been most desirable had he reproduced microscopic sections accurately, either by photomicrography or by such masterly drawings as were made by Horn and others in Brödel's laboratory. The same criticism must be made of the drawings of patients. Reproductions of good photographs certainly would be far better than such drawings as are shown on pages 89, 114, 174 and 315, which seem to be little better than caricatures. Just why the author has himself made all the sketches of roentgenograms is not apparent, for they are so crudely done that even one experienced in reading plates can make little out of them. These sketches add nothing to the text. There are a distressingly large number of errors which should have been picked up in the proofreading, and it is to be hoped that a future edition will contain a more complete index.

There is so much useful information in this book that it seems a pity it has not been arranged in more accessible form; but it should be in the library of all neurologic surgeons, all students both of neurology and of neuropathology. As an example of the publisher's art, the book has all the fine qualities present in books from the Thomas press.

Études cliniques de syphiligraphie. Par ERNEST SCHULMANN, médecin des Hôpitaux de Paris. Préface du Docteur A. Sézary. Paper. Price, 40 francs. Pp. 226, with 15 illustrations. Paris: Masson & Cie, 1932.

This is not a complete treatise on clinical syphilis but a discussion of various important and interesting problems connected with the diagnosis, prophylaxis and treatment of the disease. The author has divided his work into fifteen compact, readable chapters. The first deals with the proper method of obtaining a history from the patient, pointing out the voluntary and the unintentional errors. The diagnosis of the chancre is discussed, medicolegal aspects, the importance of dates in the history of the patient, how to avoid errors in chronology, and its bearing on the prognosis and on the type of treatment best suited to the case. The second chapter contains a simple, clear treatment of the question of infectivity before the chancre is observed and the contagiousness of occult syphilis. In the chapters that follow, the author studies critically the clinical forms of syphilis without chancre, the evolution of syphilis of the central nervous system without alteration of the spinal fluid, pruritus and syphilis, syphilitic asthenia, syphilitic gastric ulcer, the significance of fever in syphilis, zoster and syphilis, syphilis manifested only by serologic evidence, sterility and syphilis, the complication of syphilis with tuberculosis, natural

immunity in syphilis, and myxedema and syphilis. These subjects are thoroughly covered and are made more impressive at many points by illustrative case histories. The book is excellently printed, the illustrations are clear, and the subject matter has been presented in a conservative and practical manner. It should be read by every practitioner, particularly the dermatologist and syphilologist.

The Nutritive Value of the Banana. Report of Researches Conducted and Superseded by the Institute of Practical Arts Research Laboratories of Physiological Chemistry, Teachers College, Columbia University. By WALTER H. EDDY, Ph.D., Professor of Physiological Chemistry, Teachers College, Columbia University. Paper. Pp. 37. New York: Bureau of Publications, Teachers College, Columbia University, 1933.

This summarizes the nutritive value of the banana, including chemical composition, character of the protein, effect on intestinal flora, acid-base value of the minerals, hematopoietic properties, effect on calcium absorption, vitamin content, and digestibility. The banana is a good source of calories, of "quick energy"; its protein is of good value, the carbohydrates are well tolerated in sprue and celiac disease and they are corrective to a considerable degree in these two conditions. The banana stimulates intestinal growth of gram-positive aciduric types and opposes development of colon forms. It effects increase of volume of the stools, producing a mild laxative action, and contributes significant quantities of calcium, magnesium, phosphorus, sulphur, iron and copper. It has an alkaline reaction to offset acidosis of acid diets, has red blood cell regenerating potency, increases utilization of calcium, is a good source of vitamins A, B, C and G, is an excellent milk modifier for infant feeding, and when ripe is almost completely digestible and is well tolerated by persons of all ages.

Opuscula selecta Neerlandicorum de arte medica. Fasciculus undecimus quem curatores miscellaneorum quae vocantur Nederlandsch Tijdschrift voor Geneeskunde collegerunt et ediderunt Amstelodami Sumptibus Societatis. Van Helmont, Gaubius, Schroeder van der Kolk. Cloth. Pp. 359, with illustrations. Amsterdam, 1932.

This volume of republications with translations of Netherlands medical classics brings contributions illustrating the history of the doctrine of vitalism in medicine. Samples of writings on vitalism by three Netherlands physicians are reprinted in the original Latin or Dutch and in German translations: Johannes Baptista van Helmont, Hieronymus Davidus Gaubius, and J. L. C. Schroeder van der Kolk.

J. B. van Helmont (1577-1644), the founder of the iatrochemical school in medicine, was a pioneer student of gases. He is said to have used first the word "gas." He held that each physiologic process is due to a special gas which is governed by a special spirit under the supreme guidance of a sensory-motive soul ("blas"). He expressed certain original ideas about immunity and has been credited with the following happy anticipatory pronouncement of the properties of convalescent serum in infections: "For he who has once recovered from that disease has not only obtained a pure balsaical blood, whereby for the future he is rendered free from any recidivation of the same evil, but also infallibly cures the same affection in his neighbour . . . and by the mysterious power of Magnetism transplants its balaam and conserving quality into the blood of another." Van Helmont is represented in this book by two tracts, one entitled *Archeus Faber* ("the internal overseer of the semen") and *Spiritus Vitalis* ("vital spirit"). The Latin form is taken from his *Ortus Medicinæ*, Amsterdam, 1648, and the German from the translation, published in Sultzbach in 1683 under the title *Aufgang der Artzney-Kunst*.

Gaubius, or Gaub (1705-1780), a pupil of Boerhaave, was professor of chemistry and medicine in Leyden. His *Institutes of Medical Pathology* was for a long time a favorite textbook. He claimed that Haller's irritability is due to a pathologic increase of "vital power." The book before us contains reprints of his *Sermo Academicus de Regimine Mentis Quod Medicorum est* (The Influence of the Soul in Healing), Leyden, 1747, in Latin and a fresh German translation by L. Hellmann of the Dutch edition in 1775.

J. L. C. Schroeder van der Kolk (1797-1862) is represented by a reprint in the original Dutch and in the German translation by J. F. H. Albers of his address in 1835 entitled *On the Difference Between the Dead Forces of Nature, Vital Forces and Soul*.

Portraits of the three physicians and the title pages of their publications are reproduced. F. M. G. De Feyfer writes a comprehensive introduction in which he reviews the various forms of vitalism in medicine from ancient times down to our own days. All who are interested in the doctrines of vitalism—the belief in a supranatural power or living principle which is not the function or manifestation of matter—will welcome this volume, which is a valuable addition to the literature of medical history.

Surgical Pathology of the Skin, Fascia, Muscles, Tendons, Blood and Lymph Vessels. By Arthur E. Hertzler, M.D., Professor of Surgery, University of Kansas. Hertzler's Monographs on Surgical Pathology. Cloth. Price, \$5. Pp. 301, with 260 illustrations. Philadelphia: J. B. Lippincott Company, 1931.

This is a new volume of Hertzler's monographs and deals with the surgical pathology of the skin, fascia, muscles, tendons, blood and lymph vessels. The book is divided into three parts. Part I deals entirely with the diseases of the skin. Part II deals with diseases of the fascia, muscles and tendons, and part III considers diseases of the blood and lymph vessels. A little more than half of the volume is devoted to diseases of the skin. Of the ten chapters in the work, five are devoted to the skin. The author has found that in his clinic more patients present themselves with hopeless malignant growths the result of neglected or maltreated simple lesions of the skin than from cancer of the uterus, mammary gland or lip. He emphasizes that adequate early treatment of these simple lesions would rid these patients of their disease but that only too often this has not been done and the patient comes because of recurrence. He points out that it is the tiny lesions which are important and are serious menaces to the patient, with ultimate danger to his life. In this connection and for this reason, melanotic lesions have received special attention. He has attempted to classify them to harmonize with his clinical experience. He says that algebraic symbols would be quite as useful as the terms now employed, and that if one can clarify the clinical problems by making subdivisions, on either a morphologic or a clinical basis, he is justified in doing so even though the fundamental anatomic factors remain obscure. He believes that Virchow was right, in a measure, in dividing melanomas into two groups, those derived from epithelial cells and those derived from connective tissue. The author believes one might better say that the one tends toward development into epithelial and the other into connective tissue, though melanomas are never epithelial and never connective in origin. They are derivatives of embryonal rests and remain outlaws throughout life. One quality of melanotic tumors, he says, has failed of general recognition. That is that the connective tissue surrounding the nevus cells never attains the full development of acidophilic tissue. The degree of this abnormality is a measure of the likelihood of subsequent malignant development. As a useful clinical classification he divides melanomas into:

- A. Benign melanotic lesions:
 - 1. Multiple.
 - 2. Solitary.
- B. Malignant melanotic lesions:
 - 1. Melanomas:
 - (a) Spheroidal cell (melanocarcinomas).
 - (b) Spindle cell (melanosarcomas).
 - 2. Chromomas:
 - (a) Intradermic.
 - (b) Subdermic.

Each of these is described in detail, both clinically and from the pathologic standpoint. The points are emphasized by reproductions of photographs of actual cases and photomicrographs of sections from these cases.

The chapter on malignant tumors of the fascia is important. The author points out that the commonest of all tumors of the fascia are malignant from the beginning, seldom justify so mild a term as lipomyxosarcoma at any stage, and are pure sarcomas from the beginning. Usually they are of neurogenic origin. These neurogenic sarcomas often are removed surgically by a mere local operation by some physician unfamiliar with their real nature. Sooner or later, local recurrence brings the patient back, and a second, wider, local removal is performed as the local recurrence is his first intimation of the malignant character of the growth. Wide local recurrence followed by metastases in the lungs usually follows. These cases call for

radical amputation. The author properly states that the literature bearing on these tumors is surprisingly meager and that this may account for the mistreatment these tumors generally receive.

The concluding chapter of the volume discusses thrombosis and embolism. In discussing the genesis of thrombosis, he sets forth the results of his experimental studies. His clinical experience has emphasized the fundamental correctness of his conclusions: never ligate a vein when in a state of reaction.

The entire volume is essentially practical. The author has fulfilled his purpose, which is to present the result of observations in the clinic or operating room, with only incidental discussions of observations in the laboratory.

The volume is well illustrated. At the end of each chapter there are references to the literature. The book is written in a direct manner, is interesting to read, and contains a mass of valuable practical clinical facts.

National Health Insurance. By G. F. McCleary, M.D., Deputy Senior Medical Officer, Ministry of Health. Cloth. Price, 6s. Pp. 185. London: H. K. Lewis & Company, Ltd., 1932.

This is an authoritative factual study of health insurance. The brief historical chapters give an excellent, compact view of the origins of such insurance and its tendency to expand in coverage and extent of benefits within each country and to more and more nations. "At first the chief object of insurance was to compensate the disabled worker for loss of wages. . . . The modern tendency is to regard sickness insurance as a means of restoring the disabled worker to health and working capacity." Therefore it becomes rather a medical service, but operated by institutions organized for the earlier purposes. As the medical services increase in importance, conflicts between the physicians and the lay institutions grow sharper. In the more recently established systems of England, France, Norway and some other countries the medical organizations have been able to do away with many of the causes of friction and secure more power in directing the medical service. In these countries there is usually free choice of physician, and questions of medical standards and discipline are largely or wholly matters of the professional association. The English system is described in detail and this constitutes the best account of its workings available. The final summing up is favorable to health insurance, but everywhere the author's conclusions and opinions are separated from his statements of facts and, in the latter, unfavorable as well as favorable features are impartially described.

Ten Years of Obstetrics and Gynecology in Private Practice: A Clinical Report of 1750 Obstetrical and 1345 Gynecological Cases, with Comparative Analyses of Many of the Larger Groups, and Detailed Case Histories of Some of the More Important and Less Common Conditions. By John L. Rothrock, A.B., M.D., F.A.C.S. Cloth. Price, \$3. Pp. 209, with 9 illustrations. New York: Paul B. Hoeber, Inc., 1933.

The cases reported and analyzed were attended by the author in the ten year period 1921-1931. The report was prepared in order that comparative figures might be drawn exclusively from private material, a source seldom available. The usual statistical reports are compiled from records of public hospitals, deal with a poorer class of patients, and represent the work of several individuals. Brief sketches of the commoner obstetric problems are presented, with illustrative case histories and short discussions. Detailed treatment of various complications, however, is usually lacking. The view expressed by the author on the treatment of puerperal eclampsia is unfortunate, as he states that "it makes little difference what method one employs, the results will be about the same." One need not review the results of the Stroganoff method versus those following cesarean section in eclampsia to realize the utter folly of such remarks. The author discusses breech presentation in an interesting and instructive manner, but one feels that there is a lack of completeness in all his presentations. This is particularly true of his treatment of the subject of anesthesia in labor. The Kielland forceps are advocated and apparently proved most satisfactory for the mid and high stations of the head. The author also advises the use of the vectis, an obsolete instrument used to aid rotation of the head in occiput posterior presentation. This may prove to be a worthy suggestion, as occiput posterior positions are indeed the bane of the obstetrician's practice. Cesarean section was performed in ninety-five cases in this series, or 5.6 per cent

of the total deliveries. The classic operation was performed thirty-seven times, transperitoneal (low) eleven times and extraperitoneal forty-four times. There was one Porro operation. The transperitoneal technic followed was that described by Hirst, in which the parietal and visceral peritoneum is united before the uterus is opened. The disadvantage of this procedure is the firm adhesion of the uterus to the anterior abdominal wall, a sequel that is not observed following the usual low cervical operation. In two instances during extraperitoneal section the bladder was perforated. In spite of this danger, the author favors this technic as the method of choice in cephalic presentations requiring cesarean section. General anesthesia was used as a routine, usually nitrous oxide and oxygen; local anesthesia was employed once for cesarean section. There was only one maternal death (1.05 per cent) following classic section for premature detachment of the placenta, death occurring from postpartum hemorrhage. Four stillbirths (4.2 per cent) occurred in the cesarean series, two of which were premature. The second portion of the book deals with gynecologic material, which is treated even more briefly than the obstetric. There is too much generalization and too little specific information, especially in relation to treatment. A statistical summary closes each section, revealing an interesting material observed by the author in a decade. It is indeed commendable that the doctor "takes stock" and makes a critical analysis of his work over a period of years, a labor that must prove most profitable to himself and interesting to others in the same field of practice.

Entstehung, Erkennung und Behandlung plötzlich einsetzender Kreislaufstörungen, mit einem Sonder Vortrag, Tod als Operationsfolge. II. Ärztlicher Fortbildungskursus in Bad Salzungen, 7. und 8. Mai 1932. Boards. Price, 6 marks. Pp. 92, with 2 illustrations. Leipzig: Georg Thieme, 1932.

This small volume is made up of the papers of a symposium on vascular accidents of the pulmonary and general circulation, including those involving the heart, eye and central nervous system, as well as a consideration of shock and death following surgical operations. Each of this series of papers is a short review of the essential points in the subject discussed and can be read with interest and profit, especially that of Klapp on thrombosis and embolism and that of Hiller on apoplexy. The conceptions expressed agree well with those generally accepted in the United States, with few exceptions. The most notable impression gained by the reader is the importance placed on vascular spasm in the pathogenesis of all types of vascular disease. Angiospasm is spoken of with assurance as the cause of many of the visual and cerebral symptoms accompanying vascular disturbances in nephritis, migraine, eclampsia and headaches of other origin, as well as in cerebral vascular accidents. The title of the book definitely describes the subject matter. It is unusual as well as interesting to find included in one volume so many diverse subjects relating to nearly all the special fields of medicine, which are yet so closely related by the etiology and pathogenesis of the lesions in that all are primarily diseases of the cardiovascular system. It impresses by the emphasis laid on the physiology of the circulatory system and its application in all the special fields of medicine.

Procedures in Tuberculosis Control for the Dispensary, Home and Sanatorium. By Benjamin Goldberg, M.D., F.A.C.P., F.A.P.H.A., Associate Professor of Medicine, University of Illinois. With a chapter on Sanatorium Planning by Thomas B. Kidner, and an Introduction by David J. Davis, M.D., Ph.D., Dean of the College of Medicine, University of Illinois, Chicago. Cloth. Price, \$4. Pp. 373, with 54 illustrations. Philadelphia: F. A. Davis Company, 1933.

The subject matter of this volume has been ready for compiling and editing for many years, and in most respects it has been creditably performed by the author. An introduction by Dr. D. J. Davis, and a chapter on sanatorium planning near the end by Thomas B. Kidner, clothe the work with high standing and authority. The book proper is divided into three main sections, involving the dispensary and the sanatorium system used in Chicago, with a smaller section on home treatment in between. The chapters on medical education and the general hospital and tuberculosis merit high praise. The housing of the tuberculous in special wings of general hospitals, although appearing radical at present, will undoubtedly be an accomplished fact within the coming generation. Most of the material, however, is similar to that appearing in the bulletins and records of the Chicago Municipal Tuberculosis Sanitarium

since its founding in 1915, with little or no mention of even the authorities who have contributed to the development of the institution. The impression is almost inescapable that the author himself was the dominant force in the movement, although the records appear to show that his rôle was more or less ephemeral. Such an unfortunate impression of "tree-carving" tends to detract from a valuable work of trail-blazing. The publisher's work is standard in every respect.

Le pneumothorax bilatéral simultané. Par M. Ascoli, directeur de la clinique médicale de l'Université de Palerme, et M. Lucacer, assistant de la clinique médicale l'Université de Palerme. Préface de F. Dumarest. Collection médecine et chirurgie pratiques, no. 54. Paper. Price, 22 francs. Pp. 102, with illustrations. Paris: Masson & Cie, 1932.

Twenty years has passed since Ascoli and Faguoli first proposed and practiced compression of the diseased portion only of the lung by low intrapleural pressures and, its corollary, bilateral simultaneous pneumothorax. The opposition of Forlanini, who advised complete collapse of the diseased lung and restricted it to one-sided disease, delayed the development of this method. Since then, the physiology of respiration has become better understood and the indications for the choice of patients suitable for bilateral collapse have improved. Ascoli and Lucacer in this little book furnish, as Dumarest says in the preface, the "indispensable guide" to phthisiotherapists who employ this treatment. As the authors caution, the treatment should be reserved to patients in a fully equipped institution and to specialists in the care of the tuberculous. The basic principles of the physiopathology of the respiratory function are thoroughly discussed and to one who has not followed recent literature present some surprising new ideas. The best indication for the method occurs when, after compression of the more diseased lung, new or old lesions become active in the opposite lung. Bilateral pneumothorax, therefore, increases the possibility of success of unilateral collapse of the lung. The contraindications, technic, conduction of treatment and complications are fully discussed. The authors do not include their own figures in the results, which are good in about 25 per cent of the cases. In an appendix they discuss primary contralateral pneumothorax, initiated by Ascoli when pleural adhesions prevent pneumothorax of the actively diseased side. Compression of the so-called good lung will sometimes result in improvement of the lesion on the active side, especially when it is combined with a phrenicectomy on the latter side.

How Do Physicians and Patients Like the Middle-Rate Plan for Hospital Care? The Second Year's Experience of the Baker Memorial Unit of the Massachusetts General Hospital, Boston. Introductory Statement. By C. Rufus Rorem, Ph.D. Attitudes of Boston Physicians Toward the Baker Memorial. By Clyde D. Frost, M.D. The People Admitted to the Baker Memorial. By Elizabeth Richards Day. Paper. Pp. 53. Chicago: Julius Rosenwald Fund, 1932.

The middle-rate plan for hospital patients was placed in operation by the medical staff and administration of the Baker Memorial Unit of the Massachusetts General Hospital, Boston, March 3, 1930. It is stated that this plan is essentially a method by which the physician, patient and hospital unite to reduce the total cost to the patient for hospitalized illnesses without interfering with the quality of service. In a summary of the first year's report, the general principles of the middle-rate plan were summarized as: (1) offering moderate rates for bed care and for special services in a hospital unit large enough to facilitate economical administration; (2) arranging cooperation with the medical staff whereby moderate fees were charged for professional services; (3) unifying, by consent of the medical staff, all financial dealings with the patient under the hospital administration, so that the patient is not presented with two or more independent bills for hospital and professional care respectively, but with a single bill, collected by the hospital, which in turn passes over to the physician his agreed fee; (4) endeavoring to minimize the amount and the costs of special nursing; (5) seeking to provide all the service at cost, without charity and without profit. For the year ended Feb. 29, 1932, 3,326 patients paid an average of \$63 each to the attending medical staff. Special nursing cost averaged \$18.44 for the entire number of patients; but, since only \$19 required such service, the average was raised to \$116 per case. It is stated that twelve physicians believed that the scale of fees fixed by the plan was satisfactory. Three, however, qualified the statement by saying "except for special cases." The chief criticism

which was frequently expressed was concerning the limited fee for long term cases and those requiring frequent consultation. It is plain that the physicians of Boston have assumed a liberal attitude toward this experiment. At first some objected to the plan on the ground that it tended to lower professional fees. Now they admit that the public deserves good medical care at prices it can afford to pay. The authors state that physicians serving at Baker Memorial Hospital and representative medical men in Metropolitan Boston concur in the belief that the middle-rate plan is a valuable experiment and that if it is successful it is likely to be undertaken elsewhere. In another section of the report it is stated that during the past two years a similar plan has been introduced at Grace Hospital, Detroit, Sydenham and Mount Sinai hospitals, New York, and Morton Memorial Infirmary, Louisville, Ky. It appears from the financial statement that the facilities provided under this plan have not been utilized sufficiently to make the plan self sustaining. The deficit during the first year of operation was \$87,143.66. The second year the deficit was \$87,566.96. This means that the ratio of income from patients to the net operating expenses was 74.1 per cent the first year and 81 per cent the second year. Under such conditions one cannot understand how a hospital can continue a plan of this nature without endowment or other means of meeting the deficit.

Arbeit und Gesundheit: Sozialmedizinische Schriftenreihe aus dem Gebiete des Reichsarbeitsministeriums. Herausgegeben von Professor Dr. Martineck, Ministerialdirektor im Reichsarbeitsministerium. Heft 22: Nervöse und seelische Störungen bei Teilnehmern am Weltkrieg, ihre ärztliche und rechtliche Beurteilung. Von Dr. Karl Weller, Facharzt für Psychiatrie. Teil 1: Nervöse und seelische Störungen psychogener und funktioneller Art. Paper. Price, 6 marks. Pp. 222, with 30 illustrations. Leipzig: Georg Thieme, 1933.

Dr. Weller has made an intensive study of organic and functional mental diseases among the participants in the World War (Germany). His study is to be embraced in two volumes. This monograph is the first volume; in it the author gives consideration to nervous and mental disorders, organic and functional. He also discusses the legal aspect and shows familiarity with both subjects. In the second volume, which will follow at a later date, the dementias will be discussed. The purpose of the present volume is to help the examiners for the German veterans' bureau to diagnose correctly claimants with nervous and mental disorders and to evaluate the influence that service in the World War had on these diseases and also to what extent the claimants are disabled for gainful occupation. The author has reviewed 200,000 case records from a district in Bavaria, which included the city of Munich and surrounding counties. He gives a short treatise on the different types of nervous and mental disorders. It is his opinion that the activities and incidents (excluding direct nerve and brain injuries) during the World War, in most of the cases, were not the cause of the mental upset but just aggravating factors in persons who had a defective personality make-up. He reviewed the psychiatric experience of former wars (the war of 1870-1871, the Russo-Japanese war and the Balkan war of 1912-1913). Part of the book is used to detail his opinion regarding legislation for disabled service-connected veterans, especially the procedure of handling the applicants and the part the examining physician plays in the whole procedure. There is a short discussion on hyperthyroidism and the associated nervous and mental disorders. Reference is made to the influence of alcohol, nicotine and syphilis on mental disorders. There is a paragraph concerning somatic diseases accompanied by mental symptoms. The author mentions as a fact that the outlook for compensation may delay in many instances the improvement of the claimant's symptoms; he gives it a special term, "rentenneurose" (compensation neurosis). In the summary he states that all the disabilities seem to be magnified in a claimant if there is a prospect of obtaining compensation and he advocates legislation to make it imperative for the management of industrial activities to employ a small percentage of partially disabled war veterans in their plants and give them full pay even if their work is below par. It appears that he hopes in that way to develop a mental attitude of self dependence in the veteran and lessen his feeling for the need of paternalistic government aid. The monograph has little appeal for the general practitioner. Its chief interest lies in the field of those engaged in the adjudication of the ex-service man's problems. The book gives evi-

dence of painstaking investigation and careful thought in its preparation. There are thirty graphic charts and many statistical tables in the book, which are helpful in interpreting the text.

British Experience with Unemployment Insurance: A Summary of Evidence Taken by the Royal Commission on Unemployment Insurance. Part V.: Financial Aspects. Monograph 11 in a Series on Social Insurance. Paper. Pp. 47. New York: Metropolitan Life Insurance Company, 1933.

British Experience with Unemployment Insurance: A Summary of Evidence Taken by the Royal Commission on Unemployment Insurance. Part VI.: Economic and Social Effects. Monograph 12 in a Series on Social Insurance. Paper. Pp. 54. New York: Metropolitan Life Insurance Company, [n. d.].

These monographs give a compact survey of the exhaustive evidence taken and reports of the royal commission. There has been constant change in the direction of extension of benefits and expansion of coverage until deficits compelled some restrictions in 1931. The committee was forced to recognize that "it is impossible satisfactorily to base the current finances of a scheme of insurance against unemployment upon a theoretical estimate of the average rate of employment over a number of years." The question of meeting the deficits caused by the present depression received a number of answers, all admittedly unsatisfactory. There was much disagreement as to the economic effects on "mobility of labor," "part time employment," "rigidity of wage rates," and "poor relief by local authorities." It was recognized that insurance might "encourage industries to maintain reserves in excess of their maximum requirements, at the expense of the insurance fund." Employers insisted that insurance maintained wages so high and increased cost of production through contributions so as to affect international competition. There seemed to be general agreement only on the general proposition that insurance offers a far better way of providing relief for the unemployed than anything else that has been suggested and therefore no one proposed its abolition. Both majority and minority reports, while offering many minor changes, did not propose any drastic alterations in the existing law.

Diagnóstico y tratamiento del cáncer. Editado por la Liga contra el Cáncer. Paper. Pp. 255, with illustrations. Havana: La casa Montalvo-Cardenas, 1932.

This treatise, edited by the League Against Cancer of Havana, contains contributions of various authors on the different phases of the diagnosis and treatment of cancer. The first chapter, by Martinez, presents a brief general review of the various theories of causation. There follows a discussion of the pathologic anatomy of tumors and the indications, technic and dangers of biopsy. The chapters on x-rays and radium present a brief review of the development of these therapeutic agents, with their physical and biologic properties. Electrodesiccation and electrocoagulation are briefly discussed. The chapter on the treatment of cancer affecting various organs presents the standard methods of treatment but omits the most recent advances in radiotherapy, particularly such developments as the Coutard technic and radium bomb therapy. This compilation on the diagnosis and treatment of cancer constitutes an accurate and brief review of the subject which should be of interest to the general practitioner. In this respect it fulfils its purpose; namely, the education of the profession in the early diagnosis and treatment of neoplastic disease.

Illustrated Primer on Fractures. Prepared by the Cooperative Committee on Fractures Under Auspices of Section on Surgery, General and Abdominal, and Section on Orthopedic Surgery, in Cooperation with Department of Scientific Exhibit of the American Medical Association. Third edition. Fabrikoid. Price, \$1. Pp. 67, with illustrations. Chicago: American Medical Association, 1933.

The third edition of this book (the first and second editions have been reviewed in this department) includes material shown in the fracture exhibits at five annual sessions of the American Medical Association, from 1927 to 1931. Many of the illustrations have been modified or redrawn. All of the legends have been reedited and some of them revised. New material includes fracture of the forearm, carpus, metacarpus and phalanges. The material has been presented in excellent form according to the most approved teaching methods. In addition to fractures, the book contains a discussion on dislocations at the shoulder. The book should be in the library of every practicing physician and surgeon.

Medicolegal

Workmen's Compensation Acts: Award of Compensation as Bar to Malpractice Suit.—Under the Michigan workmen's compensation act (Compiled Laws, 1929, sec. 8454), an employee who is injured under circumstances making some person other than his employer liable for the injury may sue that person to recover damages or may obtain compensation under the act, but he cannot do both. If the employee obtains compensation under the act, his right to recover damages from the person responsible for the injury vests in his employer or his employer's insurer, whoever paid the statutory compensation, who may then sue the responsible person for the damages for which the injured employee might otherwise have sued. Because of this statute, said the Supreme Court of Michigan, an injured employee whose injury has been aggravated by the malpractice of a physician may not, after he has been awarded compensation from his employer, sue the physician for malpractice. The amount the workman can recover under the workmen's compensation act is less than he could recover by suing the physician, and it seems unfair that the physician in such a case should benefit by the provisions of the act, to the employee's disadvantage. That, however, is a matter for the legislature to consider; courts must adhere to the provisions of the laws as enacted.

The absence from the Michigan workmen's compensation act of an express statement concerning liability for the aggravation of an industrial injury by the subsequent negligence of a third person creates some ambiguity. Under similar acts in other jurisdictions, the compensation that an employer must pay his injured employee includes compensation for the consequences of such aggravation of the injury as has been caused by malpractice, in addition to compensation for the original injury. The Supreme Court of Michigan looked with favor on that plan, in *Oleszek v. Ford Motor Co.*, 217 Mich. 318, 186 N. W. 719. If and when an employer must pay compensation for the aggravation of the industrial injury by a physician's malpractice, there is no reason why the employee's right to sue the physician should not vest in the employer, just as the employee's right to sue the responsible third person for the original injuries vests in the employer.

It was urged that an employee might be awarded compensation before he discovered the effects of the malpractice and thus he foreclosed from his remedy against the physician. The acceptance of compensation for the original injury, said the Supreme Court, does not constitute an election under the statute. The employee retains his rights against the third person who has injured him, until he has elected to accept compensation, not only for the original injury, but also for the injury resulting from the malpractice. If the evidence of injury resulting from malpractice is not discovered before the expiration of the time limit within which compensation may be claimed under the workmen's compensation act, the employee still has his rights against the physician, even though he may have accepted compensation for the original injury, as distinguished from damages for the aggravation of that injury by malpractice.—*Overbeck v. Nier* (Mich.), 246 N. W. 196; *Paydu v. De Witt* (Mich.), 246 N. W. 199.

Insurance: Squeezing a Pimple as An "Accidental" Cause of Death.—An insurance policy provided double indemnity if death occurred as a result of bodily injury effected solely through external, violent and accidental means. The insured squeezed a pimple on his face, septicemia developed, pneumonia followed, and he died. In the opinion of the Supreme Court of Minnesota, the evidence warranted the conclusion that the pressure on the pimple for the purpose of expressing the pus was external, violent and accidental means within the terms of the policy and resulted in bodily injury. The insurer pointed out that double indemnity was not payable if death resulted from bodily or mental infirmity or disease in any form, and claimed that the death resulted from an existing infirmity, the pimple. True, said the court, the insured had a pimple, but pimples are common and almost always inconsequential and harmless. Had it not been for the rupturing of the sac of the pimple by pressure, the condition that caused the insured's

death would not have arisen. The admission of the testimony of a physician, over objection, that the insured told him that the pimple had been squeezed, was erroneous. A physician may testify as to the present physical condition of his patient, and what the patient said concerning that condition, particularly as to ills, pains and symptoms arising from an accident or sickness, but anything concerning the nature of past events, such as the cause of the injury or sickness, is inadmissible in an action to recover damages for an injury.—*Stroumen v. Prudential Ins. Co.* (Minn.), 245 N. W. 632.

When a Physiotherapist Practices Medicine.—The defendant, Mari, was licensed to practice physiotherapy in the state of New York. The statute under which he was licensed provides that a license issued under its authority shall authorize the licensee to treat diseases under the supervision of duly licensed physicians but shall not permit him to practice medicine. A rule promulgated by the Board of Regents of New York requires a registered physiotherapist to keep a written prescription, signed by a licensed physician, for each patient treated by the physiotherapist, which prescription shall state the diagnosis and the type of treatment ordered. Mari's office and office equipment had all the evidences of a physician's office. A policewoman, who subsequently appeared as a witness for the prosecution, called there. The defendant told her that he was Dr. Mari. At his request she described symptoms. He took her family history. He made "an intimate personal examination," tested her reflexes, looked into her throat and palpated her abdomen. He examined a specimen of her urine and told her he found a trace of albumin in it. He took her blood pressure and was about to take blood for a blood test, but his patient objected and he desisted. Mari then had his patient place her hands under a thermolite. This treatment had continued for about a half hour, when a Dr. Andrei, a licensed physician, entered. He tried to examine the patient, but she refused his services. He nevertheless wrote a prescription for her. Mari was convicted of the illegal practice of medicine, the conviction was affirmed by the appellate division, and he appealed to the Court of Appeals of New York.

To account for the presence of Dr. Andrei in Mari's office, said the Court of Appeals, we must take as true the evidence showing that he was summoned by or for the defendant, Mari. It may be assumed, said the court, that Dr. Andrei telephoned to Mari instructions what to do while awaiting his arrival; it is not contended that such a practice is unusual, but such a practice has no sanction in law. To say that the statute contemplates such a procedure would be to open the door so wide to evasion as to leave the statute a mere futility. It is no defense that Mari acted in good faith or did only what was customary. The only question is whether he violated the statute, and of this there seems to be no doubt. The judgment of conviction was affirmed.—*People v. Mari* (N. Y.), 183 N. E. 858.

Injunction Not Available to Prevent Practice by Holder of Unrevoked License.—By an act of the Tennessee legislature, Private Acts of Tennessee, 1923, chapter 679, Millard I. Hartley was licensed to practice medicine. All persons who at the time of the passage of this act had practiced medicine for ten years or more in any Tennessee county or counties with not less than 12,225 nor more than 12,235 population, according to the federal census of 1920, were licensed by the act to practice within such counties. The act required the state board of medical examiners to issue to any person proving that he was entitled thereto a certificate licensing him so to practice. Hartley had practiced in Johnson and Carter counties for more than twenty years, and the board therefore issued to him a "certificate of permanent license," which Hartley duly recorded in the counties in which he had practiced.

At a later date, the state of Tennessee, at the instance of the Tennessee state board of medical examiners, filed a bill to enjoin Hartley from practicing medicine in the state. This bill was filed under authority of an act entitled An Act to define and provide for the abatement of certain public nuisances, Public Acts of 1919, chapter 158, which declares that the practice of any profession is a public nuisance if the practice of it without a license is prohibited by law and the practitioner holds no license. The chancery court of Carter county, in which the bill was filed, dismissed it, and the state appealed to

the Supreme Court of Tennessee. The bill was based on the theory that Hartley's license was void because the act by which he was licensed was itself unconstitutional and void. The Supreme Court, without considering the constitutionality of the act, rejected this theory. The issuance of a license, it said, is authority for the licentiate to practice. The bill had been dismissed in the court below on the theory that the state board of medical examiners had issued to Hartley a certificate of permanent license and was therefore estopped from denying its validity; but on this theory of the case the court declined to pass. Nor would it pass on the right of the board to cancel or revoke Hartley's license, if the license had been wrongfully issued, since the cancellation or revocation of that license was not involved in the proceeding. The act of 1919, authorizing the issue of injunctions to prevent unlawful practice, said the court, applies only to a person engaged in practice without a license, and since Hartley had a license that the board had issued and had not revoked, the act had no application to him. When a board clothed with exclusive power to issue a license exercises that power, the licentiate may exercise the privilege conferred by his license, until his authority to act is lawfully revoked.—*State ex rel, State Board of Medical Examiners v. Hartley (Tenn.)*, 54 S. W. (2d) 960.

Workmen's Compensation Acts: Compensation for Loss of Remaining Eye.—In childhood, the petitioner lost the vision of his left eye from disease. His right eye was destroyed at the defendant's plant by an accident arising out of and in the course of petitioner's employment. The industrial injury, plus the loss of the left eye during childhood, resulted in blindness. The trial court awarded compensation only for the loss of the eye destroyed by the industrial injury and the employee appealed to the Supreme Court of Tennessee. He contended that he should have been awarded compensation for permanent total disability. The employee's permanent total disability, said the Supreme Court, was not the result of an injury but of an injury that destroyed the vision of one eye, plus the affliction that destroyed the vision of the other eye. The statute, prescribing as it does compensation for industrial injury only and measuring it by the specific loss of a member regardless of the effect on capacity to work, forbids the addition of the preexisting loss of a member by disease to a subsequent loss of a member through industrial injury, for the purpose of transferring the measure of compensation from the lower to the higher schedule. In prescribing compensation for injury to vision, the legislature did not consider the organs of sight as a unit. Each eye was considered separately, and compensation related to its specific loss; the loss of one eye constituting permanent partial disability and the loss of both eyes constituting total permanent disability. The judgment of the trial court was therefore affirmed.—*Catlett v. Chattanooga Handle Co. (Tenn.)*, 55 S. W. (2d.) 257.

Accident Insurance: Sodium Fluoride Poisoning; "Visible Contusion or Wound" Construed.—Schenkat took a quantity of sodium fluoride accidentally, mistaking it for epsom salt. Three hours after taking the poison he died. He was insured under a double indemnity policy, payable if death should result from bodily injury effected solely through external, violent and accidental means, independently and exclusively of all other causes. The policy provided that, except in case of drowning or asphyxiation, the external, violent and accidental means which caused death should be evidenced by a "visible contusion or wound on the exterior of the body." Sahara Schenkat sued the insurer, to recover benefits payable under the policy. At the conclusion of the trial, on a directed verdict in favor of the plaintiff, the court entered judgment, and the insurer appealed to the U. S. circuit court of appeals, seventh circuit.

The evidence showed that the sodium fluoride taken by Schenkat, the insured, produced the following effects: "Insured became violently ill; was nauseated; perspired freely; vomited blood; lips and tongue swollen; became pale; body discolored; marked paralysis; abdomen rigid; suffered great pain." The U. S. circuit court of appeals quoted *Thompson v. Loyal Prot. Ass'n*, 167 Mich. 31, 132 N. W. 554, in which the Supreme Court of Michigan held that the following definition of a wound, given by the trial court for the guidance of the jury,

was correct, namely: "In legal medicine the word 'wounds' means injuries of every description that affect either the hard or soft parts of the body, and it comprehends bruises, contusions, fractures, luxations, etc. In law the word means any lesion of the body." "We hold," said the circuit court of appeals, "that the plaintiff was entitled to recover under the admitted facts of this case. The insured died as a direct result of bodily injury effected solely through external, violent and accidental means, independently and exclusively of all other causes." As evidence of such a death, the policy required "a visible contusion or wound on the exterior of the body." We hold, said the court, that this evidence was present.—*Mutual Life Ins. Co. of New York v. Schenkat (U. S. C. C. A.)*, 62 Fed. (2d) 236.

Evidence: Judicial Notice that Morphine is a Derivative of Opium.—The appellant in this case was convicted on an information which charged her with the sale of six ounces of morphine. She appealed on the ground that the trial court erred in overruling her demurrer by which she contended that the indictment under which she was convicted was fatally defective in that it did not allege that morphine is a salt or a derivative of opium. The United States circuit court of appeals, fifth circuit, held that the allegation was not necessary, since the trial court was entitled to take judicial notice of the fact that morphine is a derivative of opium.—*James v. United States*, 61 Fed. (2d) 912.

Insanity: Admissibility of Lay Testimony.—The opinions of nonexpert witnesses as to the insanity, the mental condition and the capacity of a person charged with crime to distinguish between right and wrong are admissible when such witnesses have had opportunities to observe or converse with such person and when they state their reasons and the facts observed on which they base their opinions. Such opinions, to be admissible, must be limited to conclusions drawn from the specific facts thus disclosed. It is for the jury to determine the weight to be given to such testimony.—*People v. Witte (Ill.)*, 183 N. E. 622.

Society Proceedings

COMING MEETINGS

- American Academy of Ophthalmology and Otolaryngology, Boston, September 18-22. Dr. William P. Wherry, 1500 Medical Arts Building, Omaha, Executive Secretary.
- American Association of Obstetricians, Gynecologists and Abdominal Surgeons, Lucerne-in-Quebec, Canada, September 11-14. Dr. Magnus A. Tate, 19 West Seventh Street, Cincinnati, Secretary.
- American Association of Railway Surgeons, Chicago, August 10-12. Dr. Louis J. Mitchell, 29 East Madison Street, Chicago, Secretary.
- American Congress of Physical Therapy, Chicago, September 11-15. Dr. F. B. Balmer, 185 North Wabash Avenue, Chicago, Secretary.
- American Roentgen Ray Society, Chicago, September 25-30. Dr. Eugene P. Fendergrass, 3400 Spruce Street, Philadelphia, Secretary.
- Association of Military Surgeons of the United States, Chicago, September 25-27. Dr. J. R. Kean, Army Medical Museum, Washington, D. C., Secretary.
- Colorado State Medical Society, Colorado Springs, September 14-16. Mr. Harvey T. Sethman, 537 Republic Building, Denver, Executive Secretary.
- Delaware, Medical Society of, Wilmington, September 26-27. Dr. W. O. La Motte, 604 Medical Arts Building, Wilmington, Secretary.
- Idaho State Medical Association, Twin Falls, September 18-19. Dr. Harold W. Stone, 105 North Eighth Street, Boise, Secretary.
- Indiana State Medical Association, French Lick, September 25-27. Mr. T. A. Hendricks, 23 East Ohio Street, Indianapolis, Executive Secretary.
- Kentucky State Medical Association, Murray, September 11-14. Dr. A. T. McCormack, 532 West Main Street, Louisville, Secretary.
- Michigan State Medical Society, Grand Rapids, September 12-14. Dr. F. C. Warnshuis, 148 Monroe Avenue, Grand Rapids, Secretary.
- National Medical Association, Chicago, August 13-14. Dr. Walter G. Alexander, 136 West Kinney Street, Newark, New Jersey, General Secretary.
- Nevada State Medical Association, Las Vegas, September 29-30. Dr. Horace J. Brown, 120 North Virginia Street, Reno, Secretary.
- New England Surgical Society, Boston, September 29-30. Dr. J. M. Birnie, 14 Chestnut Street, Springfield, Mass., Secretary.
- Ohio State Medical Association, Akron, September 7-8. Mr. Don K. Martin, 131 East State Street, Columbus, Executive Secretary.
- Utah State Medical Association, Salt Lake City, September 14-16. Dr. L. R. Cowan, 305 Medical Arts Building, Salt Lake City, Secretary.
- Washington State Medical Association, Seattle, August 28-30. Dr. Curtis H. Thomson, 1305 Fourth Avenue, Seattle, Secretary.
- Western Branch Society, American Urological Association, Vancouver, B. C., August 3-5. Dr. George W. Hartman, 999 Sutter Street, San Francisco, Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

American Journal of Medical Sciences, Philadelphia

185:453-600 (April) 1933

Classification of Diseases of Lipoid Metabolism and Gaucher's Disease.

L. Pick, Berlin, Germany.—p. 453.

*Spontaneous Subarachnoid Hemorrhage. H. F. Dowling, Baltimore.—p. 469.

Use of Various Gases in Encephalography: Summary of Two Hundred and Ten Cases, Using Simultaneous Displacement Apparatus. F. Liberson, New York.—p. 478.

Neurologic Complications of Serum Sickness. J. B. Doyle, Los Angeles.—p. 484.

Congenital Hemihypertrophy: Report of Eight Cases. E. G. Wakefield and E. A. Hines, Jr., Rochester, Minn.—p. 493.

Hypoglycemic Convulsions with Hypoplasia of Pancreas. H. M. Winans, Dallas, Texas.—p. 500.

Use of Ephedrine During Spinal Anesthesia for Relief of Paralytic Ileus: Therapeutic Fallacy. A. M. Winograd, D. A. Hirsch and R. D. Barnard, Chicago.—p. 506.

Alleged Antagonism Between Digitalis and Diphtheria Toxin. H. Gold and Margaret M. Klumpp, New York, in collaboration with T. D. Slagle.—p. 509.

Acute Angiospastic Retinitis: Occurrence in Cases of Severe Hypertensive and Renal Disease. H. P. Wagener, N. W. Barker and C. F. Burke, Rochester, Minn.—p. 517.

Stenosis of Isthmus (Coarctation) of Aorta: Report of Three Cases with Remarks on Clinical Aspects. E. C. Eppinger and P. A. H. Midelfart, Boston.—p. 528.

*Simple Test for Capillary Resistance: "Flicking" Test. H. W. Jones and L. M. Tocantins, Philadelphia.—p. 535.

Studies of Anemia in Pregnancy: III. Etiologic Relationship of Gastric Secretory Defects and Dietary Deficiency to Hypochromic and Macrocytic (Pernicious) Anemias of Pregnancy and Treatment of These Conditions. M. B. Strauss and W. B. Castle, Boston.—p. 539.

*Agranulocytic Angina (Pernicious Leukopenia): Study Based on Eighteen Cases with Nine Necropsies. T. Fitz-Hugh, Jr., and B. I. Comroe, Philadelphia.—p. 552.

Diaphragmatic Hernia Associated with Secondary Anemia. K. D. Gardner, San Francisco.—p. 561.

*Parenteral Liver Extract Therapy in Treatment of Pellagra: Preliminary Report. R. L. Ramsdell and W. H. Magness, Dallas, Texas.—p. 568.

Spontaneous Subarachnoid Hemorrhage.—Dowling reports twelve cases of spontaneous subarachnoid hemorrhage. He concludes that: 1. A variety of pathologic conditions may cause hemorrhage into the subarachnoid space. 2. The syndrome may present a wide variety of symptoms and signs. 3. In every case of coma of unknown origin, a diagnostic spinal puncture is imperative. 4. Headache is a prominent and sometimes the only symptom. A diagnostic spinal puncture is therefore justified in any case of unexplained headache. The relief of intracranial pressure is the end sought for, whether by repeated spinal drainage, intravenous injections of hypertonic dextrose solution, or frequent doses of magnesium sulphate by mouth. The author's procedure is to perform one puncture for diagnostic purposes and no more for one week (unless marked pressure symptoms require it). He allows this time for the bleeding vessel to attain some degree of repair. After this the patient is given a puncture every three days (or oftener, in the presence of markedly increased intracranial pressure) until the fluid is colorless and the abnormal signs and symptoms have all disappeared. Intravenous injections of dextrose solution and drastic purgation are reserved for cases in which spinal drainage alone fails to give relief.

Simple Test for Capillary Resistance.—Jones and Tocantins describe a test for capillary resistance as follows: A tourniquet is applied from 2 to 3 inches above the elbow for five minutes as for the capillary resistance test. After four minutes, by flicking the middle finger against the distended vein three or four times petechiae appear. A control may be performed above the tourniquet by flicking with similar force, with a resultant erythema, but in most instances no petechiae appear. The authors performed the flicking test in 108 normal persons on

whom the capillary resistance test was performed. A comparison brought out the following points: Of the 108 persons, 55 had both negative capillary resistance and flicking tests; 33 had a negative capillary resistance test and also a positive flicking test. In each instance of a positive capillary resistance test there was also a positive flicking test. On the other hand, not all cases in which the flicking test was positive showed a positive capillary resistance test. The total in this group having positive flicking tests was 49 per cent of the normal group. There was an equal frequency of positive flicking tests in persons who gave a personal or family history of hemorrhagic disposition, as in those whose family or personal history was negative. Of thirty patients who gave a history of frequent nosebleed, eighteen showed a positive flicking test, whereas only thirteen showed a positive capillary resistance test. Of seven who stated that they bruised easily, four gave a positive flicking test, while only two gave a positive capillary resistance test.

Agranulocytic Angina.—Fitz-Hugh and Comroe report the data on eighteen cases of agranulocytic angina (pernicious leukopenia) with nine necropsies. All but four are dead, a mortality of 78 per cent. Of these four, only two can be considered cured. The most promising treatment, aside from blood transfusion, seems to be pentnucleotide, although the authors' experience with this substance has not been favorable. It seems more definitely to be useless in chronic cases of the disease. Necropsy study has shown in more than half of the cases thus examined a plentiful supply in the leukopoietic centers of the progenitors of the blood leukocytes. This virtual hyperplasia is in marked contrast to the profound peripheral leukopenia characteristic of the disease and strengthens the previous suggestion of a hypothesis of primary "maturation arrest" rather than primary "aplasia" to account for the hematologic phenomena of the disease. Agranulocytic angina (pernicious leukopenia) seems to be a disease entity, although it is so closely simulated by certain other conditions that its nosologic status may remain debatable until a potent specific therapy is available or some other pathognomonic feature is discovered.

Liver Extract in Treatment of Pellagra.—Ramsdell and Magness treated twenty-two unselected cases of pellagra with liver extract intramuscularly without a death and with rapid marked clinical improvement. They believe that severe cases in either young or old people, often fatal in a short time, can be treated successfully with liver extract. In patients with severe mental depression or marked gastro-intestinal disturbances who refuse to eat, this method of treatment will give quicker results than dietary treatment. It is simple and much easier to carry out than dietary treatment. A combination of liver extract and the usual dietary treatment would probably give better results than either alone. The time of hospitalization was greatly reduced. The treatment consisted of rest in bed and a general home diet without any additional foods containing vitamin G. Liver extract number 343 was given intramuscularly in daily doses of 2 cc. The usual site of injection was the deltoid or gluteal region. Practically no inconvenience was experienced from the injections. No other medication of any kind was used. There was a moderate amount of anemia in all cases. In a few cases in which reticulocyte counts were made the highest response was 4.7 per cent. Achlorhydria was present in 81 per cent.

 *Oral Administration of Iron in Hypochromic Anemia. C. W. Heath, Boston.—p. 459.

Syphilitic Disease of Pulmonary Artery.—Karsner points out that productive-cicatrical syphilitic disease of the pulmonary artery, i. e., of the Döhle-Heller type, is extremely uncommon but occurs often enough to justify its consideration in clinical diagnosis. Eleven cases, anatomically proved by reasonably liberal interpretation, are now on record. Eight of these would be regarded as clearly established by the most exacting criteria. Gummatous types of lesion about equal the productive-cicatrical type in incidence, but this ratio may be changed as additional cases are reported. The proportion of productive-cicatrical to gummatous lesions is markedly higher in the aorta than in the pulmonary artery. All cases of productive-cicatrical lesions in the main stem of the pulmonary artery show local or diffuse dilatation of the vessel. Associated disease of the smaller pulmonary arteries is by no means constant. Thrombosis is more frequently associated with productive-cicatrical lesions of the pulmonary artery than with the same lesions of the aorta. The anatomic character of the lesion, as it affects both the aorta and the pulmonary artery, is essentially the same. Both the aorta and the pulmonary artery show productive-cicatrical lesions in about half the cases, but this does not of necessity mean that the disease in one vessel is an extension from the lesion in the other vessel. The disease affects the sexes about equally and has been found at the age extremes of 28 and 58 years, with the maximum incidence in the sixth decade. It is associated with cardiac difficulties and ultimately congestive heart failure, and it may exhibit a fairly characteristic roentgenogram. The most frequent murmur is a systolic murmur over the pulmonic area. Occlusion of a main branch of the pulmonary artery appears to have some relation to development and progress of pulmonary tuberculosis on the affected side.

Effect of Drugs on Cardiac Standstill.—Nathanson induced prolonged cardiac standstill by pressure on the carotid sinus in studying the effect of drugs on the rhythmic function of the human heart. He observed that the exaggerated carotid sinus reflex in man could be abolished by atropine. Epinephrine had a powerful effect on the impulse-initiating mechanism of the ventricles and consistently prevented cardiac standstill by the induction of an idioventricular rhythm. The stimulation of cardiac rhythmicity by the administration of epinephrine passed off within an hour after a subcutaneous injection. The effect returned after massage of the site of injection. Ephedrine

had no effect on a patient who repeatedly responded to epinephrine with initiation of a ventricular rhythm. Barium chloride abolished cardiac arrest in one patient by the formation of a new center in the auricles and in another by the development of an idioventricular rhythm. Calcium gluconate had no influence on the cardiac standstill. Digitalis definitely prolonged the period of cardiac standstill induced by pressure on the carotid sinus. This effect was abolished by atropine. Caffeine in a therapeutic dose had no effect on the duration of the cardiac arrest.

Comparison of Serum Therapy for Lobar Pneumonia.—Sutliff and his associates made a comparison between the symptomatic effects obtained in early type I lobar pneumonia by the administration of concentrated type-specific antipneumococcal serum and of horse serum globulin solution containing no specific antipneumococcal antibodies. The two preparations were prepared and administered in the same manner. In eight patients who first received nonspecific therapy and later received specific therapy, the greater effectiveness of the latter was obvious. In thirteen specifically treated patients who recovered, the duration of the disease was shorter than in the ten nonspecifically treated patients who recovered. Bacteremia was not present after therapy in any of the sixteen specifically treated patients, but bacteremia remained present in five, appeared for the first time in three and disappeared in two of thirteen nonspecifically treated patients. An extension of the consolidation of the lung was not observed after therapy in any of the sixteen specifically treated patients, but extensions were observed in five of thirteen patients receiving nonspecific therapy. A temporary symptomatic change was observed in each of the patients receiving nonspecific therapy, but the improvement in patients receiving specific therapy was permanent in every instance.

Iron in Hypochromic Anemia.—Heath analyzed eighty-four patients presenting hypochromic anemia with respect to the hematopoietic response to oral administration of iron. The percentage of utilization of orally administered iron, as determined by the total amount of iron gained in the circulating hemoglobin, varies inversely with the size of the dosage. It is possible, during the period of rapid gain of hemoglobin, when iron dosage orally is low, to have as much as 50 per cent of utilization. The average percentage of utilization of iron in the eighty-four patients during the entire period of recovery was 3.4. The percentage utilization of iron in idiopathic hypochromic anemia is less than in uncomplicated hypochromic anemia due to a chronic loss of blood. Patients with idiopathic hypochromic anemia usually require an indefinite continuation of iron therapy. The maintenance dose of iron in these cases is usually smaller than the dose required for maximum blood regeneration in the period of recovery. Toxic symptoms following the oral administration of iron and ammonium citrate not infrequently occur, but the maximum amount of iron administered orally in this form that is eventually tolerated by the patients is, as a rule, from 1 to 2 Gm. daily. The author feels that the influence that the addition of copper to iron may have in the treatment of hypochromic anemia in adults is at the most a minor one and that it is inadvisable to give copper salts as a routine measure in hypochromic anemia in adults. To be certain of giving adequate amounts of iron in hypochromic anemia, it is necessary to give large doses, such as 6 Gm. of iron and ammonium citrate daily, corresponding to 1 Gm. of metallic iron. Ferrous salts can be equally effective in somewhat smaller doses.

 Strategic Position in Treatment of Syphilis. Mary H. Swan, Chicago.—p. 209.

Bladder Infections.—Gelvin, in tracing acute bladder infections, keeps the patient in bed, applies an ice bag to the suprapubic region, orders a bland diet, and gives fluids to the extent of comfort. He believes that at this stage a balsamic, combined with codeine or morphine, is the most soothing type of treatment, and accordingly he gives either 5 minims (0.3 cc.) of copaiba four times a day, or 5 minims of oil of sandal four times a day, and one-fourth grain (0.016 Gm.) of codeine every four hours, or one-fourth grain (0.016 Gm.) of morphine as required. Daily enemas should be given, and no instrumentation should be attempted during the first week. By the end of the first week irrigations of the bladder with solution of boric acid may be begun, followed by the instillation of 2 ounces (60 cc.) of a mixture of olive oil and oil of cajuput, or 16 ounces (475 cc.) of olive oil and 4 ounces (120 cc.) of oil of cajuput. During the second week, a rectal examination should be made or, if the patient is a woman, bimanual examination followed by a cystoscopic examination. If the infection is due to the colon bacillus, the author uses methenamine, which he considers almost specific, giving $7\frac{1}{2}$ grains (0.5 Gm.) with 5 grains (0.3 Gm.) of acid sodium phosphate every four hours until the urine is positive for formaldehyde. During the third and fourth weeks, urinary antiseptics should be continued; but, instead of following the boric acid solution irrigation with an oil mixture, 2 ounces of a 5 per cent solution of neosilvol should be instilled. During the fifth and sixth week, the 5 per cent solution of neosilvol should be increased to 7.5 per cent and later to 10 per cent. The bladder is usually entirely normal by the end of from seven to ten weeks. In chronic cystitis or chronic infections, the first step in the treatment is to look for the focus. The use of colonic irrigation or acidophilus culture will frequently clean the colon and lessen its flora. Any chronic constipation should be corrected by appropriate means. A urinary antiseptic should be given constantly, and methenamine is by far the best, unless the invading organism belongs to the coccus family. In using methenamine it is essential that enough be given to obtain free formaldehyde in the urine, the presence of which can easily be determined by adding to a few cubic centimeters of urine 5 minims (0.3 cc.) of a 0.5 per cent solution of sodium phenol hydrogen hydrochloride, 5 minims of a 0.5 per cent solution of sodium nitroperoxide, and an excess of sodium hydrate. A bluish green color is positive for formaldehyde.

Copper Content of Urine.—Rabinowitch examined the urines of fifty hospital patients, selected at random, except that histories were carefully taken in order to exclude cases in which there was any suggestion of undue exposure to copper from treatment or occupation. The copper content of the urines ranged between traces and 0.41 mg. per liter and between traces and 0.7 mg. in twenty-four hours. The copper contents of the urine of three normal persons observed over a period of ten days corresponded to those noted in the entire group. In two copper "balance" experiments in which the subjects were fed copper, the amounts found were 0.63 and 0.81 mg. per liter and 0.84 and 1.01 mg. in twenty-four hours, respectively.

Clostridium Botulinum in Frozen Fruits.—Wallace and Park's investigation was undertaken to determine whether or not botulism could occur through the agency of frozen foods. The data from their studies would indicate that, if foods are canned properly and used immediately after defrosting, there is little danger of botulism from frozen foods. Toxin is not readily destroyed by freezing, but there is little chance of toxin being present in properly prepared frozen foods. Toxin was not produced in these studies before freezing nor, with few exceptions, during freezing. It must be remembered that the inoculations used were massive compared with the natural inoculation encountered in food for canning, and while the few cases in which toxin was formed or liberated during freezing might seem important in this study, in the canning industry they probably would not be so considered because of this difference in inoculation. The spores of Clostridium botulinum are resistant to freezing and once in frozen food they probably remain there for long periods of time. This is not of great importance if foods are canned and frozen properly, and if they are consumed soon after thawing. If foods containing spores are allowed to thaw and stand at room temperature for several days before using, they may become dangerous. This is especially true of frozen vegetables.

Cataphoretic Velocity of Streptococci Isolated in Encephalitis.—Rosenow and Jensen state that the streptococci as isolated from the nasopharynx and other areas of infection, especially the apexes of pulpless teeth, and sometimes from the blood and involved organs of persons suffering from encephalitis and other diseases of the nervous system, possess a characteristic neurotropic cataphoretic velocity. The velocity of the streptococci as isolated in cases of encephalitis shifted toward the slow velocity of the streptococci from influenza during epidemic waves of influenza. The marked neurotropic type of velocity of the streptococci found during convalescence from influenza suggests, perhaps, why encephalitis and other diseases of the nervous system, such as epidemic hiccup, poli-encephalomyelitis, radiculitis and neuritis, are so prone to occur following attacks of influenza or epidemics of influenza. The serums of almost all patients having encephalitis and certain other diseases of the nervous system had specific velocity-slowness effects on the respective strains of streptococci isolated in cases of encephalitis and having neurotropic velocity. Cataphoretic measurements of the streptococci isolated from areas of infection and measurements of the specific slowing effect of

the serum of the patient have proved of value in the differential diagnosis in puzzling cases.

Isolating Tubercle Bacilli from Blood.—In conformity with earlier observations, Cohn found acetic acid toxic to human and bovine tubercle bacilli, while sulphuric acid is innocuous in the concentration previously recommended (an amount equal to 2 volumes of 6 per cent sulphuric acid for thirty minutes at 37 C.). An analysis of Loewenstein's method (acetic acid hemolysis and a medium containing asparagine, egg and potato flour) discloses that the medium is satisfactory for growing small numbers of tubercle bacilli but that its preparation is unnecessarily involved, as it contains a few unessential expensive materials, and that acetic acid is bacteriostatic to small numbers of tubercle bacilli, as determined by actual static tests and by practical tests with human and animal blood containing tubercle bacilli which were recoverable by another method (sulphuric acid treatment and inspissated glycerin water-egg yolk medium). Acetic acid as used by Loewenstein is innocuous to saprophytic acid-fast bacilli, and if these are present in the blood they may be recovered by this method but not by the sulphuric acid method.

Staphylococci and Actinomycetes.—Novak and Henrich recovered a yellow staphylococcus from triturated, Berkefeld-filtered cultures of an actinomycete after incubation for five weeks at room temperature. This organism was culturally and morphologically identical with staphylococci on ordinary routine mediums. On dextrose agar, rods and branching filaments developed from the coccoid forms. Filaments or rods reverted to cocci when transferred again to plain agar. Smooth and rough colonies were obtained from cultures of the yellow staphylococcus. Rod and coccoid forms appeared in both smooth and rough colonies. A G type culture (similar to the G forms of Hadley) was obtained from aged broth cultures of the organism. The elements in the G culture ranged in size from minute to normal. These G forms demonstrated no filamentous properties and were strictly bacterial in nature. The authors suggest that their observations support the theory that the staphylococci are related to the actinomycetes.

Antibodies in Placental Extracts.—McKhann and Chu made a number of different tests to determine the presence of immune bodies in the placental protein extracts. They observed that protein material obtained from human placentas by extraction with a 2 per cent solution of sodium chloride and refined by precipitation with ammonium sulphate contains substances, presumably antibodies, which (1) neutralize diphtheria toxin, (2) blanch scarlet fever rashes, (3) neutralize poliomyelitic virus, and (4) prevent measles in exposed, susceptible patients. In the course of hospitalization for other causes, fifteen children, nonimmune to measles, became thoroughly exposed to the disease, and in seven cases so closely exposed that infection would seem to have been a certainty. These children received placental protein extracts by intramuscular injection within five days after the exposure to measles. Fourteen of the patients who received the placental extracts escaped measles, while one child, after a period of incubation prolonged to nineteen days, had a mild, modified form of the disease. In contrast to these children who received placental extracts, three children, similarly exposed to measles, received, on the fourth day of exposure, 30 cc. each of adult whole blood by intramuscular injection; modified measles developed in all. Two children who through faulty histories were thought to have had measles and who received no serum contracted typical measles. The experience with these five children indicates the thoroughness of the exposure of the total group and justifies the conclusion that some, at least, of the children who received placental protein extract were protected.

Relation of Jugular Foramina to Epilepsy.—Davis used the following technic in a series of roentgen examinations of the jugular foramina: The patient is placed in the supine position on a table, with the shoulders at the extreme head end, so that the head and neck extend beyond the end of the table. A Potter-Bucky diaphragm is placed at the head of the table so that its superior surface is 3 inches lower than the table on which the patient is lying. The patient's head is then tipped back until the top of his head, in the region of the lambda, rests on the Potter-Bucky diaphragm. The projection is correct when the angles of the jaws are in the plane which is determined by the focal spot of the x-ray tube, the left external auditory meatus and the right external auditory meatus. Care should be taken that the line between the focal spot and the center of the film is exactly in the midsagittal plane of the skull; then a restraining band is placed across the mandible. The roentgenograms are always made stereoscopically, by shifting the tube $1\frac{1}{2}$ inches in each direction, in the midsagittal plane. Stereoscopic shifts from side to side are not as satisfactory as those made longitudinally. Using a 40-inch target-film distance, an exposure of 300 milliamperes seconds may be used, varying in kilovoltage according to the thickness of the patient's head, or a standard setting of 100 kilovolts and 15 milliamperes may be selected, with a variation of the time from five to forty seconds, according to the thickness of the patient's head. The author made studies of forty patients with epileptic convulsions, twenty-nine of whom had foramina which were larger on the right, and eleven on the left. Ten patients presenting varied diagnoses were studied, and nine were found to have the larger foramen on the right and one on the left. The combined areas of the two foramina in ten patients of the convulsive group were found to be less in seven instances than the group presenting varied diagnoses. The author made roentgenograms of seven cases of hydrocephalus, in six of which the foramina were too minute to permit accurate measurement.

- Separation of Old Uterine Scar After Multiple Cesarean Sections. A. Van Ravenswaay, Boonville.—p. 167.

Differentiation of True Diabetes and Pseudodiabetes.—Glassberg offers a modification of the long used dextrose tolerance test as a means of differentiating true diabetes and pseudodiabetes. After a fourteen hour fast he makes the patient lie down for an hour's rest, at the beginning of which the bladder is emptied and the urine discarded and the patient is given two glasses of water to drink. After the patient has rested for fifty-five minutes, fasting blood and urine samples are taken for sugar determination. (Only when the fasting true blood sugar is above 175 mg. per hundred cubic centimeters is a diagnosis of diabetes mellitus made and the test omitted.) At

the end of the hour's rest the patient should take 100 Gm. of dextrose dissolved in two glasses of water flavored with the juice of one lemon. One hour later, blood and urine samples are taken for sugar determination and the patient is again given two glasses of water. Two hours after this, blood and urine samples are again taken for sugar determination. The author bases his classification on the following data, after the ingestion of 100 Gm. of dextrose: In adequate insulin secretion, prompt secretion, low normal, will show 80 mg. of sugar in 100 cc. of fasting blood, 95 mg. after one hour, and 70 mg. after three hours; fairly prompt secretion, medium normal, will show 80 mg. of sugar in 100 cc. of fasting blood, 150 mg. after one hour, and 80 mg. after three hours; delayed secretion, high normal, will show 80 mg. of sugar in 100 cc. of fasting blood, 270 mg. after one hour, and 120 mg. after three hours. Potential diabetic patients (usually obese persons must be treated for obesity and as diabetic patients) will show 135 mg. of sugar in 100 cc. of fasting blood, 270 mg. after one hour, and from 60 to 120 mg. after three hours. Inadequate insulin secretion in typical diabetic patients will show from 80 to 200 mg. of sugar in 100 cc. of fasting blood, from 230 to 390 mg. after one hour, and from 250 to 470 mg. after three hours. Glycosuria may occur at any of the foregoing blood sugar levels, but by itself it has no significance.

Immune Blood for Measles.—On the basis of a study of 214 children exposed to measles, 162 of whom were definitely exposed, Kaiser concludes that during a measles epidemic immune adult whole blood may be effectively used to assure that the patient will have an attenuated attack which confers a permanent immunity. He observed that the use of 10 cc. of whole blood has been sufficient to modify an attack of measles and materially reduce the incidence of complications. The use of 10 cc. of immune whole blood will not completely protect children who have been definitely exposed to measles. Much larger amounts are necessary for complete protection. The use of immune whole blood, usually parental, is simple, safe, inexpensive and effective in the treatment of measles.

Anesthesia for Electrosurgical Removal of Tonsils.—Maillard noted that an injection of a 2 per cent solution of procaine with epinephrine (1:2,500), made in the region of the superior fossa of the tonsils and infiltrating behind the capsule to a depth of about 1 inch, caused complete anesthesia of the tonsil, soft palate and base of the tongue within from five to ten minutes on the injected side. The loss of sensation in these regions is apparently due to an infiltration of the branches of the glossopharyngeal nerve that supply this area. It was possible to repeat this condition at each weekly visit on the same patient for a series of treatments. The author has given approximately fifty injections and has obtained the desired anesthesia in all instances. The postoperative results have been the same as with the use of the various topical anesthetics. The first indication of anesthesia is usually the presence of a nasal intonation of the patient's speech. One of the reactions noted in patients has been the regurgitation of liquid through the nasal orifices when attempting to drink water. This may be attributed to a disturbance of the normal reflex of swallowing, caused by the loss of sensation. There were also a few instances of increased lacrimation and a feeling of warmth on the anesthetized side of the face owing to involvement of the sympathetic nerve fibers. All these reactions were of short duration and not alarming in character.

Radiologic Observations in Low Back Pain.—Duncan reviews the records of 500 consecutive patients with the predominating complaint of distress of one or another type in the lower part of the back. About 170 were women who showed a more marked hollowing of the lower back than normal, free movement in all directions, with the production of typical discomfort on hyperextension of the spine, and tenderness on pressure over the lumbosacral joints and the lower lumbar spinous processes. In two thirds of these patients the roentgenograms were reported as negative, while the other third showed either a sacralization of the fifth or sixth lumbar transverse process, mild arthritic changes, or a slight scoliosis to one or the other side. In no case did the roentgen observations materially influence the treatment instituted, but they substantiated the indications for it. In this type of case, nothing supplants the regimen of adequate rest, the avoidance of fatigue, the elimination of focal infection, the adoption of a sane dietetic routine, the application of local heat, massage, instruction in muscle reeducation, with the correction of mechanical defects, and, in a fairly high proportion of cases, the adoption of a brace or corset. Of the 500 patients, 230 were typified by the short, thickset man who has done heavy work and who from his early thirties may have been subject to recurrent attacks of lumbago, with periods of perfect freedom between attacks. In 158 of these 230 cases there were changes demonstrated radiologically which would have been anticipated from the clinical examination. Many of these patients had an early arthritic process without any radiologic evidence of it. In this group there is a distinct discrepancy between the clinical impression and the radiologic observations in many instances. In the seventy-two cases in which the roentgen observations were reported as normal, it is apparent that, without adequate data obtained from the history and physical examination, the difficulty of the therapeutic problem becomes much greater. In this group the presence of radiologic changes facilitates solution of the problem, but the absence of gross changes does not demonstrate that the disease is not present in these patients with arthritic symptoms. The author concludes that there exists a sufficiently large element of error in the diagnosis of low back pain, regardless of the thoroughness and comprehensiveness of the clinical investigation, to make roentgenographic examination of the area obligatory in order that there may be some degree of certainty as to the fundamental factors involved in the production of the disability.

Intestinal Adhesions.—Leigh believes that, in cases of appendicitis, adhesions can be delayed and that proper drainage materials will drain just as long as necessary, provided real drains are used, the patient is properly elevated, the side position is arranged, and fluids are administered in as large amounts as the patient will stand. Tubes must be large, soft, thick walled and noncompressible. They should extend down into the pelvis and in other directions if indicated. They should be brought out at the outer (right) end of a transverse incision, the bed should be elevated sufficiently high, and the patient placed far enough on the right side to make the outer ends of the tubes their lowest point. Fluids will gravitate readily down to the tubes and run out into the dressings. Wicks of gauze placed lightly in the tubes will facilitate the drainage. As much salt solution as the rectum will absorb should be administered by the rectal drip with a visible dropper. In addition, saline solution may be given subcutaneously and intravenously as indicated. The patient should receive nothing by mouth except water until the stomach will tolerate food, and he should be nourished by intravenous dextrose, though usually simple fluids may be administered on the second or third day. The author concludes that the delaying of adhesions is important in many other than appendix cases, such as gunshot wounds of the abdomen, drainage following ruptured duodenal ulcer, and other infected abdominal conditions.

Treatment of Acute Arsenic Poisoning.—Bond induced arsenic poisoning in apparently healthy dogs, following a twenty-four hour period of starvation. As a source of arsenic he employed solution of potassium arsenite, which he administered from a pipet into a funnel connected with a stomach tube and rinsed down with 25 cc. of tap water. The mortality of a series of thirteen dogs given 0.5 cc. of the solution per kilogram of body weight was 46.1 per cent, and that of twenty-four dogs given 0.75 per kilogram of body weight was 100 per cent. In all animals treated with sodium hydrosulphite, from 0.75 to 1 cc. per kilogram doses of solution of potassium arsenite were employed. The antidote, 100 mg. per kilogram in a 10 per cent solution, was given immediately afterward and rinsed down

with 25 cc. of normal solution of hydrochloric acid. The results indicate that the compound possesses definite value if administered immediately following the oral administration of a fatal dose of potassium arsenite. The author determined that in a fatal dose of arsenic the antidote was ineffective after the lapse of fifteen minutes. While it is often difficult to secure experimental evidence to justify certain conclusions, he believes that sodium hydrosulphite possesses a definite beneficial action in preventing the serious intoxication resulting from sublethal doses of potassium arsenite, and that the time interval of effective treatment would be considerably prolonged with weaker concentrations of arsenic and by the presence of food in the stomach. The antidote itself is of low toxicity. Dogs recover from the oral administration of 1 Gm. per kilogram of body weight. Gross and histologic studies on animals that have received large doses of sodium hydrosulphite reveal no pathologic changes.

Some Phases of Contract Practice: Outline of Some Important Questions Which Deserve Immediate Consideration. R. G. Leland, Chicago.—p. 180.

Excretory Urography.—Nichols states that excretory urography is a valuable adjunct to other diagnostic procedures and is almost universally applicable. This method determines the functional as well as the anatomic condition of the urinary tract. No artificial means should be used to accentuate the shadows, as this precludes the advantages of this method. No greater concentration of the iodine than 5 or 6 per cent will be excreted by the kidney with a normal excretion threshold. The technic of application is comparable to and apparently may be done with no greater difficulty or danger than is encountered in the practice of intravenous cholecystography. An entirely new understanding of some phases of kidney dynamics is illustrated by intravenous urography. For instance, the normally functioning kidney pelvis is almost completely filled instead of empty as was believed formerly. There is a systolic and diastolic rhythm in the pelvis of the kidney. The true shape and position of the ureter can be observed without distortion, and also its peristalsis with alternate narrowing and distention, thus giving a definite identity to the ureteral stricture. The observations of intravenous urography are most valuable in the presence of hydronephrosis and of calculi. This method is not well suited to the study of infectious processes in the kidney other than tuberculosis. Renal tuberculosis in its early stages is also difficult to diagnose by the intravenous pyelogram. The use of this method of urography eliminates the controversy as to whether or not bilateral pyelograms should be made, and also settles the question as to whether pyelography should be attempted in the presence of renal tuberculosis. The intravenous method does not yield sufficient information in most cases of renal tumor, particularly in the early stages. All information possibly obtainable must be used in the diagnosis of questionable cases, including history, urinary observations, cystoscopic examination, and especially the opinion of a competent urologist.

Diagnosis and Treatment of Common Heart Conditions.—Cherry points out that many of the common heart conditions are easily diagnosed and treated by ordinary clinical means, although graphic methods such as electrocardiograms may be helpful or necessary in doubtful cases. In the diagnosis of heart failure, clinical symptoms are much more important than physical signs or graphic methods. The earliest symptom of cardiac failure is dyspnea, and this should never be minimized but should lead to a careful study of the patient. Many cases of coronary infarctions have in the past been diagnosed as attacks of "acute indigestion," but there is no longer any reason for this mistake. When digitalis is given after the total amount necessary has been calculated and when the heart

rate is used as a guide of its maximum effect, there will be no risk of overdosage, and small amounts of digitalis can thereafter be used daily to maintain this effect.

Migraine.—Podolsky reports seven cases of migraine which he treated with ergotamine tartrate. He believes migraine to be initiated by some mental or physical stimulus, which may or may not have a pathologic background. If due to some disease condition, such as an inflamed gallbladder, the diseased organ should be removed. But migraine is an imbalance, and this imbalance must also be destroyed if complete success is to be attained. The migrainous syndrome depends for the most part on the overirritation of the cerebral arterioles. The most logical form of medication is that which aims to depress this overstimulation with its consequent spasm. Ergotamine tartrate seems to be capable of accomplishing this aim.

"Grasping" Movements in Lesions of Frontal Lobe.—A study of eight patients presenting lesions of the frontal lobe has led Walshe and Robertson to the conclusion that phenomena included under the various headings of "tonic innervation," "the grasp reflex," "forced grasping and groping," and the like are found to be capable of analysis into two separable components, the one volitional and the other reflex. (1) The volitional component includes grasping movements of the fingers, with which movements of the hand and arm through space are sometimes associated. The stimuli to which they are responses are visual and tactile. Often both are operative, and it is only when the patient has the use of vision that movements of the limb as a whole occur. Tactile stimuli alone evoke nothing but grasping movements of the fingers, the hand and arm remaining still. (2) The reflex component consists in the tonic innervation of muscles when, and only when, these are subjected to the proprioceptive stimulus of stretch. Tactile or visual stimuli are not adequate to produce it. It may occur in the conscious or in the unconscious patient, and it is entirely outside the patient's control. The stimulus and the response are fixed and uniform and indicate that one is dealing with a true tonic reflex of the segmental nervous system, and one in which the cerebral cortex plays no part. Of the eight cases which form the basis of the authors' study, six are reported. In all there was evidence of the presence of a lesion involving the frontal lobe, and in all but one there were signs of an associated pyramidal lesion. In this one patient pyramidal signs never developed, and it is probable that grasping and tonic phenomena preceded the appearance of the signs in the others. When found, pyramidal signs are such as to indicate a relatively slight impairment of function in this system of neurons. Apraxia was not observed in any of the authors' patients. Not every one of their patients showed the full range of the grasping and tonic phenomena, and those who have done so have not shown it throughout the whole period of observation. These phenomena develop gradually, reach full development, and then with the progress of the illness they undergo a progressive restriction of range, accompanied by an increasing impairment of consciousness, until finally with the onset of stupor and semiconsciousness nothing remains but tonic innervation elicited by stretching the muscles involved. Under the conditions of a progressive dissolution of nervous function, this component has been the last to disappear. All the patients showed some unequivocal signs of impairment of psychic function—some signs of dissolution of function in the highest cerebral centers—and the authors believe this to be an invariable concomitant of grasping movements, and probably also of tonic innervation.

Biologic Test in Hodgkin's Disease.—Van Rooyen subjected enlarged lymph nodes removed from five patients with Hodgkin's disease to the test devised by Gordon. He obtained three typical positive results, one doubtful result and one negative result. He noted that this lymphadenomatous tissue, when ground, suspended in broth, and kept at 4 C. for more than ten days, produces striking effects when introduced into the brains of rabbits. It was also evident that these effects appear to be specific in character, for it has been shown that similarly prepared suspensions of lymphoid tissue removed in cases that clinically resembled Hodgkin's disease yielded negative results on test. Such cases have included glandular tuberculosis, lymphosarcoma and leukemia, all of which may be regarded as the commonest forms of lymphatic enlargement that may simulate Hodgkin's disease in temperate climates. The author does not give a detailed account of his experiments, which have been directed toward ascertaining the precise nature of the agent responsible for paralysis, ataxia and muscular wasting in rabbits, but the results obtained indicate that the autolysis, disintegration and cellular destruction of lymphadenomatous tissue liberate a product that is capable of producing an encephalitic syndrome in rabbits and guinea-pigs. Neither the inoculum nor the brain of an animal that succumbs to the condition shows the presence of bacteria after lengthy periods of observation. The author believes that the changes produced in rabbits cannot be interpreted on the basis of nervous changes following the introduction of a simple nonspecific irritating substance into the brain. Thus it can be demonstrated that substances such as a streptococcus toxin, sodium nucleate, aleuronat, quinine, urethane or finely powdered glass, which are capable of producing inflammatory tissue reactions, may be introduced into the brain of a rabbit with impunity. Indeed, these irritants may even be introduced in combination into the same animal on repeated occasions without the least visible effect. The author suggests that lymph nodes removed at biopsy in suggestive cases of Hodgkin's disease should not only be examined histologically and bacteriologically but should also be subjected to Gordon's biologic test.

 *Butyric Acid in Treatment of Cancer. J. Watson.—p. 746.

Blood Pressure in Male Adults.—On the basis of a study of more than 20,000 cases (male candidates for the Royal Air Force), Treadgold concludes that age, between 18 and 40, and proportionate height and weight have little effect on blood pressure. Abnormal body build is a pronounced factor, blood pressure varying from 118/75 in the lightest underweight group to 132/82 in the heaviest overweight group. Cardiovascular inefficiency, as judged by Royal Air Force tests and standards, accentuates these differences in body build. The emotional factor on first examination is of great importance. It affects mainly the systolic pressure. Although most marked in the unfit, it is comparatively common in fit candidates and its transitory nature is shown by following up such patients during their service. The height of the diastolic pressure is of great value in determining whether these cases are potential cases of raised blood pressure. The psychoneuroses seem to play little part in the causation of raised blood pressure in healthy young adults. Enlargement of the thyroid in these men is associated with a high percentage of cardiovascular inefficiency and, after allowing for this, both systolic and diastolic pressures are slightly above normal. Functional albuminuria has no effect on blood pressure, but glycosuria of the renal or lag type causes a slight rise of both systolic and diastolic pressures. Cases with a past history of scarlet fever show a slight rise in the diastolic pressure only, probably because of unsuspected renal involvement in a small percentage of such cases. Extremely hot climates tend to lower blood pressure, but moderately warm countries produce no effect. Hypotension, even when the systolic pressure is below 100, can be present in perfect health. The characteristics of the fit hypotensive person are a higher degree of cardiovascular efficiency than normal, and a tendency to underweight. It is rarely encountered on first examination owing to the emotional factor, but a diastolic pressure of 70 or below is always suggestive of its presence under normal conditions. Hypotension was present in 3 per cent of the fit pilots. Raised blood pressure, i. e., cases presenting systolic pressure of 140 and over, constituted 6 per cent of the fit pilots. Two per cent have blood pressure of 140/90 and over. Their characteristics were a tendency to overweight and poorer cardiovascular efficiency than normal. Blood pressure is higher on entry than in the normal fit candidate. Pulse pressure varies with the height of the systolic pressure, but relatively large pulse pressures with a low systolic pressure may coexist with perfect health. Small pulse pressures with normal systolic and high diastolic pressure are suggestive of a pathologic cause, and all cases of a persistent diastolic pressure over 90 require investigation irrespective of the height of the systolic pressure. The tendency to either hypotension or hypertension is probably a constitutional one, and such factors as obesity and toxemia, when they affect blood pressure, probably do so by emphasizing this constitutional tendency.

Butyric Acid in Treatment of Cancer.—Watson states that butyric acid has a destructive action on cancer of many

parts of the body, while it has a much less injurious effect on normal tissues; i. e., it is markedly selective. It is useful in cleaning up fungating malignant ulcers and rendering them suitable for treatment by surgery or radium. It can be made to destroy and delay the spread of growths in inoperable cancer of the rectum and stomach, and it destroys superficial papillomas. While the author used butyrate of quinine he was able as a rule to get the cervix cleared but was conscious of the limitations in its power of destruction. Since he has used a mixture of butyric acid and diatomaceous earth, cases of moderate severity have been rapidly prepared for Wertheim's method and the results have been good, without any trouble from pelvic sepsis. The author used a mixture of diatomaceous earth powder and butyric acid (from 40 to 50 per cent) in gelatin capsules. In treating cancer of the uterus the cervix is first curetted to remove as much as possible of the fungating mass. Care must be taken to avoid damage to the bladder and rectum, for the last vestiges of diseased tissue can be removed more safely by the chemical than by the mechanical agent. The cavity is then packed with gelatin capsules filled with the 50 per cent mixture of butyric acid and diatomaceous earth and the vagina is closed by the insertion of a plug of gauze or absorbent cotton. A small quantity of chalk may be placed in the upper part of the plug to neutralize any acid in the discharge. The 50 per cent mixture does little or no harm to the normal tissue and is just strong enough to break down the trabeculae, which are partially involved in the disease, and so opens up the pockets which might otherwise interfere with the complete destruction of the diseased tissues. The author's experience has been that, soon in the course of treatment, the patient is relieved of pain and improves in general well being.

Infection of Placenta and Fetus in Eclampsia.—Penfold and Butler examined twenty-five placentas, seventeen in cases of antepartum eclampsia, seven from intrapartum and one from a postpartum case. They were unable to isolate from these placentas any organism that appeared to them to be etiologically related to eclampsia. Coliform organisms were frequently found in the placentas of a series of women suffering from eclampsia. The presence of these organisms was closely correlated with the induction of labor. Their presence was likewise closely associated with a high fetal or neonatal mortality, but the authors have no positive evidence from their series that this mortality was caused by the placental infections. The frequency with which coliform infections of the new-born occur, described in the literature, has probably been largely due to infection of the fetus from the contaminated placenta.

*Syphilis in Children. G. Norrie.—p. 359.

Gastro-Enteritis. L. Male.—p. 364.

Enlargement of Lymphatic Glands in Children. P. L. Hipsley.—p. 368.

Syphilis in Children.—Norrie states that, in order to prevent syphilis in children, both parents should be treated and that the mother should be treated while pregnant, but, failing that, everything depends on the early diagnosis and adequate treatment of the child. Vigorous treatment should be instituted immediately after the diagnosis is made, because children respond more rapidly to treatment. A combined course of arsenic and bismuth compounds has been found to be most effective and is given by means of injections once a week. In urgent cases, the arsenical preparation is given intravenously into a scalp vein or the external jugular vein, and in the older child into a vein of the arm. In cases in which it is difficult to give drugs intravenously, the arsenic preparation may be given intramuscularly in the gluteal region. The bismuth preparation is injected intramuscularly. A course of six doses of neoarsphenamine followed by eight doses of a bismuth preparation may be given as a routine. A small amount of each drug may be given for the first dose, for example, for a baby of a few

weeks, 0.075 Gm. of neoarsphenamine may be given intravenously, followed by five doses of 0.15 Gm. each; then 0.5 cc. of an oily preparation of bismuth followed by seven doses of 1 cc. each. The doses may be increased with the age of patients up to 0.45 Gm. of neoarsphenamine and as much as 4 cc. of the bismuth preparation. In the author's patients, few ill effects were seen. No jaundice or dermatitis occurred from the arsenical preparation, but in some cases there was rarely marked vomiting and diarrhea. An interval of one month was allowed after a course of treatment, during which time potassium iodide was given to the older patients. At the end of the rest period, a Wassermann test is done and two full courses of treatment are given after the Wassermann reaction first fails to occur and, if the serum continues to give no reaction, no further injections are given. For the ensuing year, mercury is given orally for two-monthly periods in the form of mercury and chalk, from 0.01 to 0.32 Gm. three times a day, followed by intervals of two months in which no treatment is given. The child is kept under observation for another year, during which time no treatment is given. Wassermann tests are done every six months during this time, and if at the end of this period the tests have yielded no reaction, the child is considered cured.

Lactose Fermenting Coliform Bacilli in Dysentery.—Tang isolated seven strains of late lactose fermenting and one strain of non-lactose fermenting coliform bacilli from eight cases of mild dysentery. The earliest fermentation of lactose was seen on the fourth day and the latest on the fourteenth day. When peptone water was used as the medium for fermentation, the action was further delayed. The late lactose fermenters were classified as members of the genus *Escherichia* or the so-called colon lactic group and the non-lactose fermenter as a member of the genus of the aerobacter or the aerogenes group according to the Voges-Proskauer reaction and methyl red and other cultural tests. These organisms were distinct from *Sonne's bacillus* both culturally and serologically. The author discusses their relation to dysentery.

*Late Results of Treatment of Epididymal Tuberculosis. M. de Langre.—p. 377.

Action of Massive Ureteral Irrigation by Janet's Method: Experiences in Acute Case of Blennorrhagic Epididymitis. G. S. Epstein.—p. 403.

Epididymal Tuberculosis.—De Langre studied the late results of treatment of epididymal tuberculosis in sixty-two cases in Legueu's clinic. The patients were treated by epididymectomy or castration. Twenty-seven were cured or improved, while twenty had genital sequelae, three had urinary sequelae and eleven died from renal or pulmonary tuberculosis, tuberculous meningitis or unknown causes. These poor results are due to the fact that epididymal tuberculosis is usually associated with other tuberculous lesions. These may be pulmonary or renal, bilateral epididymal or vesiculoprosthetic lesions. The habitual coexistence of the latter (80 per cent) is the chief cause of the unfavorable prognosis of treatment of epididymal tuberculosis. These lesions usually remain latent but are the point of departure for infection of the other side or of any other organ. A statistical study of the results of various forms of treatment shows that epididymectomy is the best method. This is corroborated by a pathogenic study which shows that epididymitis is usually secondary. In case of a lesion limited to the tail of the epididymis, medical treatment may be tried before resort-

ing to epididymectomy. If the whole epididymis is invaded, epididymectomy is absolutely indicated even if the lesions are extensive, as the testis is often healthy. A small lesion of the testis near the epididymis may be extirpated in conjunction with the epididymectomy. Castration should be reserved for wide invasion of the testis. In case of bilateral lesions, double epididymectomy should be done to protect both testes. In case of advanced lesions, epididymectomy performed on the less affected side will permit castration on the other. Castration should never be bilateral, because of the important internal function of the testes. Surgical intervention must be followed by medical therapy to avoid recurrences and infection of other organs. Periodic examinations of the urine to discover latent renal tuberculosis and periodic examinations of the patient to permit immediate treatment of infections of the other side are recommended.

*Juxta-Articular Nodosities and Their Relation to Syphilis. R. Burnier.—p. 995.

Juxta-Articular Nodosities and Their Relation to Syphilis.—Burnier discusses under the name of juxta-articular nodosities a form of subcutaneous nodules that occur in the vicinity of bones, chiefly around articulations, the olecranon being the site of predilection. They are round or oval and are usually firm and mobile under the skin, but they may soften and ulcerate, leaving a scar. The average number is from two to four, although fifty have been observed. Their development is chronic and they are usually painless. Microscopically they appear to consist of fibrous tissue, partly degenerated. They occur in men and women, most frequently between the ages of 30 and 50. Their incidence is not limited to the tropics, as was formerly believed, but they have been found in all countries. The etiology of these nodules has been much discussed. In tropical countries they seem to have a multiple origin, mycosis, filariasis or frambesia being most frequently involved. In nontropical countries a syphilitic origin is most common. In 98 per cent of nontropical cases of extra-articular nodosity the Wassermann reaction was positive. The nodosities frequently occur together with symptoms of tertiary syphilis, more rarely with symptoms of secondary syphilis and never with a chancre. If a nodule is found in a patient who has never been to the tropics, a test for syphilis should be performed immediately, as it is usually a fibrous or fibroid syphiloma which will probably disappear with antisyphilitic treatment, especially if it is of recent origin.

- *Method of Cranioplasty: Repair of Cranial Wall by Grafts, Thin Osseous Layers Sawed from Internal Cortex of Tibia. E. Juvara.—p. 401.
Therapy of General Streptococcal Infection. H. Germain.—p. 423.
Spinal Anesthesia with Nupercaine. L. Lambert.—p. 459.

Method of Cranioplasty.—For the reconstitution of cranial defects by autografts, Juvara employs wide, long, thin osseous lamina, sawed off from the interior cortex of the tibia parallel to the cutaneous surface of the bone. The first part of the operation consists in preparing the cranial opening. The soft parts are incised at the site of the old scar, care being taken to keep the dura intact. The periosteum is incised, detached and pushed back a centimeter on the side of the short edges of the gap. The edges are freshened with a chisel, the short edges being given a beveled surface. To obtain the bone graft, an incision is made over the middle of the interior face of the right tibia. The aponeuroses along the edges of the bone are incised and the muscular insertions along the lower edge are detached a little. The length of the desired graft is marked on the periosteum. Starting at the upper mark with a Farabeuf saw, the blade of which is inserted at a right angle, a layer of bone from 1.5 to 2 mm. thick and of the desired

length is removed from the surface of the tibia. This thin layer of bone is covered with periosteum on one side; the other side is slightly striated from the action of the saw. This side, which is to come in contact with the dura, is polished with a file and the ends are slightly beveled to fit the beveled short edges of the cranial gap. The osseous plate is then curved by squeezing between the jaws of special pressure forceps designed by the author to be adapted exactly to the convexity of the brain. The graft is then put in place, with the extremities on the beveled edges of the cranial opening. The detached periosteal flaps are placed over the graft and sutured with fine catgut to the periosteum of the graft, the skin is sutured and a slightly compressive bandage is applied. The technic described is employed in case of a cranial opening that has the width of the anterior face of the tibia. If the opening is narrower, the graft must be cut down with cutting pliers after its removal or with a chisel before its removal. If the cranial gap is wider than the tibia, two strips of bone are detached from the tibia and grafted into the opening with their edges together. In the rare event of an opening more than twice the width of the tibia, the grafts may be spaced a small distance apart, or three strips of bone may be employed.

*Importance of Enterococci in Genesis of Phlegmonous Adenitis of Neck. P. Marri.—p. 320.
Congenital Dilatation of Choledochus. L. Ugelli.—p. 343.

Enterococci in Phlegmonous Adenitis of Neck.—Marri states that common agents of phlegmonous adenitis are micro-organisms with morphologic, biologic and cultural characteristics that classify them as enterococci. He treated sixteen patients; by intravenous injection in rabbits he isolated the hemolytic and extremely virulent *Staphylococcus pyogenes-aureus* from the pus of three patients and, in the remaining, he found in pure culture micro-organisms of weak pathogenic power, which he relegated to the group of enterococci. In culture, enterococci differ from micro-organisms of a related group (*Streptococci-pneumococci*) in that they are more variable in form, size and disposition. They have considerable vitality, which generally causes them to be mistaken for hemolytic or nonhemolytic, common, pus-forming streptococci, especially in cultures containing bile. They sometimes develop at outside temperature on ordinary mediums without deriving any advantages from mediums of special composition. On blood-agar their employment varies frequently, their hemolytic properties are negative or intermittently positive and the aspect of brown or slate-gray or greenish colonies is more constant. They have a tendency to develop into anaerobes, especially if recently isolated. They may develop on gelatin at 16 C. and coagulate milk after a lapse of four or five days. They develop best on bile mediums of the strongest concentration. They are capable of development in mediums in which ethylhydrocupreine hydrochloride is found in concentrations of 1:10,000 and 1:20,000. They show a slight resistance to heat (half an hour at 60 C.). They have no real pathogenic effect even in the strongest doses on white mice and on rabbits, in which subcutaneous injection may produce a torpid abscess that is spontaneously cured on opening. Bacteriologic diagnosis is of great importance in cases in which specific serotherapy or vaccinothérapie is held necessary. The clinical course of the disease is generally long and benign, owing to the lack of virulence of the enterococci. The course, however, is more rapid and accompanied by more serious symptoms when the causal agents are the virulent staphylococci. Incisions made in the foci of infection following phlegmonous adenitis due to attenuated bacilli constitute sufficient treatment.

- *Quinidine Treatment in Heart Diseases. F. Vega.—p. 817.
Pure *Staphylococcus Septicemia*: Four Cases. G. Suarez.—p. 830.

Quinidine Treatment in Heart Diseases.—Vega warns against the dangers of quinidine treatment in heart diseases and states that it is advisable to restrict the administration of quinidine (especially of quinidine sulphate) and to prescribe it

only in cases controlled by the electrocardiogram which do not demand the administration of digitalis. Quinidine treatment is indicated in arrhythmia not complicated by cardiac insufficiency, in alterations of the muscular fibers of the heart or advanced mitral stenosis, in early and paroxysmal auricular fibrillation without cardiac decompensation and in arrhythmia of thyrotoxic origin, intractable to the causal treatment. It is contraindicated in cardiac myopathy, in carditis in evolution with active infection, in advanced mitral stenosis of old duration and in cases of intense circulatory insufficiency in which a cardiotonic treatment with digitalis is the only indication to obtain a normal rhythm of the heart. Digitalis, as preliminary treatment to the administration of quinidine, may cause heart failure. Before administering quinidine it is necessary to wait until all the digitalis stored in the organism is eliminated, in order to avoid any dangerous synergetic reaction and because digitalis may produce a latent block of the heart which may rapidly develop by the administration of quinidine and cause death. During the period preceding the administration of quinidine, insulin may be given to great advantage. Although most of the satisfactory results of quinidine are obtained in patients in whom digitalis has not been previously used, it seems advisable to keep in mind that digitalis is the most proper treatment of auricular fibrillation and, on this basis, to administer it in order to reestablish the potentiality of the cardiac muscle by increasing the coronary nutrition. If digitalis does not cause the heart rhythm to become normal, it is advisable to give quinidine according to the indications previously stated. Quinidine treatment gives better results in auricular paroxysmal fibrillation than in chronic fibrillation. The latter, according to Pardee's dictum, is a truly auricular myocarditis in which the administration of digitalis is the only sure resource. Quinidine, because it causes intense depression of the heart, should be carefully prescribed and the physician should observe the patient as frequently as possible. It is for these reasons that its use should be excluded both from emergency medication and from rural practice.

Amidopyrine-Fast Fever.—Petrányi observed that, in nurslings and small children who have uncomplicated pneumonia or influenza, the fever can be checked by adequate doses of amidopyrine. If the fever does not disappear, or if the temperature rises again after a while, that is, if the fever becomes "amidopyrine-fast," a malignant change in the primary disease must be assumed (toxic pneumonia, influenza), or a complication is developing or already present. Unsuccessful antipyresis frequently has a diagnostic value in pediatrics, because as a rule the fever becomes amidopyrine fast before the development of the clinical symptoms. Failure of the antipyresis has a prognostic significance, since the fever that becomes refractory during the first few days indicates malignancy of the primary disease. If the fever increases in spite of the administration of amidopyrine, this also is a bad sign. However, the fact that the fever can be influenced by amidopyrine is no proof of the benign character of the disease.

Relations Between Acetonemic Vomiting and Scarlet Fever.—In patients with scarlet fever the history nearly always reveals vomiting and the urine usually contains acetone, according to von Kostyal. He thinks it probable that acetonemia is present before the exanthem becomes manifest. Acetonemia is also present in conditions in which scarlet fever develops as a complication, such as in burns, after surgical interventions, in tonsillitis and after delivery. Moreover, other cutaneous eruptions, such as urticaria, have been noted in patients with acetonemia. Urticaria develops occasionally during menstruation, and it has been determined that menstruation is accom-

panied by impaired hepatic function, acidosis and acetonemia. The author considers three modes of pathogenesis of scarlet fever, the exogenous (pathogenic micro-organisms) the endogenous and a combination of these two factors. He calls attention to the rôle of the diet in the development of scarlet fever. An excess of milk and eggs, particularly if there is an anaphylaxis toward these foods, impairs the liver, in which case the organism is no longer protected against toxins. The author points out that it would be interesting to determine whether diet can influence the Dick test, or what influence an acetonemic condition exerts on the Dick test. The fact that it was possible to arrest acetonemic vomiting by means of intravenous administration of convalescent serum from scarlet fever patients is another indication of a relation between the two conditions. Persons who do not contract scarlet fever, although they are exposed to it, are not necessarily immune to it but do not develop it because their skin is incapable of producing the exanthem. The author reports the cases of eight puerperal women in one ward, some of whom developed scarlet fever while others developed tonsillitis or tonsillitis with urticaria; yet none of them had had scarlet fever previously, and it is hardly possible that the pathogenic organism was not the same in all these cases. He cites border cases between scarlet fever and acetonemic vomiting. He thinks that the incidence of concurrence of acetonemic vomiting and tonsillitis is practically the same as that of scarlet fever and differs from the latter only by the absence of the exanthem. He does not consider all these ideas "proved facts" but thinks them worthy of further investigation.

Bone Atrophy After Fractures.—Heydemann states that atrophy of the bone is demonstrable in roentgenograms after a loss of not less than 15 per cent of calcium. Acute traumatic atrophy of the bone is the result of a circulatory disturbance. The author emphasizes that it is the interference with the venous return and the presence of compensatory hyperemia rather than the interference with the arterial blood supply that is responsible. The more tissue destruction, soft or bony, the quicker and the more pronounced is the atrophy of the bone. Extensive traumatization of soft tissues is more likely to cause atrophy of the bone than extensive damage to the bone without much accompanying destruction of the soft tissues. The first evidence of atrophy is usually seen in the metaphyses and in the subchondral areas. Atrophy of the bone delays healing in adults and retards bony growth in the young. Pure atrophy of disuse occurs only in elderly people and is a matter of months, whereas acute traumatic atrophy can be observed as early as two weeks after a fracture. Some degree of atrophy occurs after most fractures and is demonstrable in roentgenograms if sufficient attention is paid to the peripheral portions of the bone close to the joint. The author feels that the subject of atrophy of the bone deserves more attention because it is frequently the cause of pain on passive or active movements.

Acute Circulatory Weakness and Its Treatment.—Külbs emphasizes that, although heart and vessels are so closely connected that they can hardly be considered separately, it is

nevertheless advisable to differentiate vasomotor weakness and heart failure in the therapy of circulatory insufficiency. Vasomotor weakness may develop in the course of many different conditions, such as a number of infectious diseases, various forms of poisoning, overexertion and sudden changes in the temperature. He describes two cases indicating that severe, life-endangering conditions may develop as the result of hypersusceptibility to external stimuli or to overexertion, without demonstrable cardiac or vascular involvement. Circulatory weakness may develop in arteriosclerosis, in mitral stenosis and in mental excitations, perhaps as the result of an overtaking of the extracardiac sympathetic nervous system. Acute failure of the cardiac muscle is most frequently the result of mechanical factors, of direct or indirect traumas, or of thrombi in the heart or in the coronary system. That septic infectious diseases may lead to toxic impairment of the musculature has been proved repeatedly. In this event not only the vasomotor apparatus but also the cardiac muscle is at fault. This disturbance can be experimentally produced in animals poisoned by means of digitalis or of strophanthin, and the electrocardiogram usually shows sinus tachycardia, extrasystoles and ventricular fibrillation. Disorders in the lesser circulation, such as spontaneous pneumothorax, hemothorax, pulmonary infarct and pulmonary edema, and disturbances in the coronary circulation may lead to cardiac insufficiency. The author discusses the independence of certain vascular regions and shows how the disturbances in each of them can best be counteracted. In case of the coronary arteries, dilatation can be effected best by means of nitrites, xanthines (caffeine, theobromine or a theophylline preparation) or epinephrine, whereas constriction can be obtained by nicotine. He discusses the treatment of disturbances in the pulmonary system, the cerebral vessels, the splanchnic region and the cutaneous vessels, and of cardiac weakness, operative shock, cardiac asthma, angina pectoris and infarcts.

Retrogression of Exophthalmos After Ovarian Therapy.—Halpern reports the history of a girl, aged 21, who, eight months previously, had developed an exophthalmos on the right side. An enlargement of the thyroid was not noticeable and the basal metabolism was normal. But at times there was slight tachycardia, and the fingers showed a slight tremor. There were no signs for a local etiology of the exophthalmos. The history revealed that menstruation, although regular, was of short duration and that the flow was scanty. Libido was entirely absent. The genitalia were somewhat hypoplastic. The assumption of a correlative regulation of thecretory organs and the ovarian insufficiency (scanty menstruation, hypoplastic genitalia, lack of libido) induced the author to try ovarian therapy. The patient was given desiccated ovarian substance three times daily. After three weeks a considerable improvement of the exophthalmos was noticeable and the menstruation that set in during the third week of the ovarian treatment was more profuse and lasted longer. After the exophthalmos had largely disappeared, an attempt was made to discontinue the ovarian therapy, but the protrusion of the eye returned. After five weeks the exophthalmos had completely disappeared.

- Effective Method of Resuscitation in Drowned Persons. F. Mocny.—p. 894.

Ileus.—In discussing diagnosis, Anschütz states that during the early stage the symptom of the metallic, splashing sound is significant, provided it is accompanied by intestinal occlusion that cannot be overcome by enemas. He emphasizes the great diagnostic value of roentgenoscopy and states that the contrast clyster does not have to be feared, since it is less trying for the patient than a rectoscopy. He discusses the indications for surgical intervention and he stresses the value of early opera-

tion. As to the method of operation, he advises that the incision be made as near the obstruction as possible and that eventeration be avoided. Evacuation of the obstructed intestine during the operation he considers unnecessary and inadvisable. He points out that in case of incarcerated hernia evacuation is not done, although the condition of the intestinal wall and the intestinal contents are practically the same as in ileus. Moreover, evacuation involves great dangers, particularly infection, and is inadvisable in view of the reestablishment of the intestinal peristalsis. In comparing the results of operations in which the intestine was opened with those of interventions in which the intestine was left intact, the author found that the mortality rate was much smaller in the latter group (21 per cent compared to 64 per cent). These figures, as well as the analysis of the causes of death and the age of the patients in the two groups, convinced the author that the advantages of evacuating the intestine during the ileus operation do not outweigh the disadvantages.

Surgical Disorders of Stomach and Human Psyche.—Examination of 942 patients with gastric complaints revealed to Krecke that 186 had carcinoma and 242 had ulcer, while in 514 anatomic changes were not detectable. Most of the latter group had so-called primary gastro-intestinal disturbances. The examination revealed in most cases irregularities in the hydrochloric acid secretion, such as anacidity, subacidity or hyperacidity. Others had gastroparesis and still others were troubled with spastic conditions of the colon. However, the author is convinced that these disturbances are not the true cause of the disorder but that in the majority of these patients the psychic equilibrium is impaired. It has been proved that psychic impressions exert great influence on the function of the gastro-intestinal tract, and the anamnesis should aim to determine whether a psychic trauma preceded the gastric disturbances. It is necessary for the surgeon to have some psychologic knowledge, so that he may have an understanding of the psychic origin of certain disturbances. Many patients report spontaneously that their gastric disorder dates back to a great shock, anger or sorrow. The repetition of irritating experiences may cause the gastric disturbances. Merely to tell him that the disorder is a nervous condition is inadvisable, because "nervous" means to the average layman simply "imaginary." If the examination reveals that the hydrochloric acid secretion is disturbed, the patient should be told so, for this generally satisfies him. The physician may explain that this disturbance in the acidity is due to a change in the sympathetic nerves or in the solar plexus. If roentgenoscopy reveals changes in the duodenal bulb, the patient may be given an explanation of this condition. It is inadvisable, however, to designate disturbances in the intestinal activity simply as constipation, but it should be explained as a spastic condition of the intestine.

Roentgen Therapy of Polycythemia Rubra.—Holfelder and Reisner report the histories of fifteen patients with polycythemia. In fourteen the polycythemia was the Vaquez-Osler type with enlargement of the spleen and with normal or slightly increased blood pressure, and in one it was of the Gaisböck type with high blood pressure but without enlargement of the spleen. The authors gained the impression that roentgen irra-

diation of the marrow of the tubular bones influences the blood picture as well as the general condition, and they irradiated the tubular bones in the following sequence: both legs below the knee, the right thigh, the left thigh, and the upper part of the right and left arms. Since the marrow of the sternum is an important element in polycythemia, they irradiated it also, and in severe cases they applied the roentgen rays likewise to the spinal column; but they do not consider so important the irradiation of the flat bones, particularly the scapular and pelvic bones, although some authors have expressed the opinion that the increased hematopoiesis of polycythemia involves mainly the short and flat bones. In order to be effective, the single doses should be from 70 to 90 per cent of the unit skin dose, for smaller doses do not produce such good effects. It is advisable to irradiate the tubular bones in rapid sequence, because smaller doses administered after longer intervals readily accustom the patient to the rays. In successful irradiation, the total doses varied between 6,000 and 12,000 roentgens administered in from four to seven weeks. The irradiated fields should be as large as possible (20 by 24 cm.). If there is a relapse, irradiation should be repeated but the patients are usually well for from nine months to two years and the tissues have time to recover from the effects of the large doses sufficiently, so that a new series of treatments can be given without danger. Roentgen irradiation of the entire body has also been recommended for the treatment of polycythemia, but the authors consider irradiation of the spleen, included in this generalized treatment, a disadvantage and therefore recommend that the spleen be cut off from the rays by lead protectors. Bucky obtained a decrease of the erythrocytes by irradiation with borderline rays. The slight penetrability of these rays makes it doubtful whether they influence the bone marrow directly, and Bucky supposes that the bone marrow is influenced indirectly by way of the cutaneous sympathetic nervous system. The authors think that irradiation of the marrow of the tubular bones by means of large fields and high doses of hard rays is still the method of choice in the treatment of polycythemia.

Roentgen Irradiation in Inoperable Tumors.—The favorable results obtained with protracted fractional intensive roentgen irradiation in inoperable carcinomas of the tongue, the tonsils or the hypopharynx induced Schumacher to employ the same treatment in inoperable or relapsing malignant growths of the female genitalia and of the breast. His technic was such that only one field was irradiated a day with a surface dose of 200 roentgens. When the general condition or the blood status was greatly impaired, the irradiation was discontinued for several days. In tumors of the genitalia the rays were generally applied to four fields, two abdominal and two sacral, or one abdominal, one dorsal and two lateral fields. The focus-skin distance was from 50 to 60 cm. Carcinoma of the breast was usually irradiated as one field and at a distance of from 70 to 80 cm. The aim was to apply ten times 200 roentgens to each field. The focus doses averaged from 2,000 to 3,000 roentgens. The treatment required as a rule from four to six weeks. In the beginning the irradiations were usually well tolerated, but toward the end the patient's general condition was frequently such that the irradiations had to be interrupted for a while. Nearly all the patients lost weight. The blood counts, taken twice a week, revealed a decrease of the leukocytes, particularly the lymphocytes, but the changes in the other formed elements of the blood were relatively slight. Generally, the skin reactions did not appear until after the sixth application, but toward the end of the irradiations the fields were swollen, erythematous and sprinkled with red stippling. The sacral field often showed considerable exfoliation, which subsided within three weeks. The urinary bladder and the intestine, which in the pelvic irradiations received considerable doses, showed comparatively slight reactions. Of eight inoperable carcinomas of the uterus, three reacted so favorably to the treatments that only small remnants persisted at the end of the treatment, while three similar cases remained refractory and two were exacerbated during the treatment. Two recurrences in the lateral pelvic wall disappeared entirely following the protracted treatment, but a number of uterine carcinomas that had already been unsuccessfully treated with radium were refractory to protracted intensive roentgen treatment. In twelve inoperable ovarian carcinomas the therapeutic

results of the protracted roentgen treatment were considerably more favorable than in the uterine carcinomas. Not one of the twelve cases was entirely refractory. Recurrences of mammary carcinomas likewise reacted favorably. However, sarcomas could not be influenced by means of this method. A disadvantage of the protracted roentgen irradiation is that the initial favorable results may eventually be reversed later, in that the metastases grow faster. The author considers this a warning against forced irradiation and against a further increase in the dosage administered at one sitting.

Investigation on Kidney Function According to Rehberg's Creatinin Method. H. C. A. Lassen.—p. 143.

*Phosphatases of Organism. E. Jacobsen.—p. 162.

Phosphatases of Organism.—Jacobsen's experiments indicate that the same enzyme sets free the various phosphoric esters, and he suggests the term "general phosphatases" for this enzyme. His further experiments establish a new, specific phosphatase. The substrate is found in the phosphates of the blood corpuscles. The new principle is relatively abundant in liver extracts, in which the content of general phosphatase is small, while kidney extracts, in spite of a large content of the general phosphatase, poorly set free the phosphates of the blood. Treatment with alcohol weakens the new principle more than the earlier known principle and, unlike the latter, it is not destroyed by heating in weak acid solution.

Histologic Changes in Mammary Glands in So-Called Gynecomastia and Its Relation to Cystic Mastopathy in Men. C. von Numers.—p. 388.

Skin Tuberculosis in Lepers.—Lie reports a case of leprosy with scrofuloderma of the neck. Typical tubercle bacilli were cultivated from the swollen lymph nodes of the neck. Necropsy showed tuberculous changes in these glands and in one bronchial gland. He states that, since different disorders may appear simultaneously in leprosy, the causes of processes not typically leprosy must be carefully studied and not simply referred to the *lepra bacillus*.

Rosacea-Keratitis.—Kissmeyer describes a marked case in a woman, aged 33, with pannus-like vascularized infiltration, deep subepithelial whitish, often calcium-like, infiltration and ulceration of the cornea. He believes that a number of the cases described as rodent ulcer of the cornea are probably of the rosacea kind. Therapy consists partly in application of sulphated bitumen-zinc-petrolatum ointment and partly in removal with a sharp curet.

Eclampsism.—Hoffström ascribes the primary cause of eclampsism to a hypocalcemia due to hypofunction or dysfunction of the parathyroid glands and finds his theory supported by the results of experiments with a four-day treatment plan. After venesection a combined treatment with parathyroid hormone, vitamin D and calcium is given, the first two days with inanition treatment and greatly limited water intake.

*Atypical Amyloidosis. B. von Bonsdorff.—p. 447.

Atypical Amyloidosis.—In von Bonsdorff's patient, aged 51, there developed shortly after fracture of a rib and within two or three months firm, symmetrical tumor formations up to the size of a child's head, in the region of the large joints, with one below the right shoulder. Small, button-shaped tumors appeared on the tongue and in the oral mucous membrane. The tumors are thought to have originated in the soft parts and the destructive changes, roentgenologically established in the osseous system in the vicinity of the tumors, are assumed

to be due to pressure exerted by the tumor mass. These changes affected the bone marrow, causing a disturbance in the calcium metabolism with a tendency to hypocalcemia at the start of the disorder and hypercalcemia at the end. There were increasing exhaustion, without noteworthy increase in the size of the tumors, and fatal outcome after one and one-half years. The tumors, well defined from the surrounding tissue, consisted of deposits of a whitish yellow, homogeneous, amyloid-like substance, structureless and metachromatically stainable with cresyl and gentian violet. Transportation of the amyloid-like substance had apparently occurred to the regional lymph nodes. The kidneys revealed numerous atrophied glomeruli with signs of nephrosis. The tumor mass consisted mainly of a protein substance from which nine different amino acids were differentiated. Thirty-three cases of amyloid tumors are cited. The author ascribes classic as well as atypical amyloidosis to disturbances in the protein metabolism of the organism. In his opinion a relation exists between myelomas and atypical amyloidosis, whether or not the latter appears with multiple myelomas. He believes that in his case trauma was a factor in the origin of the atypical amyloidosis.

Balantidium Coli Diarrhea and Intestinal Polyposis. O. Hanneborg.—p. 650.

Contribution to Treatment of Condylar Y Fractures with Some Fractures of Diaphysis: Preliminary Report. M. H. Gjessing.—p. 660.

Atypical Traits in Dementia Paralytica.—Sæthre says that out of 135 cases of dementia paralytica without any anti-syphilitic treatment four presented a completely negative Wassermann reaction in the blood and spinal fluid. One of these, observed for one year during which no treatment was given, gave a negative Wassermann reaction at four different times. Necropsy disclosed a typical picture of dementia paralytica. Two cases present exceptions to the rule that patients with neurorelapse do not later on develop dementia paralytica. In the fourth case, one of locomotor ataxia treated with malaria, paroxysmal megalomania ("psychic Jackson spasms"), developed one and one-half years later. This gradually changed to a fairly typical dementia paralytica.

Gradenigo's Syndrome and Inflammation in Pyramidal Apex.—Galtung reports four cases in which Gradenigo's syndrome appeared after an acute otitis media, in one case before, in the three after, antrotomy. All patients recovered, one after antrotomy alone, two after antrotomy with revision, and one after conservative medical operation according to Bárány with subsequent Frenchner's petrositis operation. In only one case was there roentgenologic and clinical proof of inflammation in the pyramidal apex. In a fifth case necropsy showed inflammation in the pyramidal apex without its having produced Gradenigo's syndrome wholly or in part.

Multiple Tuberculous Spondylitis.—Thrap-Meyer describes seven cases, six presenting two tuberculous foci in the spinal column and one presenting three, all separated by sound vertebrae. A lymphohematogenic origin of these multiple foci is regarded as most frequent and probable, and contact infection through a sedimentation abscess extremely rare. In

one of these cases the latter mode of infection is thought probable. In all the cases the subjective symptoms were localized about the caudal focus. There were no symptoms from the spinal cord.

Uppsala Medical Society 1832-1932: Pages from History of Our Medical Development. U. Quensel.—p. 409.

Tuberculosis of Aorta and Tuberculous Aneurysm of Aorta.—Gellerstedt and Säfwenberg describe a case of erosion of the abdominal aorta due to an old cheesy paravertebral tuberculosis of the lymph nodes. As a result of the erosion a false retroperitoneal aneurysm developed, which caused a rupture-like protrusion of the diaphragm into the pleural cavity. The roentgen diagnosis was intra-abdominal tumor. On operation the pulpy discharge from the tumor suggested sarcoma or Grawitz tumor. Death was due to hemorrhage. Necropsy revealed an extensive miliary tuberculosis in most of the organs with notably small and closely located tubercles, to some extent localized in the glomeruli in the kidneys and having a marked tendency to necrosis in the liver and spleen. The twenty cases of tuberculosis of the aorta with formation of aneurysm found in the literature are cited. Diagnosis has not yet been made during life, but in the author's opinion this should theoretically not be impossible.

Changes in Brain in Normal Involution of Age.—The results of the examination of fifty brains of persons aged at least 65 years, mostly from the middle class of Munich but including two of the élite, are discussed by Gellerstedt, with remarks on the pathogenesis and the relations between anatomic results and clinical symptomatology. He says that in the aging brain the reduction of ganglion cells in the cerebral cortex usually occurs in tracts. With regard to fatty changes in the ganglion cells, earlier results are confirmed. The atrophy of the nerve cells of the cerebral cortex is not seldom combined with the appearance of atrophied or sclerotic ganglion cells. Granulovacuolar degeneration seems to be common in normal old age but localized in Ammon's horn. Alzheimer's change in the filaments is not uncommon even in mentally normal aged persons but is practically always localized in the allocortex of the temporal lobe. The senile plaques occur far oftener than is commonly supposed, with several local variants and types. Atrophy of medullary fibers is frequently demonstrable, at least in the cortex. The typical qualitative changes of the glia cells show a slightly progressive character. Regressive changes in the glia cells do not belong to the senile picture. The fatty changes in the glia afford a good indication of the degree of tissue atrophy. Histologically demonstrable iron is more extensive in the aging brain than was thought formerly. "Concrements" containing iron, probably never absent in the aged brain, vary greatly individually. Senile fibrotic changes of the blood vessels are to be distinguished from regular arteriosclerosis and probably play a part in the origin of many histologic changes of the aging brain. Plexus sclerosis is to be regarded as a phenomenon of age. Ependymitis is not characteristic of age.

THE CURABILITY OF CANCER OF THE COLON, RECTOSIGMOID AND RECTUM

CHAIRMAN'S ADDRESS

FRED W. RANKIN, M.D.

LEXINGTON, KY.

Any consideration of the ultimate results following extirpation of cancer of the large bowel, rectosigmoid and rectum which fails to take into account factors that influence favorably or unfavorably the number of survivors after a given term of years is obviously an incomplete one. While one may glibly assert and actually prove by statistics that the prognosis following successful eradication of cancer of the large bowel, rectosigmoid and rectum is more favorable than elsewhere in the alimentary tract, some reasons for these satisfactory end-results should follow in logical sequence. It is my feeling that the most important factor influencing prognosis in cancer of this or other locations is the intrinsic activity of the neoplastic cells, particularly their ability to differentiate or not differentiate from the normal. That this influence is unquestionably affected by modifying conditions present in the majority of instances is, I believe, incontestable. The extrinsic influences, or the modifying factors, which are of grave importance, are such general conditions of the host as age, coexisting debilitating diseases, and the duration and direction of the growth. To these may be added secondary factors which are the direct result of the presence of malignant neoplasms, such as anemia, loss of weight and glandular metastasis, as well as other factors local to the growth, including fixation, perforation and other local complications.

Without going into any great detail I reiterate the oft repeated statement, which has become almost axiomatic, that the youth of an individual is an unfavorable factor as compared with the less active tissue barriers of middle life or advancing years. Young tissues so potent in their resistance to acute, fulminating infectious processes are helpless to withstand the formidable offense of cancer. Their vital elasticity and resilience is far less hostile to neoplastic invasion than that of the tissues of senescence.

Some years ago, Comfort and I reviewed a series of cancers of the rectum in young people and found the prognosis hugely more unfortunate than in patients of the average age group. The duration of symptoms was shorter, the percentage of metastasis greater, the opera-

bility rate lower, and the percentage of ultimate satisfactory cures after periods of three and five years greatly decreased. The total good results, we estimated, were 50 per cent less, and the total poor ultimate results 20 per cent more, than in a group of patients of all ages taken together. In other words, the malignant growths were more active here and of a higher grade, according to Broder's index of malignancy, and consequently metastasized earlier and with a lethal outcome in a much higher percentage of cases than in the group of all age patients.

DURATION

The duration of the growth is a factor of importance, which is estimated with great difficulty, since persons do not know of the presence of a cancer until it has produced obstruction or a break in the mucous membrane which causes blood to appear in the stool. The average patient having a cancer of the colon, rectosigmoid or rectum will have known of the symptoms on an average of ten months or more before seeking advice. Naturally, ample opportunity is thus afforded a rapidly growing, highly malignant tumor to disperse cells through the lymph or blood-channels to distant bases, yet apparently this is compensated for in large measures by the low grade of the growth in the majority of cases: perhaps an explanation also of their well known tendency to remain local over a relatively long period of time. Such considerations as loss of weight, anemia and cachexia may be dismissed with the suggestion that they are either the result of a long standing malignant condition or distant metastasis, with the exception of a group of cancers of the right colon, which produce a profound anemia without visible loss of blood and without presenting any other symptoms pathognomonic of this location.

SIZE

That size of the growth has little if anything to do with the prognosis has been proved by observations on every segment of the colon. The diameters of the growths removed from patients who obtained five year surgical cures averaged up to the same figure as those obtained from the patients who died of recurrence. The probable explanation lies perhaps in the fact that the highly malignant tumors metastasize early when the parent growth is still small, while the less malignant cancers sometimes assume huge proportions before dissemination to the lymphatics begins. From the practical standpoint of operability, one sometimes resects large growths, which are frequently considered borderline cases because of their fixation, only to find no glandular involvement and to be rewarded by a satisfactory ultimate result. Such types are more likely to be discovered among right colonic cancers than those of the left side, because growths in the right half are usually

large, ulcerating, infected, and frequently more or less fixed from inflammatory adhesions rather than from direct extension of the malignant process. Actually, cancers of the cecum and ascending colon are the largest of all the growths found in the colon, whereas those in the sigmoid are the smallest; yet it is statistically shown that left colonic lesions are somewhat poorer of prognosis than are tumors of the right half.

TABLE 1.—Incidence of Glandular Involvement

| | |
|--------------|-------------|
| Grade 1..... | 27 per cent |
| Grade 2..... | 33 per cent |
| Grade 3..... | 50 per cent |
| Grade 4..... | 56 per cent |

DIRECTION OF GROWTH

One point which I feel has not been sufficiently emphasized in the past and which I believe is of considerable importance from the standpoint of prognosis is the direction of the growth. Whenever cancer of the large bowel, rectosigmoid or rectum—and all are adenocarcinomas—takes on the appearance of a polypoid or adenoid-like growth and pouches into the lumen of the bowel, one finds a malignant condition of low or average grade and little or no nodal involvement. On the other hand, when the growth is a punched-out ulcer with a large active base penetrating toward the serosal coat of the bowel, one is more likely to find a higher grade of malignancy and a larger percentage of nodal involvement.

In a study of a series of cases of cancer of the colon excluding the rectum, Olson and I found that the percentage of five year cures in growths which projected intraluminally was 62 per cent, against 41 per cent for growths that extended toward the serosa.

MATERIAL STUDIED

The material for this study on the curability of cancer of the large bowel, rectosigmoid and rectum consisted of 753 cases which were closed at the end of operation with a hopeful prognosis and either have resulted in survival over a period of five years without recurrence or have ended fatally of recurrence. The series ranges from patients who had recurrences and died a few months after surgery to patients who are now living more than twenty years after the successful removal of their cancer. In every case the pathologic specimens were available for study. The distribution of the tumors is interesting to note and is of significance prognostically. There were 187 cases of cancer of the right colon, 266 cases of the left colon, and 300 cases of cancer of the rectosigmoid and rectum. The rectosigmoid and rectal specimens were considered as a group and the colon cases arbitrarily divided into right and left halves. This division of the colon into two segments follows the natural embryologic cleavage as well as separates the two halves according to their type of symptomatology. The right half is a functional organ which develops with the small bowel and likewise has an absorptive duty; here the symptoms are physiologic disturbances. The left half of the colon, which is derived from the midgut, is a storehouse from the standpoint of function, and organic lesions in this segment produce obstructive phenomena.

I think it is not only feasible but desirable to make a distinction between the rectosigmoid and the rectum for the reason that cancers in the two locations are different symptomatically, prognostically and from the standpoint of surgical offensive.

INTRINSIC INFLUENCE

The second factor, namely, that of intrinsic influence, or the activity of the neoplastic cell, is in my judgment the most important single influence that governs prognosis. Bröders has called attention to the great difference in cancers the cells of which are undifferentiated, as compared with those which consist of differentiated cells. He has provided a system of grading the degree of malignancy on the basis of differentiation and has proved by a large series of cases that there is an important ratio between this differentiation of the cells and the ultimate outlook after treatment. The scientific criteria laid down by Bröders estimates the prognosis of cancer of the colon, rectosigmoid, rectum and elsewhere more accurately, I believe, than any other yardstick that is available.

Given the microscopic grading of the degree of malignancy in a case of cancer of the colon, rectosigmoid or rectum, and the information as to whether the glands on the specimen were or were not involved by malignant extension, one should be able to estimate with considerable accuracy the ultimate end-results. In this study it was found that the incidence of glandular involvement was in direct ratio to the grade of the malignancy as is shown in table 1.

Unquestionably, glands are involved in cancer of the colon and rectum at a late date in a high percentage of cases, for what reason I do not know, but I believe it is because of the uniformly low grade of the malignancy in these cases as registered by Bröders' index. That metastasis depends on and is in direct ratio to the intensity of the malignant invasion is, I believe, of basic significance in estimating prognosis. The evidence shows that cases with glandular involvement and cases without glandular involvement follow distinct lines and ratios, and that the incidence of five year cures in each case follows a definite progression.

Table 2 demonstrates effectively among other things that the high incidence of cases both with glandular involvement and without glandular involvement is in the average group, or group 2. Likewise the percentage of five year cures shows a direct curve, the highest five year cures being grade 1 without glandular involvement, and the lowest number of cures being grade 4 with glandular involvement. A grade 1 cancer without malignant glands has a four and one-half times better prognosis than a grade 4 cancer with malignant glands.

TABLE 2.—Grading in Cases With and Without Glandular Involvement

| | Grade 1 | Grade 2 | Grade 3 | Grade 4 |
|---|---------|---------|---------|---------|
| With Glandular Involvement (387 Cases) | | | | |
| Incidence..... | 97% | 51% | 25% | 12% |
| Five year cures..... | 44% | 24% | 13% | 15% |
| Without Glandular Involvement (466 Cases) | | | | |
| Incidence..... | 16% | 62% | 16% | 6% |
| Five year cures..... | 69% | 56% | 47% | 37% |

Table 3 shows the influence of glandular involvement on five year cures very strikingly. In the right colon are found 66 per cent of patients without nodal involvement alive at the end of five years; 56 per cent of cases of the left colon, and 48 per cent of the cases of the rectosigmoid and rectal cancers. In contrast to this, the right colon showed 39 per cent five year cures when nodal involvement is present as against 29 per cent in the left colon and 20 per cent in the rectum and rectosigmoid. The incidence of glandular involvement in the two halves of the colon was about the same, there

being a slight advantage to the left side; namely, 31 per cent as against 34 per cent. This is an unusual observation, since the ultimate prognosis in the right colon is slightly better than that of the left. Glandular involvement in the rectum, however, was considerably more frequently encountered than in either half of the large bowel, 46 per cent of the cases being recorded as showing malignant lymph nodes resected with the specimen.

TABLE 3.—Five Year Cures in Relation to Glandular Involvement

| | With Nodal Involvement | Without Nodal Involvement |
|----------------------|------------------------|---------------------------|
| Right Colon | | |
| Incidence..... | 34% | |
| Five year cures..... | 39% | 66% |
| Left Colon | | |
| Incidence..... | 31% | |
| Five year cures..... | 29% | 56% |
| Rectum | | |
| Incidence..... | 46% | |
| Five year cures..... | 20% | 45% |

It is apparent from table 4 that there is a definite correlation between the grade of malignancy and the prognosis as concerns not only the ultimate cure but likewise the rapidity with which recurrence takes place. There is great pathologic similarity between cancers of the colon and the rectum so far as grading is concerned, and one observes that a little more than half of the growths in both locations fall into grade 2.

The striking difference in the good results in the lower grades of malignant growths free of glandular involvement, as compared with the poor results obtained in the higher grades of malignant growths with involved glands, can leave no doubt as to its influence on the prognosis. As one reviews these tables, considering the relationship of glandular involvement to recurrence and postoperative life, and compares as in table 5 the five year cures in the different grades, one can scarcely escape the conclusion that the intensity of the malignant invasion is the most important factor in estimating prognosis, since the incidence of local glandular metastasis and distant implants as well depend directly on it. It seems significant, moreover, that the figures presented in these tables are the averages of a large group, while the study of the individual cases shows a considerable scattering from the median. What is prognostic for the average of a series is the dominant tendency of the individual case.

CHOICE OF SURGICAL METHODS

Methods of surgical offensive may readily be divided into three phases: (1) preliminary preparation; (2) technical maneuver; (3) postoperative care.

The principles of adequate preliminary decompression, and rehabilitation before exploration is undertaken may not be deviated from without considerable trepidation. It is an easily demonstrated fact that the vast majority of progressing neoplasms of the left colon, rectosigmoid and rectum present at some time prior to their exploration some degree of obstruction. True, it is rarely an acute stenosis, and this is a happy fact for both patient and surgeon; but the chronic increasing encroachment on the bowel lumen due to an encircling cancer in this location, though it frequently is overcome in part by purgation in attempts to empty the bowel, produces at the same time hypertrophy, edema and infection not only of the colonic wall but of the pericolic tissues, which definitely influences disadvantageously attempts to eradicate it.

Cancers of the right colon rarely produce acute obstruction but, on the other hand, are profoundly debilitating, dehydrating, and accompanied frequently by a marked anemia. Consequently the primary preliminary objective should be adequate emptying of the bowel by medical or surgical measures with a complementary regimen aiming at rehabilitation.

There are many arguments in favor of graded maneuvers in handling the vast majority of these cases: the choice of the actual operative procedure is distinctly different in the three locations.

My own preference of operation in the right colon is a graded maneuver as a routine. I prefer an end to side aseptic ileocolostomy at the first stage with a subsequent resection at a later date. I cannot emphasize too strongly the desirability of the end to side anastomosis. To sidetrack the fecal current as completely as possible and thus reduce the local infection around it is the primary object of a two stage operation. Not only can this be done much more satisfactorily by end to side operation, but the accomplishment of the second stage is greatly facilitated likewise. Furthermore, one often finds a large semifixed right colonic cancer distinctly more mobile and resectable after by-passing the fecal current over a period of time. I would not argue that it is not perfectly good surgical judgment to accomplish the resection and anastomosis in one stage in selected cases, but I believe that all such operative procedures should be regularly accompanied by a complementary ileostomy for decompression. My choice of procedure in dealing with growths beyond the hepatic flexure is an obstructive resection after whatever obstruction which has been present has been completely and adequately removed. The obstructive resection consists of radical resection of the growth and gland bearing tissues in immediate juxtaposition to it without either the hazards of primary anastomosis or the tendency to recurrence in the abdominal wall that follows a Mikulicz operation in 12 per cent of the cases. If at exploration of growths in the left colon one finds edema in the bowel wall, inflammatory reaction around the growth, and evidences of prolonged stenosis, unquestionably some decompressive measure is indicated as a first step. For this, I believe, a cecostomy by the Hendon method, using a large Pezzar catheter and witzelizing it, is preferable. This permits decompression of gas and evacuation of

TABLE 4.—Grading of Malignancy in Relation to Postoperative Length of Life

| | Grade 1 | Grade 2 | Grade 3 | Grade 4 |
|----------------------|---------|---------|---------|---------|
| Right Colon | | | | |
| Incidence..... | 16% | 53% | 21% | 10% |
| Five year cures..... | 68% | 60% | 48% | 37% |
| Left Colon | | | | |
| Incidence..... | 13% | 67% | 16% | 4% |
| Five year cures..... | 63% | 51% | 30% | 18% |
| Rectum | | | | |
| Incidence..... | 13% | 53% | 24% | 10% |
| Five year cures..... | 37% | 44% | 22% | 19% |

fecal content and at the same time allows through and through irrigations of the bowel against the time of secondary resection.

The second stage may be accomplished as an obstructive resection, or a direct anastomosis may be employed if one is satisfied with the blood supply to the two ends. Rarely, I think, should primary anastomosis with or without complementary ileostomy be attempted in the left colon, because the blood supply is uncertain. I have always been content to remove colonic cancers, be they in the right or left segment, with a complete disregard

to the length of time necessary to accomplish a successful extirpation. I do not feel that one is any more justified in giving grave consideration to the economic condition of the individual suffering with a malignant growth of the lower gastro-intestinal tract, so far as the selection of operation is concerned, than he is in operating against surgical mortality.

Problems of dealing with cancer of the rectosigmoid and rectum are many and complex. The ideal operation

TABLE 5.—*Relation of Grading to Five Year Cures*

| | Grade 1 | Grade 2 | Grade 3 | Grade 4 |
|----------------------|---------|---------|---------|---------|
| Five year cures..... | 63% | 51% | 31% | 24% |

has not yet been achieved because as the vast majority of surgeons agree the sacrifice of nature's splendid sphincteric apparatus is necessary in order to accomplish wide removal of the growth and adjacent tissue. There is some difference of opinion as to this, but my own feeling is distinctly in accord with the principles of operation as laid down by Miles. While I have not been able to do his operation as a routine without contracting the horizon of operability to a point at which I consider it too narrow, I agree with his principles heartily and practice a resection of the rectosigmoid and rectum in two stages which is almost identical with his operation in scope and principle. By this graded maneuver, which consists of an exploration and a single-barreled colostomy at the first stage, I have been able to resect many borderline growths which would certainly have been inoperable in the single stage. There still remains a definite field for operation of colostomy and posterior resection as practiced by Mummery. Jones's operation, which is a combined abdominoperineal resection in two stages, has many desirable features and his end-results suffer not at all in comparison with those of any other surgeon. The operation of segmental resection of the rectum with anastomosis, or the operation of amputation of the rectum leaving a sacral anus, may be indicated in a small group of carefully selected individuals. I have had little or no experience with either and am unconvinced of the desirability of employing them other than very occasionally.

OPERABILITY; MORTALITY; FIVE YEAR END-RESULTS

Operability and operative mortality are necessarily closely related. Too low a mortality figure reflects a low operability rate. While criteria of operability must be variable, they unquestionably should be broad, as they differ with the experience, boldness and technical skill of the operating surgeon. A fair standard of operability, I think, is one which urges the removal of all growths which are not firmly fixed to the abdominal parietes, or adjacent viscera, or have not metastasized to the liver, or those in patients whose physiologic status is so low as obviously to preclude any surgical intervention. It is difficult not to feel that there are times when a resectable growth should be removed even in the presence of liver metastasis as a palliative measure which provides a painless demise by ridding one of an ulcerating, obstructing, distressing lesion at a slight increase in operative mortality. By making every effort to extend the horizon of operability rather than contract it, one finds the death rate mounting somewhat rather than receding. But is it not worth while to maintain a hospital mortality of around 10 per cent if, by so doing, more patients out of a given number are found alive at the end of ten years after resection?

My own observations relative to operability and operative mortality are drawn from the reports of the colon service at the Mayo Clinic, where the material for this paper was obtained and which reports I presented for the past six years. During these years the operability never ranged below 50 per cent and in one year reached the highly satisfactory figure of 68 per cent. To maintain this operability rate has been a goal worth striving for, and to increase it is a hope that will probably not be realized until an earlier diagnosis in colon cases is arrived at and operation is undertaken before complications and metastasis have taken place.

In operating on the right colon during the past three years by the two stage method, I have done sixty aseptic ileocolostomies with four deaths, a mortality rate of 6.6 per cent. The mortality rate of the left half of the colon is invariably a few points higher than that of the right, but here the figures have not within the last three years exceeded 10 per cent for all types of resection. In obstructive resection I reported one series of twenty-three consecutive cases before a single casualty occurred. This low percentage, however, was advanced to 9.6 as a wider selection of cases for operation was made and a wider range of operability accepted.

In operations on cancer of the rectum and rectosigmoid the mortality figures vary even more widely than those of the colon, and one finds that the radical operations carry considerably higher death rates than the less extensive ones, such as colostomy and posterior resection, or local excision with or without colostomy, or sacrifice of the sphincter muscle.

My choice has been to employ the combined abdominoperineal resection in two stages whenever feasible, and with increasing experience I have been able to apply it in approximately three fourths of the operable cases. In the past two years and a half I have done eighty-two combined abdominoperineal resections in two stages with eight deaths; a mortality rate of 9.2 per cent.

Table 6 is an epitome of the statistical data of the total number of living and dead and the percentage of five year cures in 753 cases of cancer of the colon, rectosigmoid and rectum. It establishes a high percentage of cures over a long period of time in all three segments

TABLE 6.—*Relative Percentage of Cures in Relation to Situation of Lesion*

| | Total | Dead | Cures | Per Cent Cured |
|------------------|-------|------|-------|----------------|
| Right colon..... | 187 | 81 | 106 | 57.6 |
| Left colon..... | 266 | 139 | 127 | 47.7 |
| Rectum..... | 300 | 186 | 114 | 38.0 |
| Total..... | 753 | 406 | 347 | 45.8 |

| | Total Cases | Grade 1 | Grade 2 | Grade 3 | Grade 4 |
|----------------------|-------------|---------|---------|---------|---------|
| Number..... | 753 | 101 | 434 | 157 | 61 |
| Incidence..... | 13% | 58% | 21% | 8% | |
| Five year cures..... | | 63% | 51% | 31% | 24% |

of the large bowel. There is a noticeable decline in the percentage of cures as one rotates from right to left: the low grade right colonic cancer without glandular involvement showing 69 per cent, or better than two out of three patients alive and well at the end of five years, as against grade 4 cancer of the rectum with glandular involvement, which shows only 19 per cent alive and well at the end of the same time. When one considers that, including all grades in all segments of the lower portion of the alimentary tract, 46 per cent, or almost one out of two patients, are alive and free from recur-

rence at the end of five years and that this has been accomplished with an operability of from 50 to 60 per cent of the total group, the high curability of cancer of this portion of the gastro-intestinal tract seems established.

Security Trust Building.

THE TREATMENT OF POLYCYTHEMIA VERA

REPORT OF TWO CASES

CHARLES T. STONE, M.D.

TITUS H. HARRIS, M.D.

AND

MEYER BODANSKY, Ph.D.

GALVESTON, TEXAS

In the treatment of patients with polycythemia, in addition to the general measures employed it has been found necessary to use some agent or substance having the specific effect of destroying red blood cells without producing injury to the body as a whole. For this purpose various measures have been suggested, but at the present time there are only four that appear to warrant serious consideration; viz., irradiation, venesection, arsenic and phenylhydrazine. It is not our purpose in this paper to discuss the relative merits of these therapeutic measures, the advantages of each having been emphasized in recent articles, but we believe with Cole,¹ on the basis of the cases reported in the literature, that "results with phenylhydrazine appear to have been better than with other forms of treatment." This drug is now being widely used despite its well known effects as a powerful protoplasmic poison.

Because the therapeutic results with phenylhydrazine hydrochloride ($C_6H_5.NH.NH_2.HCl$) have been comparatively successful, the advantages of acetylphenylhydrazine ($C_6H_5.NH.NH.COCH_3$) have not been sufficiently recognized. Partly on the basis of earlier experimental work with the derivatives of hydrazine by one of us,² which showed the former compound to be much less toxic than the latter, Brown and Giffen³ considered the possibility that the acetyl substitution product may have therapeutic advantages. In the first edition of Cecil's Textbook of Medicine, Minot,⁴ in referring to the use of phenylhydrazine hydrochloride in the treatment of polycythemia, states that acetylphenylhydrazine may be less toxic and equally useful. In the second edition of this work, however, Minot⁵ makes no reference whatever to acetylphenylhydrazine. The patient employed by Bassett, Killip and McCann⁶ in their study of mineral metabolism in polycythemia vera was treated with acetylphenylhydrazine. The

authors are not aware of any other clinical studies of this condition in which acetylphenylhydrazine was employed.

There are approximately thirty reports in the literature attesting to the efficacy of phenylhydrazine hydrochloride in the treatment of polycythemia. A smaller number of reports, notably those of Barta,⁷ Giffen and Conner,⁸ McNamara and Sansum⁹ and Gouwens,¹⁰ have dealt with the untoward effects, severe and even fatal intoxications resulting from the use of this drug. Granting the possibility that with sufficient care these effects may have been largely avoided, it should nevertheless be emphasized that phenylhydrazine is a powerful protoplasmic poison, as first shown by Hoppe-Seyler,¹¹ and that even small amounts may give rise to symptoms of acute intoxication.

Our preference for acetylphenylhydrazine is based on the following considerations: (1) It is practically as effective as phenylhydrazine hydrochloride in red blood cell destruction. (2) The dosage may be controlled somewhat more readily. (3) It is less toxic than phenylhydrazine hydrochloride and thus affords a greater margin of safety in cases of overdosage and in those in which the cumulative and delayed effects of frequently repeated doses constitute a prominent feature.

This does not imply a disregard of the possibilities of acetylphenylhydrazine as a cellular poison. A substance that is so effective in blood destruction may be expected to have more general properties, but on the assumption that a compound of the type of phenylhydrazine is necessary in the treatment of polycythemia, it seems obvious that acetylphenylhydrazine possesses definite advantages. The action of both compounds has been considered in a recent study,¹² as well as in several earlier publications.

Our interest in this subject from a clinical standpoint has been stimulated by the course of two cases in which continuous acetylphenylhydrazine therapy was administered, one for a period of seven years, the other for a period of four and a half years:

REPORT OF CASES

CASE 1.—L. F., a white man, aged 30, first seen, June 13, 1919, complained chiefly of bleeding from the gums. A blood count showed red blood cells, 6,600,000; hemoglobin, 110 per cent (Sahli). He was not seen again until six and a half years later, Jan. 21, 1926, when he complained of dizziness, fulness in the head and a feeling of tightness around the heart. Excepting a very livid color to the skin and mucous membranes, and a moderately enlarged spleen, the physical examination was essentially negative. Laboratory examination revealed: red blood cells, 7,680,000; hemoglobin, 114 per cent; white blood cells, 7,900, with a normal differential count. The blood Wassermann reaction was strongly positive (it had been negative in 1919).

A short course of roentgen irradiation was given over the long bones, but without improvement in symptoms or in reduction of the red blood cell count. Owing to the severity of the symptoms, the patient was admitted to the John Sealy Hospital, March 7. Venesection (twice, 500 cc. each time) resulted in

only temporary relief as regards the patient's sensation of "fulness in the head." From March 31 until April 7, the patient received 0.1 Gm. of phenylhydrazine hydrochloride daily. This was discontinued because of severe nausea and epigastric discomfort. Treatment with phenylhydrazine hydrochloride was resumed, May 6 (average of 0.3 Gm. weekly), and for several months the red blood cell count was maintained

superficial blood vessels over the malar eminences and the nose, an enlarged spleen palpable just below the costal margin, and vascular hypertension. The blood pressure was 180 systolic, 120 diastolic. The blood count was: red blood cells, 6,700,000; hemoglobin, 124 per cent; white blood cells, 7,650, with a normal differential count.

She was started on a course of acetylphenylhydrazine treatment, 0.1 Gm. daily for ten days, at the end of which time the red count was 5,950,000 and the hemoglobin 115 per cent. No treatment was given for ten days, during which time the red blood count remained unchanged. Another course of acetylphenylhydrazine in 0.1 Gm. doses was prescribed. The patient was not seen during this period of treatment, and when she reappeared on its completion her color had changed to a sallow yellow, the red blood cell count was 2,030,000, the hemoglobin was 40 per cent, and the urine was very dark. There was no evidence at this time of injury of either the kidney or the liver. When the drug was discontinued there was rapid blood regeneration, so that within a month the red count was 4,950,000 and the hemoglobin 90 per cent. The patient was then given 0.1 Gm. of acetylphenylhydrazine weekly. Frequent blood counts taken during the succeeding months showed that the red count was being maintained at approximately the normal level. Occasional moderate rises above normal have occurred, at which times the interval between doses has been shortened from seven to five days (chart 2). Under this plan of treatment it has been possible to maintain the normal erythrocyte count, and the symptoms originally complained of have largely subsided, excepting some awkwardness in the use of her feet and legs. The blood pressure has dropped to an average of about 150 systolic, 90 diastolic. Analysis of the blood shows a slight retention of nitrogenous constituents: nonprotein nitrogen, 40 to 44 mg.; urea, 22 to 24 mg. The uric acid is characteristically somewhat high, 4.7 mg. Other values are essentially normal: serum protein, 7.38 Gm.; serum calcium, 11.4 mg.; blood creatinine, 1.5 mg.; blood sugar, 103 mg.

The leukocyte count, which was normal when the patient was first observed, now shows an intermittent tendency toward an elevation of the total count (not exceeding 13,000), with a constant relative increase in the polymorphonuclear neutrophils, from 90 to 94 per cent, and the presence of occasional myelocytes. This is not regarded as a result of the treatment but rather a manifestation of the disease.

COMMENT

In case 1, treatment with phenylhydrazine hydrochloride was accompanied by definite toxic symptoms,

Chart 1 (case 1).—Prompt return of the blood to the polycythemic status when treatment is discontinued.

below 5,000,000. The patient, nevertheless, continued to complain of weakness and nausea and was unable to resume work. Treatment with acetylphenylhydrazine was begun, September 8, and has been continued ever since. This drug was easily tolerated and produced none of the unpleasant gastro-intestinal symptoms characteristic of phenylhydrazine hydrochloride. Within a few weeks the patient returned to work and has continued his occupation without interruption. It was found that the red blood cell count could be maintained at normal by the administration of from 0.1 to 0.3 Gm. weekly. At present, the patient takes 0.1 Gm. every week or two. After the polycythemia was controlled he was given antisyphilitic treatment, and at present the Wassermann reaction is negative. As far as could be ascertained, this treatment did not affect the erythrocyte count in any way.

As a test of the therapeutic effectiveness of the acetylphenylhydrazine, the drug was discontinued after February, 1931. As shown in chart 1 the red blood cell count, which was 4,850,000, February 10, rose to 7,000,000 on April 30. It remained at this high level \pm 500,000 until June 5. The hemoglobin showed a corresponding increase. Even with a rising red blood cell count the patient did not complain of symptoms until the onset of warm weather in May, and it was thought advisable to terminate the experiment on June 5. During the winter of 1932 an attempt was made to repeat the experiment, but owing to the advent of unusually warm weather early in the spring it had to be interrupted, and the treatment with acetylphenylhydrazine was resumed. During both of these experiments the patient was not informed of the laboratory observations.

At present he is symptom free, the red blood cell count is maintained within normal limits, and the laboratory data referable to renal and hepatic function are negative. Blood chemistry shows: nonprotein nitrogen, 35.3 mg.; urea, 22 mg.; uric acid, 4.6 mg.; creatinine, 1.35 mg.; calcium, 10.8 mg.; serum protein, 7.2 Gm. per hundred cubic centimeters.

CASE 2.—Miss M. G., aged 54, a librarian, came under observation Feb. 20, 1929, because she had noted a high color of the skin and because her dentist had advised an examination on account of the dark red color of her gums. She also complained of an unusual sensation in the legs, which was described as a combination of weakness and a "feeling as if the circulation was not good."

Positive observations made on physical examination included a dark reddish hue to the skin and mucous membranes, dilated

Chart 2 (case 2).—Effect of treatment with acetylphenylhydrazine since 1929. Gaps in the chart indicate periods when the patient was not under observation.

chiefly referable to the gastro-intestinal tract, even before the red blood cell count showed any marked reduction. Seven years of treatment with acetylphenylhydrazine has conclusively demonstrated its effectiveness in the treatment of polycythemia vera, the relative lack of toxicity and the absence of disagreeable accompanying symptoms.

Patient 2 was inadvertently overdosed. It should be noted that the toxic symptoms which characterize poisoning with phenylhydrazine were practically absent in this case of severe intoxication with acetylphenylhydrazine. We believe that there is sufficient evidence in the literature to justify the assumption that if a similar error in dosage and treatment had been made with phenylhydrazine hydrochloride the results might have been more serious. The subsequent course of this case reemphasizes the satisfactory results and ease of treatment experienced over a longer period in the preceding case.

DOSAGE

In beginning treatment with acetylphenylhydrazine, 0.1 Gm. may be given daily (by mouth in a gelatin capsule) over a period of from seven to ten days, during which time the red cell count should be closely observed. Regardless of the effect of this preliminary treatment on the erythrocyte count, the drug should be discontinued for at least two weeks, because of its apparent cumulative and delayed effects. After this interval, depending on circumstances, considerable individualization in treatment becomes necessary. It may require a second course of 0.1 Gm. doses daily for a few days to a week to reduce the red cell count to a nearly normal level. When this point has been reached, treatment should again be discontinued for from seven to ten days, after which it becomes necessary to determine the maintenance dose to be given at stated intervals. While, in our cases, 0.1 Gm. of acetylphenylhydrazine at intervals of from five to seven days was found sufficient, it should be pointed out that there are individual variations and that even in a given individual the maintenance dose may vary somewhat from time to time. Provided the red blood cell count is maintained at the normal level and the patient is symptom free, it is obviously desirable to give the smallest possible maintenance dose, consistent with these objectives, in order to avoid unnecessary destruction of erythrocytes and a consequent undue stimulation of the bone marrow.

Within certain limits the symptoms in polycythemia are not solely dependent on the level of the red blood cell count, since many of the cerebral manifestations, as well as those in the extremities, result from peripheral vascular stasis. Moderate elevation in the red blood cell count may be comfortably tolerated in cool weather; whereas in warm weather it may be associated with severe symptoms. This does not imply that a higher cell count should be permitted in moderate as compared with warm weather. In fact, our experience locally indicates that the greatest freedom from symptoms obtains when the red blood cell count is consistently maintained at a normal level throughout the year.

Frequent reference is to be found in the literature to the development of a tolerance to phenylhydrazine, and that a constantly increasing dosage may be required to produce the desired effect. According to a recent statement, this has not been Stealy's¹³ experience, although it is pointed out by this observer that at times his patient showed a temporary tolerance to the drug. Our observations are essentially similar to those of Stealy. Experimental studies described elsewhere¹² have led us to the conclusion that the increased tolerance is only apparent; it is not a property acquired by the organism but is inherent in the erythrocytes. Newly formed and immature red blood corpuscles contain a larger proportion of nonhemoglobin protein, and per-

haps because of this difference in chemical composition these cells seem to be more resistant than more mature corpuscles to the action of both phenylhydrazine and acetylphenylhydrazine. If sufficient intervals are allowed between administrations of the drug, successive doses produce approximately the same effect.

CONCLUSIONS

The experience in two cases of polycythemia vera, treated with acetylphenylhydrazine over periods of seven and four and a half years, respectively, supports the view that as a therapeutic agent this compound is superior to phenylhydrazine hydrochloride. As compared with the latter, the acetyl derivative is less toxic, the dosage is more easily regulated, and it provides a greater margin of safety in cases of overdosage or in the event that the cumulative and delayed effects become pronounced.

2201 Avenue D.

ABSTRACT OF DISCUSSION

DR. MOSES BARRON, Minneapolis: In the treatment of polycythemia vera, one treats symptoms and not the disease. Polycythemia can be divided into a relative and an absolute one: a relative, from concentration of the blood as from vomiting, diarrhea or excessive perspiration. Such a polycythemia must not be treated with phenylhydrazine. In the absolute form there are two conditions, designated as erythrocytosis and erythremia. In the former there is an increase in the red blood cells secondary to some cause. Such conditions may be associated with oxygen deficiency, as in high altitudes or chronic bronchitis; with sluggish circulation, as in mitral disease; with congenital pulmonary stenosis; with defective hemoglobin, as in cases of poisoning from carbon monoxide, and sometimes with hypertension. Only the true polycythemia or erythremia, which is similar to leukemia for the leukocytes, has to be considered here. It is important to remember that the essential characteristic of this disease is a marked increase in the blood volume. This increase is produced not by increase in the plasma but by an increase in the number of red blood cells. Therefore the destruction of some of these cells reduces the blood volume. Some of the symptoms are due to the sluggish circulation resulting from the increased viscosity of the blood. Likewise an attempt is made to reduce the increased viscosity by destroying red blood cells. Theoretically the treatment with x-rays should be efficient, but it has proved ineffective. Cerebral, mesenteric and coronary thrombosis frequently develops in these cases; sometimes also hemorrhages. Thromboses may be induced by too rapid destruction of the red blood cells. One must therefore be careful not to produce too active or too rapid destruction of the erythrocytes. The authors suggested the use of acetylphenylhydrazine instead of the usual phenylhydrazine. At the Minnesota General Hospital, we find phenylhydrazine fairly reliable. Splenectomy has been used, and favorable results have been reported from the Mayo Clinic. Phenylhydrazine has been reported in the literature to be quite efficient in a large percentage of cases.

DR. NATHAN ROSENTHAL, New York: Prior to the introduction of phenylhydrazine compounds, treatment showed results which were not satisfactory, although improvements in symptoms and reduction of hemoglobin and red cells could be induced by x-rays, by blood letting or by a combination of the two. Occasionally spontaneous remissions occurred, but usually the condition was one of years of misery ended by fatal cerebral thrombosis, anemia or leukemia. Phenylhydrazine hydrochloride is without doubt a potent but toxic drug. The authors should be congratulated on their recommendation of acetylphenylhydrazine. This is based on their admirable work in proving, first, its superiority in animal experiments and, secondly, its efficacy in clinical observations. Since the important publications of Bodansky and his co-workers on the experimental studies of acetylphenylhydrazine, I have treated six cases of polycythemia vera with this drug. The dosage was similar, namely, 100 mg. given daily until a reduction in hemoglobin and red cells was found and headache and dizziness began to subside. In two

13. Stealy, C. L.: Polycythemia Vera, J. A. M. A. 98:1714-1716 (May 14) 1932.

patients with a hemoglobin of more than 140 per cent and about 10,000,000 red cells, 100 mg. had to be given daily over a period of from three to five weeks before symptomatic and hematologic improvements were noted. Acetylphenylhydrazine was given to three patients who had previously received phenylhydrazine hydrochloride. The results were better from the acetylphenylhydrazine with respect to the symptoms. The maintenance dosage varied from 100 to 400 mg. weekly. The treatment of other forms of polycythemia vera is somewhat different. In the leukemoid group both acetylphenylhydrazine and especially x-rays should be used. The treatment of thrombocytic polycythemia is not satisfactory. These patients have a tendency to develop a thrombosis following phenylhydrazine hydrochloride. This was noticed particularly in one patient, who developed, after administration of phenylhydrazine hydrochloride, splenic infarcts, mesenteric thrombosis, thrombosis of the lower end of the aorta, and frequent attacks of thrombophlebitis of the lower extremities. This patient also developed a severe anemia. He gradually improved until he was able to get about but constantly complained of marked weakness and paresthesias in the lower extremities. As the hemoglobin and red cells began to increase rapidly and dizziness returned, the patient was treated with x-rays without much effect. He was then given acetylphenylhydrazine, from which he developed a small thrombosis in one leg so that the medication had to be discontinued.

DR. C. T. STONE, Galveston, Texas: I should like to emphasize the remark of Dr. Barron, that in this discussion only polycythemia vera and not the secondary forms is being considered. We feel that acetylphenylhydrazine, and also the other methods of treatment employed at present, are purely symptomatic. They destroy the red cells and thereby reduce the blood volume and blood viscosity. There should be no misconceptions on that point. We do believe, however, from the collective experience in the literature, that a phenylhydrazine compound is the most efficient agent in accomplishing this purpose that is at present available, and we feel that the safety of acetylphenylhydrazine over any of the other derivatives so far studied is so much greater that it should replace phenylhydrazine hydrochloride in therapy. It is gratifying to learn that Dr. Rosenthal, with his larger experience in the use of acetylphenylhydrazine, has had essentially the same results.

TREATMENT OF NEUROSYPHILIS WITH MALARIA

OBSERVATIONS ON NINE HUNDRED AND EIGHTY-
FOUR CASES IN THE LAST NINE YEARS

PAUL A. O'LEARY, M.D.

AND

ASHTON L. WELSH, M.D.

Fellow in Dermatology, the Mayo Foundation
ROCHESTER, MINN.

This report is a summary of our observations on the results of treatment with malaria of a group of 984 neurosyphilitic patients between May, 1924, and May, 1932. At no time since we inoculated the first patient with *Plasmodium vivax* have we been without an active case of inoculation malaria. During our early experience with this treatment, only those patients presenting clinical and serologic evidence of dementia paralytica were inoculated, but after a year's experience one of us (P. A. O'L.) felt that it might be of value in the prevention of dementia paralytica. The main theme in this report, therefore, will be the results from the treatment with malaria of some of the various forms of neurosyphilis other than dementia paralytica.

The successful results from the treatment of dementia paralytica with malaria have been repeatedly empha-

sized in the literature of this country and Europe. Besides the successful results, there are certain other advantages from the treatment which are worthy of emphasis. In certain cases only from fourteen to seventeen days of hospitalization have been necessary. This is a significant item when compared with a two year course of treatment by intravenous and intramuscular injection of antisyphilitic drugs. It is unfortunate that all patients have not been so amenable to treatment by inoculation; in certain cases it is necessary to give a considerable number of injections of arsenical preparations and bismuth or mercury, subsequent to the course of malaria. In the treatment of certain types of neurosyphilis, the superiority of treatment with malaria, as compared to that with preparations of arsenic and other metals, has been repeatedly emphasized; this has been noted particularly in the cases of predementia paralytica in which intensive courses of arsphenamine, bismuth, mercury and tryparsamide were given without satisfactory serologic control until treatment with malaria was instituted. It must not be forgotten that the recently developed electrical contrivances for inducing fever were the outgrowth of the results obtained from malarial treatment, and are expressions of an effort to stimulate the defensive mechanism against syphilis in a simpler and more controllable manner. It is also our belief that the consideration now given by syphilotherapeutists to the adoption of means and measures of stimulating the patient's resistance to syphilis rather than endeavoring to overwhelm *Spirochaeta pallida* by intensive intravenous and intramuscular medication is one of the foremost accomplishments of treatment with malaria.

On the other hand, there are certain disadvantages in treatment with malaria which have prevented the method from becoming used as a routine in cases of neurosyphilis. The fact that it was impossible to induce chills and fever in 10 per cent of the patients inoculated, owing to their immunity to malaria, places certain limitations on the method. The need not only for hospitalization but for a hospital personnel trained in the care of these patients may be considered by opponents of the method as a definite objection to its general use. Likewise cases must be selected, in the sense that in the case of a debilitated syphilitic patient, or in the presence of advanced disease of any of the vital viscera, the therapeutic use of fever is contraindicated. The morbidity and the mortality rates have also been considered contraindications; however, we now believe that death during treatment with malaria should occur rarely, and only as the result of some accident. In our first 100 cases in which this treatment was given, the mortality rate was 5 per cent, whereas in the last four years it was 0.57 per cent. Of the total number of patients treated, 2.4 per cent have died as a direct or indirect result of the treatment. In a consideration of the disadvantages of treatment with malaria it should be noted that occasionally a patient with dementia paralytica is made worse by the treatment; in this series the clinical symptoms were accentuated in 2.2 per cent of the cases in which dementia paralytica, according to clinical evidence, was present.

DEMENCIA PARALYTICA

Appraisal of the results of treatment with malaria of patients suffering from dementia paralytica was based on the clinical status of the patient at least one year after the course had been given. If patients were treated in an asylum a remission was interpreted as

From the Section on Dermatology and Syphilology, the Mayo Clinic.
Read before the Section on Nervous and Mental Diseases at the
Eighty-Fourth Annual Session of the American Medical Association,
Milwaukee, June 15, 1933.

evidence of sufficient improvement to warrant paroling of the patient. Of the 186 cases (table) in which advanced clinical signs of dementia paralytica were sufficient to warrant institutional care, a complete remission developed in 35 per cent, and in 35 per cent patients were sufficiently benefited to be permitted to go to their homes. Another group of patients with dementia paralytica included those who did not give sufficient clinical evidence of dementia paralytica to indicate that the condition had progressed far enough to warrant their incarceration in an asylum for the insane; nevertheless a clinical diagnosis of dementia paralytica was justifiable. The criteria of the results of treatment were based on the ability of the patient to return to work of some type, not necessarily the former occupation, but any occupation with which he could support himself and his family. There were 249 patients in this group, 46 per cent of whom returned to work, and the condition of 35 per cent was decidedly improved following treatment with malaria. In 42 per cent of the cases in which the spinal fluid was reexamined recently, the tests were found to be reversed to complete negativity in all respects.

A small number of patients in the group with dementia paralytica were listed as having been improved, in whom the clinical progress of the disease had been arrested, as evidenced by the stationary clinical status and the negative serologic tests. The personality of these patients was changed, as manifested by their inability to retain employment permanently and by their lack of initiative and sense of responsibility. If such patients were observed over a period of several years, the clinical picture of slow but progressive mental deterioration was noted. The course of this progressive degeneration was not altered by the liberal use of various antisyphilitic remedies. On the other hand, in the group of patients with early dementia paralytica treated successfully, twenty-six (10.4 per cent) apparently were "cured" in the sense that tests applied to the spinal fluid and blood serum remained negative, and the mental status remained within the range of normal from five to eight years after treatment. It is our practice either to treat all patients suffering from dementia paralytica with trypanamide and bismuth, or to give a combined intraspinal course of treatment with arsphenamine and bismuth or mercury, shortly after the course of malaria. Clinical relapse was observed in 2.6 per cent of these patients.

DEMENTIA PARALYTICA SINE PARESI

The results in cases of asymptomatic dementia paralytica, or dementia paralytica sine paresi, have been highly satisfactory. Included in this group are the cases in which the disease had not progressed far enough to permit of a clinical diagnosis of dementia paralytica but in which tests of the spinal fluid had been characteristic of dementia paralytica and had failed to show satisfactory response following antisyphilitic treatment. We also included in this group cases in which serologic reactions were of the so-called chronic relapsing type; that is, serologic reactions considered characteristic of dementia paralytica became negative while the patient was under treatment, only to become positive again immediately when treatment was discontinued. In practically all of these cases intensive treatment had been given with the arsphenamines, trypanamide, mercury, bismuth and iodides, and also intraspinal treatment had been carried out before inoculation with *Plasmodium vivax*.

Following the course of malaria, three fourths of the patients manifested decided clinical improvement, and the serologic tests of the spinal fluid of half of them became completely reversed to negative. In our early experience, it was this type of case particularly that called our attention to the value of malarial treatment as a preventive of dementia paralytica. Accordingly, for the past seven years, if a patient's spinal fluid gave persistently positive serologic tests, if the patient gave evidence of potential dementia paralytica, and if it was demonstrated that routine measures of treatment failed to reverse the serologic tests, it has been our recommendation and practice to give malarial treatment. We have had eighty-five such cases, and it is worthy of comment that we have had no reversions to positive of serologic tests among patients whose spinal fluid, after malarial treatment, has given negative tests.

TABETIC FORM OF DEMENTIA PARALYTICA

There were sixty-five cases of the tabetic form of dementia paralytica. The therapeutic results, although satisfactory, were less striking than in the other forms of parenchymatous neurosyphilis. As in the groups

* These patients were treated at the Rochester State Hospital under the direction of Drs. A. F. Kilbourne and Oscar C. Heyerdale.

already considered, most of the patients were intensively treated with antisyphilitic measures before institution of the course of malaria. In 55 per cent of cases the progress of the disease was arrested to the extent that the patient could be classified as having a complete remission or as having made decided general improvement, whereas in an additional 39 per cent the patients were improved and remained capable of working at an occupation of one sort or another. None of the objective signs of the disease, such as Argyll Robertson pupils and absent knee jerks, was influenced; therefore, clinical appraisal in this group was based on the improvement in the somatic symptoms only. The proportion of reversal of serologic tests to negative among these patients was considerably less than in the two groups previously considered. In only 24 per cent were all tests of spinal fluid completely changed to negative, whereas in 71 per cent all but one of them became negative. In this latter group, the Kolmer modification of the Wassermann test was the one which continued to remain positive, while the cell count, globulin test and colloidal benzoin test became negative.

TABES DORSALIS

The patients classified as having tabes dorsalis were divided into four groups: (1) frankly tabetic patients,

with positive reactions of the spinal fluid; (2) tabetic patients with gastric crises and negative serologic tests; (3) tabetic patients with negative reactions of the spinal fluid and persistent, intractable lightning pains, and (4) patients with primary optic atrophy as a complication of *tabes dorsalis*.

Frankly Tabetic Patients with Positive Reactions of the Spinal Fluid.—It had been our earliest impression that the results in the treatment of *tabes dorsalis* by malaria were less favorable than in the treatment of *dementia paralytica*. Study of a larger series of cases has not substantiated this impression because we now find that of the 116 tabetic patients, 42 per cent were decidedly improved and 41 per cent were benefited by malarial treatment. These more satisfactory results are no doubt due, in great measure, to our efforts to give the tabetic patient the advantage of treatment with malaria earlier in the course of his disease. Considerable caution must be exercised in the malarial treatment of the patient with pronounced involvement of the lower part of the spinal cord. In two instances, rapidly progressing ataxia has terminated in paraplegia, owing to the development of myelitis during the course of malaria. Gain in weight, decrease in frequency and severity of the attacks or complete disappearance of the neuritic pains in the legs, return of libido and potentia, amelioration of gastric crises and improvement in symptoms referable to the urinary bladder have been among the benefits derived from malarial treatment. In 43 per cent of cases in this group, the reversal to negative of all serologic tests of the spinal fluid was complete.

Tabetic Patients with Gastric Crises and Negative Serologic Tests.—Among less than half of the patients with early signs of *tabes dorsalis* complicated by gastric crisis, were the results of antisyphilitic treatment successful. Those patients who derived the most benefit from routine treatment with pharmaceutical preparations as a rule gave histories of having had the episodes of crisis for a year or less, and gave manifest evidence of actively positive spinal fluid, as indicated particularly by a high cell count. The spinal fluid of many patients who derive no relief from the crises will become completely negative. It has been our experience that the patients of the latter group receive little if any good from the continued use of arsphenamine and bismuth or mercury. It is not uncommon that because of the severity of the attacks these patients readily become habitués of morphine, which adds another serious complication to their difficulties.

We have used malarial treatment in an effort to control the crises of *tabes* when the usual methods of treatment have failed. There were twenty-five patients in this series whose spinal fluid had become negative while under treatment with antisyphilitic measures, but whose gastric crises persisted. In 31 per cent, these crises almost completely disappeared after malarial treatment, whereas in 56 per cent the interval between attacks was greatly increased and the severity of the spells lessened. For example, attacks which usually lasted from three to five days were limited to four to eight hours and were more readily controlled with opiates than before treatment. The use of tryparsamide and a bismuth preparation following malarial treatment has been of material value to these patients.

Tabetic Patients with Negative Reactions of the Spinal Fluid and Persistent Intractable Lightning Pains.—This division of tabetic patients was composed of those whose spinal fluid and blood serum became

negative to test, either spontaneously or as the result of treatment, but whose "lightning pains" persisted. Continued, intensive use of the arsphenamines or other metallic medicaments offered but slight relief from the attacks of pain of these patients. As the result of long observation of twelve patients following malarial treatment we found that only 11 per cent were entirely relieved, whereas 22 per cent were benefited.

Patients with Primary Optic Atrophy as a Complication of Tabes Dorsalis.—The tabetic patients included in this group were those with the resistant complication of primary optic atrophy. It is generally accepted that intensive therapeutic measures arrest the progress of the optic atrophy in but few cases, and that occasionally the too enthusiastic use of arsenical preparations has resulted in more rapid loss of vision. We have seen an occasional case in which combined intraspinal treatment has apparently halted the failure of vision. In view of the resistance to treatment of patients with primary optic atrophy, and of the fact that other manifestations of neurosyphilis often require intensive treatment, we have used malarial therapy in conjunction with a variety of other types of treatment. Accordingly, appraisal of malarial treatment alone in relation to optic atrophy is impossible, because of the extensive additional treatment which these patients received. In only 14 per cent of the forty-eight cases in this group was the progressive loss of vision halted even temporarily, whereas in 22 per cent the process was slowed. In the majority of cases of bilateral hemianopia, temporary decrease in the visual fields was usually noted following malarial treatment, whereas in two cases in which there was rapidly progressive loss of vision complete blindness developed during the course of the treatment. Improvement in the other symptoms of *tabes dorsalis* was, as a rule, marked, even though there was a gradual but steady decrease in vision.

ASYMPTOMATIC NEUROSYPHILIS

Included under this heading were those cases in which the reaction of the spinal fluid was positive but in which the symptoms and signs were insufficient to permit of a diagnosis of neurosyphilis. These seventy-four patients were also treated with malaria after they had received intensive treatment with arsphenamine, mercury or bismuth, and large doses of potassium iodide as well as intraspinal treatments. Many of them had received fifty or more injections of arsphenamine or one of its modifications, with corresponding amounts of mercury or bismuth. It has been our purpose to give patients with this type of neurosyphilis the benefit of the routine measures of treatment before subjecting them to malarial therapy, because we believe that the majority of them will respond satisfactorily to intensive intravenous and intramuscular treatment. Our knowledge of the mechanism by which malarial treatment accomplished its results is meager, and for the present the concept that it "stimulates the patient's defense mechanism" continues to be the accepted explanation. This effect has been particularly emphasized among patients with asymptomatic neurosyphilis who had received intensive antisyphilitic treatment without favorable influence on the serologic tests but whose spinal fluid, following a course of malarial treatment, underwent rapid and permanent reversal to negativity. In 42 per cent of these seventy-four cases the spinal fluid became negative after malarial therapy, while in an additional 37 per cent the serologic evidence was

duced to a negative globulin test and cell count, and the Wassermann test remained positive. The results of this group of cases were by far the most satisfactory of those in any of the various types of neurosyphilis that we have treated. The serologic reversal, as a rule, appeared approximately one year after the course of malaria, and of particular significance is the fact that serologic relapses have been observed to date. It is hoped that longer observation of a larger series of cases will substantiate the outstanding value of malarial treatment in this type of neurosyphilis.

CONGENITAL NEUROSYPHILIS

The results from treatment with malaria of seventeen patients with congenital neurosyphilis were discouraging. Congenital cases of dementia paralytica, the tabetic form of dementia paralytica, tabes dorsalis, gastric crisis and optic atrophy were included in this group, and although certain patients derived systemic benefit, the results were far less beneficial than those noted in corresponding types of acquired neurosyphilis.

A MISCELLANEOUS GROUP OF CASES

This group included twelve cases with the following conditions: vascular neurosyphilis, meningovascular neurosyphilis, the syndrome of multiple sclerosis, meningomyelitis and meningo-encephalitis. The results following malarial treatment were discouraging, although no significant ill effects were noted. The amount of improvement was not enough to justify use of the method as a regular therapeutic measure in these uncommon types of neurosyphilis.

Severe neurorecurrences, manifested by syphilitic meningitis with high pleocytosis and clinical evidence of severe chronic meningitis, developed in three cases of acute syphilis following the inadequate use of the arsphenamines. The results from malarial treatment in these three cases were not encouraging; therefore the patients were given antisyphilitic treatment, and the results were highly satisfactory. It is significant that these three patients each had received only a few injections of neoarsphenamine at the time of their acute syphilis.

SUMMARY

Observation of almost 1,000 patients with neurosyphilis who were treated with malaria between May, 1924, and May, 1932, demonstrated that although slightly less than half of the patients with early clinical dementia paralytica were able to hold employment following the treatment, the more significant observation is that in more than three fourths of the cases of asymptomatic dementia paralytica (dementia paralytica sine paresi), clinical progress of the disease was arrested. Equally significant is the fact that following malarial treatment the serologic tests of the spinal fluid became reversed to complete negativity in almost half of the cases of asymptomatic neurosyphilis in which routine measures of treatment had previously failed to have a favorable influence on the serologic characteristics. The results in the treatment of the tabetic form of dementia paralytica and tabes dorsalis were likewise favorable in about half the cases, whereas among serologically negative tabetic patients with resistant complications, the crises and pains in the legs have been only slightly benefited. The results with patients who had congenital neurosyphilis have been discouraging.

Accordingly, we believe that malarial treatment is warranted not only in the treatment of dementia para-

lytica but particularly in the treatment of patients with neurosyphilis who are not responding favorably to treatment with the so-called antisyphilitic remedies.

ABSTRACT OF DISCUSSION

DR. WALTER FREEMAN, Washington, D. C.: The authors mention a ten-year period for checking up these results. Possibly after ten years they will find, as I have done, that not a few of these patients succumb to syphilitic lesions of other organs, the heart, the liver and the aorta. I can report on some 200 patients with dementia paralytica that have been followed for a period of from five to ten years. I have divided them into three groups: those treated during the first year, during the intermediate stage of one to three years, and those over three years. Of those treated during the first year, 59 per cent were discharged. Of those inoculated after three years, only 9 per cent were discharged. Moreover, of those who were treated in the first year, 7 per cent are now dead, and of those not treated until three years after onset, 39 per cent are dead. These figures show the necessity for early treatment. It is rather to be expected that those with minimal injury will show the best results, and those with serious injury to the spinal cord, to the optic nerve, and to the nervous system generally, as in the congenital cases, will show the worst results. Some 10 per cent of the patients of Drs. O'Leary and Welsh did not take malaria, but this objection is being overcome. My associates and I have recently been using quartan malaria with approximately 95 per cent takes, even in Negroes. The short period of treatment in malaria as opposed to the necessarily prolonged intravenous or intramuscular therapy is also something in its favor, particularly in individuals who are a little confused, a little irritable, noncooperative, and who will not return for treatment. All one has to do is to inoculate them with malaria and tell them to go home, and in two or three weeks one may expect a hurry call. The serologic responses have been rather gratifying. Progressive improvement in spinal fluid reactions continues for as long as eight years after the inoculation of malaria. The first year there is relatively little change unless the arsenicals are pushed, in which case one may get serologic complete reversal rather rapidly. If treatment is omitted, the reactions come down anyhow, but somewhat more slowly. In those patients who still show strongly positive reactions after two years and who show no substantial improvement, the outlook is bad. Even reinoculation with malaria gives poor results. Possibly there is some change in the character of the disease process. The brains in such cases show very little inflammation but the typical endarteritis of the small cortical vessels. This is probably a slowly progressive degenerative manifestation of neurosyphilis without the flamboyant picture of dementia paralytica.

DR. PAUL A. O'LEARY, Rochester, Minn.: Malaria therapy has not only produced satisfactory clinical and serologic results in phases of syphilis that have been resistant to the so-called specific remedies but has stimulated syphilotherapists to seek other means of producing fever to accomplish similar results. My experience to date with these mechanical measures has led me to agree with Dr. Freeman that the results from malaria therapy are still superior to those obtained from the electrical machines. The concept that it is the fever per se which produces the therapeutic results is tenable but is as yet not proved.

Anemia and the Hemoglobin.—My second axiom is that symptoms of anemia rarely appear until the hemoglobin has fallen below 75 per cent. There are certain exceptions to this axiom, more especially in pernicious anemia, where glossitis and nervous changes may appear with a hemoglobin percentage little below the normal. It is nevertheless a good general rule, and if a patient has a hemoglobin of 75 per cent or over, it is unlikely that weakness or dyspnea is the result of anemia. On the other hand, if the hemoglobin is below 75 per cent, the patient is truly suffering from anemia, and the next step is to decide the exact nature of the anemia. It is a short-sighted policy to begin treatment without further investigation.—Witts, L. J.: Anemia in General Practice, *Brit. M. J.* 1:1091 (June 24) 1933.

TEN YEARS' OBSERVATION OF CHILDREN WITH RHEUMATIC HEART DISEASE

From June 1922 to January 1932, at the Children's Heart Hospital in Philadelphia, we have cared for 458 children threatened with or suffering from rheumatic fever and its accompanying cardiovascular damage. In 1925, a summary of our results with 225 children seemed to warrant a continuance of our institution¹ and we reported the reasons for our belief in "the importance of prolonged convalescent care in rheumatic heart disease."² We received especial comfort at that time from the following statement by Swift:³ "A few heart hospitals where proper study of these problems could both intensively and extensively be carried out would do much toward formulating a definite plan in the treatment of a condition which up to the present has been but little permanently benefited by the methods now in vogue." In 1930, we reported our results to date and outlined the requirements for admission and the routine treatment in our convalescent hospital.⁴ We have been stimulated in this work during the past ten years through the reference of children suffering with rheumatic heart disease by many physicians in private practice and by practically every hospital in Philadelphia and its suburbs—more than forty hospitals in all. We have been encouraged by the apparent improvement in the general physical condition of the majority of these children while at the hospital and by the statement of pediatricians working in the dispensaries of these hospitals that the parents of the children returning to the clinics from the Children's Heart Hospital seem to understand the problem of combating heart disease in a much more thorough manner than do the parents of children referred from the wards of these hospitals directly to the clinics.

More recently it was realized that rheumatic fever is perhaps a streptococcic reaction in hypersensitive individuals; the apparent minimal incidence of streptococcic infections in tropical climates and the somewhat encouraging results with children suffering from rheumatic heart disease and transferred to southern Florida⁵ has brought forward the problem as to whether we were justified in maintaining a fifty-bed convalescent hospital at a cost of \$33,000 a year or whether we should use

this money to support rheumatic children in tropical climates until past the age of puberty, at which age there is suggestive evidence that "the tendency to rheumatic infection begins to diminish."⁶ Longcope⁷ has concluded that "the available statistics concerning the geographical distribution of rheumatic fever indicate that the disease is very rare or almost unknown in the tropics and much less commonly observed in the warm portions of the midtemperate zones than in the cooler portions."

Our present study of the condition of the 458 children cared for at our hospital during a ten year period with a more intensive study of some 141 children in this group, selected because of the more complete data available in their case histories, may help to answer the query and at the same time offer a small contribution of additional information concerning rheumatic fever in children as it has existed in Philadelphia during the past ten years. The case histories of the smaller group were made available through the cooperation of the Pennsylvania, Children's, St. Christopher's, Graduate, University, Mount Sinai and Bryn Mawr hospitals.

As suggested by Paul's⁸ review of the epidemiology of rheumatic fever, we have attempted to study the racial factor; the familial incidence; the age of primary manifestation; the seasonal incidence of primary manifestation and reactivations; the part of the city in which the home is located at the time of primary manifestation and reactivations with the character of the subsoil; the amount of dampness; the social conditions; the effect of malnutrition and defective diets; the incidence of tonsillitis and the results of tonsillectomy; the length

The only comparable studies extending over a period of ten years which we have been able to discover are those of Coombs⁹ and of Wilson and her associates.⁶ In the former, of 253 patients with undoubted cardiac infection in Bristol, England, 21.4 per cent had died ten years after the primary manifestation of rheumatic fever—a figure identical with ours. In the latter group of 395 patients, three fourths of whom suffered from undoubted cardiac infection, only 11.9 per cent had died in ten years. The latter group had the primary manifestation at the same average age as ours; that is, 7.3 years. This apparently much better result with only dispensary observation and care is discouraging when compared with that of our group, which, in addition, has had convalescent hospital treatment. It must be remembered, however, that in Wilson's⁶ group "the majority of children came from moderately well-to-do homes of the industrial laboring class," while the children in our group, in the vast majority of cases, came from the very poorest laboring class in Philadelphia. We must reluctantly admit, however, that the mortality in this disease, as reported to date, seems to be about the same, no matter what the treatment.

In considering the group of 124 children who stayed at the hospital less than two months, it must be remembered that it includes many children, overwhelmed by the infection, who never should have been sent from the hospital wards to a convalescent hospital, many of whom were returned to the city hospitals within a few weeks. The families of other children in this group failed to cooperate in the treatment. These two factors help to explain the high percentage of deaths in this group (36.2), and the high percentage in which our follow-up has been unsuccessful (37.9). The group that stayed longest at the hospital—twelve months or more—includes those children with a low grade infection but an apparent inability under the best of circumstances to arrest the disease even temporarily.

9. Coombs, C. F.: Rheumatic Heart Disease, New York, William Wood & Co., 1924.

THE RACIAL FACTOR

Unfortunately, the value of any conclusions that might be drawn from our figures as to the racial incidence in this disease is reduced by location of the hospitals from which these cases were drawn—near the centers of the Italian and Hebrew populations in Philadelphia—plus the racial characteristic among the Jewish families of availing themselves most promptly of the unusual advantages that our hospital offers. Yet it is interesting to note in other studies that rheumatic fever seems to have an especial predilection for these two racial strains.

Similar factors, such as racially characteristic diets and the usual location of the more recent immigrants from Italy, Poland, Russia and Ireland in the parts of Philadelphia in which hygienic conditions are not of the best and which supply the majority of dispensary and ward patients in the hospitals from which these children come, have prevented satisfactorily controlled conclusions as to the part insufficient or defective diets, dampness, subsoil and poor hygienic conditions may play in the development of rheumatic heart disease. Generally speaking, however, these children came from the lowest social strata of the poorest districts of Philadelphia. Most of the families were indigent, and these factors were probably contributing factors in the development and progress of the disease in our patients.

THE FAMILIAL INCIDENCE

Among the 141 children with the most complete histories, we find thirty-four families in which there were at least two cases of rheumatic heart disease, thirteen families in which there were at least three cases of rheumatic heart disease, and one family in which there were at least five cases of rheumatic heart disease. We believe that satisfactory information as to the familial incidence of this disease can be obtained only through clinical histories and complete physical examinations of every member of the families from which these children come; that is, through studies similar to that of St. Lawrence.¹⁰ Further, it is our firm conviction that it is the duty of every practicing physician to carry out this procedure in his practice and that a similar responsibility lies with every heart clinic and heart hospital treating rheumatic heart disease. In cases of tuberculosis, physicians, clinics and sanatoriums carry out routine physical examinations and roentgen studies on every member of the family of the patients treated,

TABLE 3.—Children Discharged from Children's Heart Hospital Classified by Chief Racial Groups

| Parentage | Total Children | | Deceased Children | |
|----------------------------------|----------------|----------|-------------------|----------|
| | Number | Per Cent | Number | Per Cent |
| Total of four racial groups..... | 124 | 100.0 | 41 | 100.0 |
| Italian..... | 46 | 37.1 | 13 | 31.7 |
| Hebrew..... | 36 | 29.0 | 14 | 34.2 |
| American..... | 29 | 23.4 | 11 | 26.8 |
| Irish..... | 13 | 10.5 | 3 | 7.3 |

and it seems only right that such family studies should be made in the campaign against rheumatic heart disease, since the latter disease appears to have at least as high a familial incidence as the former.

AGE OF PRIMARY MANIFESTATION

In considering the value of table 5 in prognosis, two facts must be kept in mind. Many primary manifesta-

10. St. Lawrence, William: The Family Association of Cardiac Disease, Acute Rheumatic Fever and Chorea: A Study of One Hundred Families, J. A. M. A. 79: 2051 (Dec. 16) 1922.

tions of rheumatic fever go unrecognized and the discovery of heart damage a number of years later may be erroneously considered the time of primary manifestation. In the second place, we have gained the impression that children subject to rheumatic fever appear to divide themselves into three general groups: one in which the primary manifestation seems to induce

TABLE 4.—*The Functional Classification of Patients with Heart Disease**

Organic Heart Disease:

Class I: Patients with organic heart disease, able to carry on ordinary physical activity without discomfort

Class II: Patients with organic heart disease, unable to carry on ordinary physical activity without discomfort

A. Activity slightly limited

B. Activity greatly limited

Class III: Patients with organic heart disease, and with symptoms or signs of heart failure, when at rest, unable to carry on any physical activity without discomfort

Class E—Possible Heart Disease:

Patients who show abnormal signs or symptoms referable to the heart but in whom the diagnosis of heart disease is uncertain

Class F—Potential Heart Disease:

Patients without circulatory disease whom it is advisable to follow because of the presence or history of an etiologic factor which might cause disease

* Bainton, J. H.; Munley, W. C.; Levy, R. L., and Pardee, H. E. B.: Criteria for the Classification and Diagnosis of Heart Disease, American Heart Association, 450 Seventh Avenue, New York, 1933.

relative immunity toward further reactivations, and thus the primary manifestation is the one and only manifestation of the disease except the resultant cardiovascular damage; a second group in which there appears to be no evidence of rheumatic activity between the reactivations, but reactivations may be frequent until the child succumbs to an especially virulent one or, between the ages of 12 and 16, appears to develop a relative immunity to the disease and is left with the resultant cardiovascular damage practically stationary; a third in which the resistance to the infection seems low and the child is overwhelmed by the infection and dies within one or two years or else runs a constant febrile course or at least maintains constant evidences of a low grade activity with a toxic death in from three to five years or the gradual development of an apparent immunity at or just after puberty. It is in the last group that intravenous vaccine seems to offer the greatest possibilities in treatment.

In the group reported by Coombs,⁹ the average age of primary manifestation was just under 10.2 years. Our figure more nearly simulates Paul's¹¹ of 7.0 years and Poynton's¹² of 7.0 years, and is identical with Wilson's¹⁴ figure in a series of 413 children; namely, 7.3 years.

SEASONAL INCIDENCE OF PRIMARY MANIFESTATION AND REACTIVATIONS

It is most important to ascertain the seasonal incidence of rheumatic fever in those parts of the country in which this disease is most prevalent. Coombs⁹ finds the incidence maximal in England during the months of December and January; Levine¹³ finds it maximal in Boston during February; we find it maximal in Philadelphia during March, and the observations of Swift

and Wilson¹⁴ suggest that it may be maximal in New York later in the spring.

It naturally follows that the presumed methods of preventing primary infections in children or adults of rheumatic families or of minimizing reactivations in those suffering with rheumatic heart disease should be stressed during the months of highest incidence in the localities in which these individuals live.

We were unable to secure accurate information as to the interval between leaving our hospital and the next reactivation, nor could we secure satisfactory evidence as to the relationship of reactivations to "sore throats," "common colds" and other forms of infection of the upper respiratory tract in other members of the families. We believe that such information can be obtained only by specially trained physicians devoting their entire time to a study such as that reported by Paul and Salinger¹⁵ in New Haven. Similar studies certainly seem indicated when one considers the suggestive work of Dochez,¹⁶ in which it appears that the virus of the common cold may not only prepare the oropharynx for invasion of bacteria but even transform such bacteria as are commonly found in the oropharynx from a nonvirulent to a virulent form. It is admittedly a difficult problem to prevent the spread of a common cold through a household, and yet, if successful, this may prevent reactivation or even death in children with latent rheumatic heart disease.

Most physicians have educated their patients as to the possibility of reactivation of tuberculosis in patients in whom this disease has been arrested and as to the possibility of transmission of this disease by the individual to other members of the family. It seems probable that members of rheumatic families may transmit a virulent streptococcus or a common cold to a child in their family suffering with rheumatic heart disease. Thus, in rheumatic fever a child should be protected

TABLE 5.—*Age at Time of Primary Manifestation as Compared with Present Functional Classification*

from the members of the family, as in tuberculosis the members of the family are protected from the individual suffering with that infection.

TONSILLITIS AND THE EFFECT OF TONSILLECTOMY

There is a history of tonsillectomy and adenectomy previous to the primary manifestation in 30 of 141 of the more carefully studied cases. In seven of these, a

careful nose and throat examination by an otolaryngologist has proved the operative results unsatisfactory. In 92 of these 141 more carefully studied children, the primary manifestation of rheumatic fever occurred before tonsillectomy and adenectomy. In 9 of these the results were found to be unsatisfactory but the otolaryngologist has not yet completed his investigation of the nose, throat and sinuses of the entire group. Our impression has been that in the majority of cases rheumatic children do better after tonsillectomy, although we have no actual proof that such an operation pre-

Seasonal prevalence of primary manifestations and reactivations of rheumatic fever; 279 (61 per cent) of 457 primary manifestations and reactivations occurred between December and May.

vents the primary manifestation of rheumatic fever or minimizes the reactivations. We must agree with the conclusion of Wilson and her associates⁶ that "the routine removal of the tonsils for the prevention of rheumatic heart disease in children is not based on conclusive data," and yet since Mackie¹⁷ states that "tonsillar infection was found to be more than twice as prevalent in rheumatic fever cases as in 400 non-rheumatic controls," and, in the most extensive study of this subject, namely, that of Kaiser,¹⁸ it is suggested that the first attacks of rheumatic manifestations occurred 34 per cent less often in the tonsillectomized group, we still feel justified in insisting on tonsillectomy before a child can be admitted to our heart hospital. We believe that the matter of sinus infection in the average rheumatic child has not received the attention with careful transillumination and roentgen studies which it warrants.

PREMATURE CONTRACTIONS AND AURICULAR FIBRILLATION

Of the group in which we have the most complete case histories, premature contractions have been found in fourteen. Auricular fibrillation has been found in ten of this group of 141. The latter arrhythmia occurred in children having had frequent reactivations and extensive cardiac damage and usually developed only a few months before the death of the child. In other words, in the majority of rheumatic children, auricular fibrillation seems to be usually almost a terminal event.

VALVULAR DAMAGE IN RELATION TO PROGNOSIS

Table 7 confirms our clinical impression that the mortality in rheumatic fever depends more on the severity of the toxemia and the poor resistance of the host than on the number of valves involved. In a

study by Levy¹⁹ of 100 children under 15 years of age with rheumatic heart disease involving the mitral valve and with signs of congestive failure, an accompanying aortic insufficiency was present in 81 children, and yet his first conclusion is that "heart failure in childhood is brought on by frequent reactivations." Our observations confirm this conclusion.

For the following reasons we believe that we may give an affirmative answer to our primary question as to the justification of continuing our treatment of rheumatic heart disease in the Children's Heart Hospital: 1. Our results are as satisfactory as those in any similar group of children which we find reported. 2. Careful training of the parents while their children are at our hospital appears to be a valuable contribution in the treatment of this disease in the social group from which these children are drawn. 3. The transfer of such a large group of children—with or without their families—to a tropical or semitropical climate does not seem practical, and the results of such a procedure have not as yet been fully established.

Finally, after a year's experience by one of us²⁰ with intravenous streptococcus vaccine preparations and a careful review of the experimental and clinical observations and results of Swift and Wilson,¹⁴ Coburn and Pauli,²¹ Clawson,²² and Collis and Sheldon,²³ we have begun treating our patients intravenously with a streptococcus nucleoprotein which Swift has kindly prepared for us at the Hospital of the Rockefeller Institute for Medical Research.

SUMMARY

1. In order to secure an efficient, accurate and valuable follow-up of groups of children with rheumatic heart disease treated in heart hospitals or cardiac clinics, the full time of a specially trained physician and at least one social service worker is absolutely necessary.
2. The average age of the primary manifestation of rheumatic fever in a group of 458 children in a con-

totally disabled and 182 (59.3 per cent) are working or able to work or go to school.

4. Accurate information as to the incidence of common colds, sore throats and other infections of the respiratory tract in other members of the family and their relationship to primary manifestations and reactivations of rheumatic fever cannot be obtained by questioning the children or their parents unless this problem and its possible importance has beforehand been carefully explained and frequently reiterated to the patient and each member of the family.

5. Measures to protect children with rheumatic heart disease from the common cold and other infections of the respiratory tract, both by hypothesis and by actual experience, offer, so far as we can judge, the most practical form of prophylactic treatment that at the present time can be freely recommended.

6. The use of intravenous preparations of hemolytic streptococci with the hope of lessening hypersensitivity is still in the experimental stage but offers much promise.

7. Of a total of 428 primary manifestations and reactivations of which we have positive information, 61 per cent occurred during or between the months of December and May, with a peak of 65 (15.2 per cent) during March. In Philadelphia during these months, the suggested prophylactic measures mentioned should be especially stressed in susceptible children between the ages of 6 and 10 years—the years during which

13. We believe that a continuance of the treatment of children with rheumatic heart disease in convalescent hospitals in those areas in which rheumatic fever is prevalent is still justified.

ABSTRACT OF DISCUSSION

DR. T. DUCKETT JONES, Boston: Rheumatic fever and the resultant heart disease remain one of the blankest chapters of the infectious disease group. With the extensive crippling and high mortality, it becomes a major problem. The fact that the etiologic agent is unknown renders this problem difficult. The hemolytic streptococcus has been strongly indicted as this agent, but final proof of its etiologic significance is lacking. Rest is by far the most important therapeutic measure. Most students agree that rest in bed is advisable so long as there is evidence of active rheumatic fever. The evaluation of the type of therapy which the authors have discussed is most important and will help to determine more accurately just how much rest and care these patients need and what effect this has on the prognosis. It may be well to stress that the actual degree of valvular disease is not always important in these cases and is not a prognostic point of great significance. The severity and frequency of the reactivations or recurrences are important and determine the prognosis in the child or young adult. It is more important in these patients to determine the absence or presence of active rheumatic fever than to pay attention to whether or not one hears a mitral diastolic murmur. Circulatory mechanics plays a more important rôle in the patient above 30 years of age with a rheumatic heart disease. This may be the result of early degenerative lesions in addition to the already present rheumatic disease. The prognosis in those patients with conspicuous cardiac enlargement is as a rule quite grave.

DR. ALBERT G. YOUNG, Boston: A fact of great interest to the entire profession is that, despite all the care and money expended within ten years, 21 per cent of these children are dead and 46 per cent are either dead or hopelessly disabled: very disappointing when one considers that they were given the best treatment we have to offer. It is known that, in certain populous areas, having a climate marked by rain, dampness and changeable weather, rheumatic fever and infectious arthritis are most prevalent. In these areas the streptococci most generally considered as the etiologic agents of the disease are found growing in the upper respiratory tract of most of the inhabitants. If all children could be sent away from such districts, to the Southwest or the South, until they reached the age of puberty, perhaps there would be much less rheumatic fever. However, that is impossible. One must not look too closely to determine the exact organism that may be the cause of this disease, because it is conceivable that, wherever there is a large number of streptococci present, any one of the number may produce the disease. The present method of treatment is supportive and not combative. If the patient has good resistance he may recover. It is a challenge to the profession to consider this disease from a point of view directed toward aggressive rather than supportive treatment. I am looking at rheumatic fever and inflammatory rheumatism as nonspecific allergic processes, and I believe that progressive therapy must be instituted to combat them. Each patient must be treated in an aggressive as well as a supportive manner. Perhaps desensitization to streptococci will prove feasible, but I also believe that the problem should be investigated from the standpoint of chemotherapy. There are certain compounds that are known to have some possibility in preventing allergic inflammatory reactions. They deserve more study. In view of the fact that serologic efforts have not been crowned by too much success, physicians should enlist the aid of the chemist, the pharmacologist, the internist and the pathologist. It is work like that of Dr. Stroud and his co-workers that brings the whole situation to a focus.

DR. WILLIAM D. STROUD, Philadelphia: The points brought up by Dr. Jones which I believe to be of especial importance are, first, the prevalence of this disease, and, second, our meager knowledge as to positive measures of prevention and treatment. As Dr. Longcope said to me a few years ago, "This is the dis-

primary manifestations and reactivations are most apt to occur.

8. In our group, by far the greatest number of patients were of Italian, Hebrew, American and Irish parentage, in the order named.

9. There seems to be a familial incidence at least as high as that in tuberculosis.

10. Although we have no positive proof that the routine removal of tonsils prevents primary manifestations or minimizes reactivations of rheumatic fever, we believe that such a procedure, plus a careful study of the sinuses, is still justified in the type of child included in this study.

11. Premature contractions are found with relative infrequency in this group, and auricular fibrillation, if found, is usually a terminal or near terminal event.

12. The valve or number of valves involved in rheumatic heart disease in childhood has little to do with prognosis as compared to the virulence of the infection, the resistance of the host and the number of reactivations.

ease of which we probably know least and which is as important as any problem in cardiovascular disease." The familial incidence of this disease is worthy of note. As Dr. Bierring has said concerning hypertensive arteriosclerotic cardiovascular disease, so with rheumatic heart disease it may be possible through its familial incidence to ascertain the children most susceptible and to institute a few preventive measures of which there is some knowledge at an early age and thus possibly obtain better results. I would emphasize the importance of careful observation of these children throughout their lives. The common cold is of great importance in relation to these children and it may possibly be the cause of reactivations with an occasional fatal outcome. Dochez has shown recently that when positive cultures of influenza bacilli and the pneumococci were found in the throats of chimpanzees, a common cold apparently transformed these influenza bacilli and pneumococci from nonvirulent to virulent forms. This brings up the question as to the relationship of the common cold to acute manifestations of rheumatic fever in children with rheumatic heart disease.

HEPATOSPLENOGRAPHY WITH THORIUM DIOXIDE SOL

CLINICAL EXPERIENCE WITH ONE HUNDRED PATIENTS

WALLACE M. YATER, M.D.

AND

LAURENCE S. OTELL, M.D.

WASHINGTON, D. C.

Although the Council on Pharmacy and Chemistry of the American Medical Association in December, 1932, reported unfavorably on the intravenous use of thorium dioxide,¹ it did not entirely condemn its use but urged great caution therein. The study of the Council did not reveal serious ill effects, so far as clinical experience was concerned, with the use of thorium dioxide sol administered intravenously, but it brought forward the possibilities of latent radioactivity, remote partial conversion of the metal into more radioactive mesothorium and radiothorium and sensitization of tissues to x-ray or radium therapy. These possibilities are all due to the facts that thorium dioxide is a heavy metal with some radioactivity and that after being phagocytosed by the reticulo-endothelial cells of the body it is extremely slowly excreted from the body, probably requiring years to be completely removed. Although we had used this metal for roentgenographic demonstration of structural changes of the liver and spleen for nearly two years in a large series of patients without having noted any serious immediate or remote effects, we immediately adopted an attitude of greater caution after the publication of the report of the Council and confined the use of the metal to patients who did not have a reasonable chance of long life. In reporting our experience with this method of diagnosis in 100 patients, we would urge a similar method of selection of patients on those who desire to employ it.

Although Einhorn and Stewart² were apparently the first to undertake the development of a method of "visualizing" the liver and spleen, using tetraiodophenolphthalein and diiodoatophan. Paul Radt of Berlin was the first to use a thorium compound for this

purpose, and to him³ is due the greatest amount of credit for developing hepatosplenography, although many others have added valuable information on the subject.⁴ A few months after Radt's original reports we became interested, and at the annual session of the Association in New Orleans in May, 1932, we reported on the use of the method in forty patients.⁵ We were greatly impressed with the results, and since then our enthusiasm has not waned.

ANIMAL EXPERIMENTATION

A number of investigators have reported results of animal experimentation with thorium dioxide sol. The metal is removed from the blood stream several hours after intravenous injection by the cells of the reticulo-endothelial system in the liver, spleen, bone marrow, lymph nodes and to some extent by the lungs, heart, ovaries and suprarenal glands. It is eliminated very slowly; in fact, some of it may remain in the tissues for years. Various authors report different rates of elimination. The liver apparently loses the substance faster than other organs. Elimination may occur mainly through the bile and urine, as indicated by the work of Leipert,⁶ but apparently it may take place also by cellular transport to the lungs and be removed by the bronchial mucus, as shown by Kadrnka⁷ and by Irwin.⁸

Histologically, the metal appears as greenish, refractive granules in the reticulo-endothelial cells, which appear globular and in which the nucleus is displaced to the periphery. The larger the dose, the greater the engorgement of the cells.

Pathologic changes in animals, thought to be due to the foreign substance, have been reported by some investigators, but many have concluded that the damage is transitory or negligible. The work of Tripoli and Haam,⁹ which has been followed to some extent by one of us (Yater), leads us to believe that in the dosage used in man there is no danger of direct injury due to the presence of the thorium dioxide in the tissues.

Lambin¹⁰ studied the effect of injections in rabbits on the blood picture. Moderate doses produced an

erythroblastic reaction, while large doses produced a pronounced anemia, recovery from which was spontaneous. A phase of leukopenia followed the injections, but this changed to a longer phase of leukocytosis, first of granulocytes and later of monocytes. Popper and Klein¹¹ in similar experiments did not find changes in

and has pointed out the various probable functions of these cells. Apparently not one of these functions is seriously or even moderately impaired by the method under discussion.

RADIOACTIVITY OF THORIUM DIOXIDE SOL (THOROTRAST)

Seventy-five cubic centimeters of thorium dioxide sol (Thorotrast¹⁷) contains a quantity of thorium dioxide equivalent in alpha-ray activity to 1.5 to 3.0 micrograms of radium. The beta-ray and gamma-ray activity of this amount of thorium dioxide is probably too feeble to be of physiologic significance, but the alpha-ray activity is thought to be sufficient to be a potential source of danger when dispersed through the tissues. Proofs of ill effects from this source, however, are thus far totally lacking, nor is there any published work which shows that there is either further increase in radioactivity with the passage of time or sensitization of tissues to roentgen rays by thorium dioxide sol. Radt¹⁸ has observed no ill effects of any kind after three and a half years of extensive experience with thorium dioxide sol both in animals and in man. Neither have we observed any changes attributable to the presence of thorium dioxide in the tissues of patients after more than two years. One patient with myeloid leukemia who has had seven roentgen treatments during two years following the injections of colloidal solution of thorium dioxide has remained in excellent condition and has not shown any evidence of sensitization to x-rays. Another patient has had a similar experience during a shorter period of time.

REACTIONS DUE TO THORIUM DIOXIDE SOL

Reactions following the injection of thorium dioxide sol into the blood stream have been few and mild. Occasionally there is a slight transitory discomfort, mild tension of the limbs, chilly sensations, or a mod-

Fig. 1.—Area of lessened density in liver shadow, proved to be primary carcinoma of the liver.

the blood picture of any importance. Thrombocytopenic purpura was produced in several rabbits by Shih and Jung¹² with doses of thorium dioxide sol several times greater than those used in man. In this connection, we have not observed significant changes in the platelet count in several of our patients following the injections.

The question concerning the effect of partial blockade of the reticulo-endothelial system by thorium dioxide sol on the immune reactions of the body to infection has been satisfactorily answered by Held,¹³ by Vara-López and Thorbeck,¹⁴ and by Randerath and Schlesinger.¹⁵ These workers concluded in the main that the presence of large amounts of the metal in the reticulo-endothelial cells has no very appreciable effect on antibody formation, hemolysin titer, albumin-globulin coefficient, reciprocal storage capacity of the cells or, in general, on the defense mechanism of the body against infection. One of us¹⁶ has reviewed the subject of the physiology of the reticulo-endothelial system

17. Thorotrast is the trade name given by the Heyden Chemical Corporation to its stabilized, colloidal solution of thorium dioxide, which contains 25 per cent by volume of thorium dioxide. Thorotrast has been the preparation of thorium dioxide used by us and others for hepatosplenography.

18. Radt, Paul: Personal communication to the authors.

fever occurred in only 4 of 100 patients on whom we used the method. A patient with Banti's disease complained of severe pain in the lumbar region and chest followed by spasmodic contractions of the rectus abdominis muscles, which subsided without residual symptoms or signs. Another patient complained of transient lumbar pain after the first injection. A child had some puffiness of the eyelids and face for three days. A fourth patient, who died as the result of

renal insufficiency has been deduced by Kadrnka⁷ as a contraindication, since this author thinks that most of the thorium dioxide sol may be eliminated through the bile and urine, and its continuous presence in the circulating blood might be detrimental. Whether the latter is true or not, one would hardly desire to make use of the metal in patients with such a serious condition.

METHOD OF ADMINISTRATION

In adults of average size, 25 cc. of thorium dioxide sol is administered intravenously on each of three successive days. In children the dose is reduced roughly in proportion to the weight. More accurate estimation of dosage on the basis of body weight is apparently unnecessary. In general, the density of the roentgen shadows of the liver and spleen depends on the quantity of the medium administered and the anatomic and functional integrity of the cells that store it. If only the outlines of the liver and spleen are desired, the dose may be reduced one half or even one third. Fractional doses are used in order to eliminate the shock that might be produced by the injection of too large a dose of foreign material.

Films may be taken at any time after four hours following the last injection, but preferably twenty-four hours later. The night before the examination the patient is given the usual evening meal and at bedtime 8 Gm. of compound licorice powder. The morning of the examination a cleansing enema is given and the patient is advised to come to the x-ray department without breakfast. Films are taken in both the prone and the supine position on the Bucky diaphragm. The tube is centered over the ensiform cartilage. The following technic has been used in patients of the average physique: 60 kilovolts peak at 100 milliamperes for three and one-half seconds at a 25-inch distance. It is well in most individuals to place the film transversely

Fig. 3.—Atrophic cirrhosis of liver. Small size of liver and diffuse mottling are obvious. The spleen is enlarged and apparently bigger than the liver. (Compare with figure 2.)

hemorrhage from a traumatically ruptured spleen, had vomiting and transient collapse, which may or may not have been due to an injection of thorium dioxide.

Büngeler and Krautwig¹⁹ reported a case of fatal rupture of an enlarged spleen occurring twenty-two hours after a second injection of thorium dioxide sol. Many of our patients had enlarged spleens, but the only one who had a reaction was the one with Banti's disease. Stewart, Einhorn and Illick²⁰ noted hematemesis in a patient with Banti's disease and jaundice, which may have been due to the use of colloid solution of thorium dioxide.

CONTRAINDICATIONS FOR THE TEST

In view of the uncertainty of the effect of alpha radiation by thorium dioxide and the possibility of remote conversion of some of the substance to a more radioactive preparation, we suggest that for the present thorium dioxide sol be used only for patients who are subjects of a rapidly fatal disease. In our experience there have been practically no contraindications for the use of the test from other standpoints. In the case of patients who have lived for many months after the injections, there have been no apparent ill effects. Even extremely ill patients have not appeared to be harmed by the procedure, although moribund patients should naturally not be subjected to it. It is possible that the use of the method may be inadvisable in hemorrhagic conditions and in patients with active tuberculosis. Simultaneous severe liver disease and

Fig. 4.—Microscopic section of liver of patient whose x-ray films are shown in figures 2 and 3, showing islands of liver tissue containing thorium dioxide sol (black dots) surrounded by fibrous tissue. Reduced from a photomicrograph with a magnification of 72 diameters.

in order to get a good image of the spleen and liver on the same film. A more comprehensive idea of the structural characteristics of the liver and spleen is obtained by making several exposures within a range of 10 kilovolts of this dosage. Careful technic is essential in securing films that show details of structural change.

19. Büngeler, W., and Krautwig, J.: Ist die Hepato-Lienographie mit Thorotrast eine unschädliche diagnostische Methode, *Klin. Wchnschr.* 11: 142-144 (Jan. 23) 1932.

20. Stewart, W. H.; Einhorn, Max, and Illick, H. E.: Hepatography and Lienography Following the Injection of Thorium Dioxide Sol (Thorotrast), *Am. J. Roentgenol.* 27: 53-58 (Jan.) 1932.

APPEARANCE AND SIZE OF THE NORMAL LIVER AND SPLEEN

In good films the liver should cast a homogeneous shadow of approximately the same density as the spine. The spleen normally has a density slightly less than that of the liver shadow, and about the same as that of the ribs.

Fig. 5.—Atrophic cirrhosis of liver. Liver shadow is homogeneous but of greatly reduced density. Spleen is enlarged.

In determining whether the liver and spleen are normal in size, it is necessary to know what the average normal size of these organs is. We obtained very little help from the literature in this regard, and unfortunately a sufficient number of individuals without alteration of the liver and spleen has not been studied to form a basis for this comparison. The only work of any value in reference to the size of the liver is that of Pfahler,²¹ who compiled tables of the size of the liver in subjects of both sexes, of different ages and of varying heights and weights. These data were computed from flat films of the abdomen. Pfahler found that there was very little variation in adults in the size of the liver determined roentgenographically. Two measurements of the liver shadow were taken; one was the "length," which was measured from the highest point of the upper border to the lowest border of the tip of the right lobe; the second measurement was made obliquely from the upper border to the lower border in a direction that gave the maximum measurement of the apparent thickness of the liver. The average normal length of the liver shadow was 21.3 cm., with limits of approximately 18 to 22 cm., and the average oblique measurement was 12.8 cm., with limits of approximately 10 to 14 cm. These data, while the best available, are obviously inaccurate because of the indistinctness of the liver shadow in such films. The measurements were only comparative, since the short distance between the tube and the film (25 inches) produced some distortion.

After the use of thorium dioxide sol, the right lobe of the liver appears to constitute most of the organ. The left lobe looks very small and is frequently obscured by the shadow of the spine. The left extremity of the liver rarely extends more than 8 cm. to the

left of the midline. It comes to an acute angle under the left leaf of the diaphragm. The presence of ascites may give a false impression of the size of the liver, causing it to appear smaller than it should.

Comparative determinations of the size of the spleen are still more difficult, since the spleen normally varies a great deal in size from time to time. Also, in normal subjects after the injection of thorium dioxide sol the spleen may not be well visualized because of gas in the stomach. Even in cases of splenomegaly there may be some difficulty with this method in accurately determining the limits of the spleen for the same reason. Nevertheless, after experience with the method one may be able to estimate fairly accurately the size of the spleen, and changes in the size of the spleen in the same individual may be followed. The spleen may be considered to be of normal size if it occupies the space of two ribs and two interspaces. For recording our measurements, we have used the greatest dimension and the dimension taken at a right angle to this through the middle of the organ.

STUDY OF CASES

We found the method of greatest value for the following purposes:

1. To detect whether enlargement of the liver or spleen accounts for the presence of a tumor found by physical examination in the upper part of the abdomen. Sometimes we were surprised to find that what was thought to be a tumor of the kidney or some other organ was a tumor of the liver, and vice versa.

2. To determine whether the liver is cirrhotic or contains tumor masses. Atrophic cirrhosis, hypertrophic cirrhosis, syphilitic scarring, metastatic car-

Fig. 6.—Hypertrophic cirrhosis of liver. Moderate splenomegaly.

cinoma or sarcoma, primary tumor, abscess, cyst and amyloidosis can all be readily "visualized." Abscess, cyst and primary tumor may give some trouble in differential diagnosis. Reeves and Apple²² have recently reported an abscess of the liver which was successfully diagnosed.

3. To ascertain the presence or absence of metastases in the liver prior to operation in patients found to have cancer and for whom operation is contemplated. Ericksen and Rigler²³ have recently emphasized this point.

Less important uses are:

4. To settle the question whether there is rupture of the liver or spleen.

Fig. 7.—Scarred liver resulting from gummatous syphilis (hepar lobatum). The spleen is considerably enlarged.

5. To determine whether subacute or chronic jaundice is due to intrahepatic disease or obstruction of the common bile duct.

9. To study diseases of the spleen.

The accompanying table shows the diagnoses of the condition of the liver and spleen in our hundred patients, together with the number of the cases of each kind in which the diagnosis was confirmed by operation and biopsy or by necropsy. More than one third of these patients are known to have died as a result of the disease for which they were hospitalized. Undoubtedly, a number of others have also died.

1. *Detection of Nature of Mass in the Upper Part of the Abdomen.*—As illustrations of the value of the method for this purpose, two cases may be briefly cited:

A woman, aged 56, was found on physical examination to have a large mass in the right upper quadrant of the abdomen. This mass felt quite like a large tumor of the right kidney and was thought to be a hypernephroma. Hepatosplenography (fig. 1) revealed, however, an enlarged right lobe of the liver containing a large, somewhat irregular area of lessened density, which was diagnosed primary carcinoma of the liver. Operation and biopsy revealed this diagnosis to be correct.

A man, aged 64, showed on physical examination a large mass in the epigastrium which appeared as though it might have been a tumor of the liver. Hepatosplenography showed that the liver was normal. Necropsy revealed a large lymphosarcoma of the abdomen.

2. *Diagnosis of Liver Disease.*—For this purpose, hepatosplenography is of great value. The characteristic appearances of various conditions of the liver are as follows:

Atrophic Cirrhosis: One of two characteristic pictures may be given by this condition. The liver may be smaller than normal and diffusely mottled with small areas of opacity in a background of greatly lessened density (figs. 2 and 3). The spleen is practically always

Fig. 8.—Liver invaded by large metastatic carcinomatous lesions. The necropsy specimen is shown in figure 9.

moderately enlarged. The appearance is due to the fact that there are relatively large islands of regenerated liver tissue throughout a very fibrotic organ. The islands of liver tissue contain reticulo-endothelial cells and hence thorium dioxide sol, whereas the surrounding fibrous tissue is devoid of reticulo-endothelial cells (fig. 4). The areas of opacity represent, therefore, the islands of remaining liver parenchyma.

The other appearance is that of a liver of perhaps normal or nearly normal size but which casts a homogeneous shadow of definitely reduced density (fig. 5). The spleen is practically always moderately enlarged. The appearance of the liver is due to the fact that there is a fine meshwork of fibrous tissue throughout the organ with small islands of regenerated liver tissue

Fig. 9.—Liver at necropsy of patient whose antemortem roentgenogram is shown in figure 8.

embedded therein. The result is a generalized reduction of reticulo-endothelial cells, since regenerated liver tissue contains a much smaller amount of these cells than normally and there is also an actual reduction in the amount of liver tissue.

Hypertrophic Cirrhosis: A more active regenerative process in the liver produced by a more active toxic or infectious agent results in a greatly enlarged liver rather than a shrunken one. The appearance of the liver in the film is, therefore, that of an enlarged organ casting a homogeneous shadow of lessened density (fig. 6). In some instances there may be a suggestion of mottling. The spleen is usually moderately enlarged.

Syphilis of the Liver: Syphilitic cirrhosis of the Laënnec type produces the same appearance as atrophic cirrhosis. The gross scarring resulting from the healing of gummas (*hepar lobatum*) gives, however, a characteristic appearance. There is gross deformity and lobulation, which is shown exceedingly well in figure 7. The picture is quite different from that of metastatic carcinoma, since there are no definite, rounded areas of reduced density.

Metastatic Carcinoma: The evidence given by hepatosplenography is incontrovertible. There are multiple, large and small, rounded areas of greatly reduced density in an enlarged organ (figs. 8, 9 and 10). These areas are usually surrounded by a halo of increased density. The spleen is practically always normal in size. The appearance of the liver is due to the fact that carcinomatous tissue does not contain reticulo-endothelial cells.

Primary Tumor: A single primary tumor produces a large area of reduced density with a somewhat irregular but usually fairly sharp outline in an enlarged organ (fig. 1). The halo of increased density is usually lacking. The spleen is not enlarged.

Abscess: A solitary abscess produces much the same appearance as a single primary tumor, except that the outline may not be as well defined and the area may be more peripheral. Multiple abscesses produce multiple areas of this kind. The spleen may be somewhat enlarged.

Cyst: A cyst produces a round, sharply defined area of reduced density. The spleen is usually not enlarged.

Amyloidosis: One of our patients had amyloidosis due to chronic, suppurating tuberculous spondylitis. The liver was much enlarged, of reduced density, and absolutely homogeneous. The spleen was moderately enlarged but of normal density. The appearance was that of hypertrophic cirrhosis, but there was not the slightest suggestion of mottling.

Other Diseases of the Liver: Catarrhal jaundice shows nothing definitive in the film. The liver is usually moderately enlarged, especially the right lobe, but is of practically normal density; the spleen may be slightly enlarged. Toxic hepatitis gives a similar picture. In passive congestion of the liver, there is some enlargement of the liver shadow and perhaps some slight diminution of density; the spleen is not enlarged. Focal necrosis is suggested by the presence of small vacuoles throughout the liver shadow.

3. Detection of Metastases in the Liver.—The importance of knowing whether metastases are present in the liver in a patient known to have a carcinoma, particularly of an abdominal viscus, is self evident. This knowledge may be the deciding factor in settling the question of the advisability of undertaking surgical relief. We are using the method almost as a routine for this purpose.

4. Diagnosis of Rupture of the Liver or Spleen.—Our experience in this field includes two cases. In one,

Fig. 10.—Metastatic carcinoma of liver, giving Swiss cheese appearance.

a little girl had been crushed by an automobile and was suffering severe abdominal pain. Injection of 15 cc. of thorium dioxide sol intravenously followed by the taking of films after four hours showed the liver and spleen to be intact. Operation was deferred, and the child left the hospital in forty-eight hours. In a similar case the surgeon operated on a man for rupture of the liver, found an intact liver and blood in the abdomen, made another incision over the spleen and found a

lacerated spleen but could not remove it. After injection of 25 cc. of thorium dioxide sol intravenously, the diagnosis could be made from the film. Had the patient received the benefit of this procedure before operation, he would have been saved the primary operation. It requires but one dose of the metal to determine whether rupture of one of these organs exists, and the

Fig. 11.—Obstructive jaundice. Dilated intrahepatic bile ducts "visualized" in enlarged right lobe.

films may be taken at the end of four hours. This amount of thorium dioxide is probably devoid of remote ill effects.

5. Determination of the Cause of Jaundice.—In several instances we have been able to determine whether jaundice was due to intrahepatic disease or to obstruction of the common bile duct, a rather important question that frequently arises. In three instances, the dilated intrahepatic ducts were seen as branching channels of greatly reduced density, and in all three obstruction of the common bile duct was found to exist (fig. 11). This appearance would probably be obtained only in cases in which the obstruction had existed for a few weeks, since time is necessary to cause dilatation of the ducts sufficient for "visualization." In other cases, operation was obviated because dilatation of the intrahepatic bile ducts was not demonstrated.

6. Follow-Up of the Progress of Hepatic or Splenic Disease.—We have taken films of patients at intervals of months after giving thorium dioxide sol. Usually there was no appreciable change. Undoubtedly changes could readily be detected, however, if any important ones occurred. After months, there was very little reduction of density of the shadows of the liver and spleen in most of our cases, although, in a few, definite reduction was noted.

7. Ascertaining the Position of the Diaphragm.—In one case very valuable information was obtained in regard to the position of the diaphragm. A woman with weakness, loss of weight and fever was found to have evidence of disease on physical examination in the region of the right side of the diaphragm. Fluoroscopic examination revealed elevation and greatly diminished motion of the right side of the diaphragm. Since the patient had had an appendectomy some weeks previously, it was thought she might have a subphrenic abscess. Hepatosplenography revealed the fact that the

liver, normal in size and structure, was elevated *en masse*, pushing the diaphragm up. The case was probably one, therefore, of eventration of the right diaphragm. Later, a low-grade pelvic abscess was found, and operation cured the patient of her symptoms. In another case, hepatosplenography demonstrated that the lesion was above the right diaphragm, when flat x-ray films showed what might have been a subphrenic abscess.

8. Diagnosis of Ascites.—The use of thorium dioxide sol to determine simply whether ascites exists is not recommended, but ascites is easily demonstrated by separation of the liver and sometimes of the spleen from the lateral walls of the abdomen. In some cases ascites was shown roentgenographically to exist when its presence was not suspected on physical examination.

9. Study of Diseases of the Spleen.—Hepatosplenography is not of very great value in the diagnosis of diseases of the spleen. Splenomegaly is readily detected, but specific or diagnostic structural changes are not often noted. In an untreated case of chronic leukemia, the enlarged spleen may cast a shadow of reduced density, owing to leukemic infiltration (fig. 12). After treatment the spleen is seen to be smaller and of normal density. No abnormality of the splenic shadow was noted in early sickle-cell anemia, xanthomatosis, Banti's disease or purpura haemorrhagica. In Banti's disease one might expect to find the fibrotic organ casting a lighter shadow than the normal spleen, but we have not seen such a case. It is conceivable that tumor, abscess, infarct or cyst of the spleen might be demonstrable. Accessory spleens are easily "visualized."

SUMMARY AND CONCLUSIONS

Hepatosplenography with thorium dioxide sol may not be without remote danger, owing to radioactivity.

Fig. 12.—Myeloid leukemia, with enlarged spleen: *a*, of less than normal density.

Its value, however, as an aid in the diagnosis of diseases of the liver and spleen has been amply demonstrated. In the 100 cases which form the basis of this report, serious immediate and remote (after two and a half years) ill effects have not been observed.

The method is of value as follows:

1. In detecting the nature of a mass in the upper part of the abdomen.

2. To determine the presence and kind of hepatic disease (atrophic cirrhosis, hypertrophic cirrhosis, syphilis of the liver, metastatic malignant lesions, primary tumor, abscess, cyst and amyloidosis).
3. To ascertain whether metastatic lesions are present in the liver if operation is contemplated for cancer.
4. To demonstrate rupture of the liver or spleen.
5. To determine the cause of jaundice (whether intrahepatic or due to obstruction of the common bile duct).
6. To follow the progress of hepatic or splenic disease.
7. To demonstrate whether a lesion is above or below the diaphragm.
8. To diagnose ascites.
9. To study diseases of the spleen.

PRIMARY STAPHYLOCOCCIC PNEUMONIA

HOBART A. REIMANN, M.D.
MINNEAPOLIS

Increase in knowledge of acute bacterial pulmonary disease requires a revision in the terminology of lung infections. Anatomic or descriptive terms such as lobar, lobular, croupous, fibrinous or catarrhal pneumonia are no longer acceptable and will become as obsolete as the designation "enteric fever." It is not of much importance clinically, for example, whether in enteritis the ulcers are present solely in the ileum or in the colon, but it is extremely important whether the disease is due to the typhoid bacillus or to *Endamoeba histolytica*. Similarly, it is of no great moment from the standpoint of specific prophylaxis, therapy or prognosis whether the lesion in pneumonia is in the alveoli or in the interstitial tissue, but it is of great importance whether the infection is due to the type I pneumococcus or the staphylococcus. In other words, etiologic diagnoses must eventually supplant anatomic diagnoses.

It is surprising that the term "bronchopneumonia" is still used to cover a variety of infections, although over forty years ago, during the influenza pandemic of 1889, Netter¹ and others found pure cultures of various organisms in a high percentage of cases, indicating that specific diagnosis was possible. Several difficulties have contributed to the reluctance of most clinicians to accept an etiologic basis for the diagnosis of acute pulmonary infections. In the first place, when examining the sputum, it is seldom safe to consider the organisms present as the causative agent of the pneumonia unless one form or another is constantly present, almost to the exclusion of all others. Secondly, there is a natural reluctance to perform routine lung puncture to determine the organisms present in the pneumonic area. Thirdly, the development in the blood of specific agglutinins for the causative organisms, which was so important a factor in the recognition and differentiation of bacillary diseases of the gastro-intestinal tract, does not as a rule occur in pulmonary infections due to various cocci. Lastly, it is possible that the difficulties involved in the control of epidemic air-borne diseases such as

pneumonia, even if the etiologic factors were known, as compared with the relative ease of controlling food-borne gastro-intestinal infections, have further tended to lessen interest in this field.

If progress is to be made in the specific prophylaxis and therapy of primary acute pulmonary infections similar to the progress that has been made in regard to acute intestinal infections since their recognition as specific etiologic entities, as Cole² emphasizes, it will be necessary to regard all cases of pneumonia in the light of the causative agent. When this is accomplished, the development of specific prophylaxis and therapy will be greatly facilitated. Chiefly through the efforts of Cole have attempts again been made to classify acute pulmonary infections on an etiologic basis. Thus, typical lobar, croupous or fibrinous pneumonia becomes type I, II or III pneumococcus lobar pneumonia. Primary bronchopneumonia or lobular or catarrhal pneumonia is classified broadly as "atypical" pneumonia to distinguish it from typical lobar pneumonia, and specifically as pneumococcic (usually group IV), streptococcic, influenza bacillus, staphylococcic, Friedländer bacillus, plague pneumonia, and so forth, depending on the causative organism. By this method of classification confusion is obviated, since, for example, type III or group IV pneumococci may give rise to inflammation which clinically or anatomically may be classed either as lobar pneumonia or as bronchopneumonia. Any organisms associated with bronchopneumonia may occasionally produce inflammation limited to one lobe, which, anatomically speaking, would be considered by some as lobar pneumonia.

Adequate clinical and pathologic descriptions are available for pneumococcic lobar pneumonia and for pneumonia due to group IV pneumococci and streptococci. Much less attention has been given to primary bronchogenic staphylococcic pneumonia, and for this reason the following cases are presented.

Staphylococcic infection of the lung characterized by sudden onset, remittent fever, purulent sputum and abscess formation was described in 1904 by Fraenkel.³ He isolated the staphylococcus in pure culture directly from the lung of a patient whose clinical course closely resembled that of case 1 in this report. Fraenkel also observed multiple lung abscesses in many fatal cases of "influenzal pneumonia." The small abscesses tended to become confluent if the patient lived long enough. Because of the rapidly fatal course of most cases, the condition was seldom diagnosed. Even before 1900, Weichselbaum, Pfeiffer, Ribbert, Marchand and Leichtenstern⁴ noted the frequency with which "influenzal pneumonia" terminated in abscess formation. Staphylococcic pneumonia in epidemic form was described in 1919 by Chickering and Park,⁵ who reported 153 cases. Most of their patients were ill with influenza before the development of pneumonia. The onset of the pneumonia was usually gradual. The clinical course was severe and was characterized by peculiar cyanosis, a dirty pink, purulent sputum, often a leukopenia and a high mortality rate. At necropsy, the characteristic observations were the presence of numerous miliary or microscopic abscesses. If the patient lived long enough,

5. Chickering, H. T., and Park, J. H.: Staphylococcus Aureus Pneumonia, J. A. M. A. 72: 617 (March 1) 1919.

From the Department of Medicine, University Hospital, University of Minnesota Medical School.

Read before the Section on Practice of Medicine at the Eighty-Fourth Annual Session of the American Medical Association, Milwaukee, June 16, 1933.

1. Netter: Etude bactériologique de la bronchopneumonie, Arch. de méd. expér. et d'anat. path. 4: 28, 1892.

multiple large coalescent abscess cavities were found to be present.

In Cole's² series of 211 cases of primary atypical pneumonia, 19 (9 per cent) were associated with the staphylococcus. The clinical picture of his cases agreed in general with those described by Chickering. Habbe,⁶ who made cultures at necropsy from the lungs of 270 cases of pneumonia, isolated the staphylococcus in pure culture from 5 and in association with pneumococci in 4 of 131 cases of "croupous" pneumonia. Out of ninety-three cases of "bronchopneumonia" the staphylococcus was found in pure culture in thirteen cases and mixed with other organisms in eight cases. In "grip pneumonia" the staphylococcus was present in eight of twenty cases (40 per cent) in pure culture and in combination with other

Fig. 1 (case 1, tenth day).—Fairly dense consolidation of the upper portion of the left lung, showing numerous rarefied areas.

bacteria in five others. Out of twenty cases of "whooping cough pneumonia," the staphylococcus was isolated from two. The terminology used by Habbe in classifying pneumonia as croupous pneumonia, bronchopneumonia, grip pneumonia and whooping cough pneumonia, each in turn associated with a variety of bacteria, further emphasizes the confusion of nomenclature and the need for classification on an etiologic basis alone.

Other publications also show the relative incidence of staphylococcal infections of the lung. Lyon⁷ made lung punctures in eighteen cases of bronchopneumonia in children. The staphylococcus was isolated in pure culture from four and in combination with other bacteria from two. Lyon considered the staphylococcus as the important agent in bronchopneumonia in 9.6 per cent of his cases and with a death rate of 80 per cent. Menten⁸ found the staphylococcus alone in 11 cases and mixed with other bacteria in 65 instances during bacteriologic studies of the lungs of 131 cases of pneumonia in children at necropsy. Gundel⁹ found staphylococci mixed with other bacteria in 7 of 102 cases of bronchopneumonia at necropsy. These recent studies show that the incidence of staphylococcal lung infection has not changed materially since Netter's report in

1892, in which he found the staphylococcus in pure culture in 7.7 per cent of his cases.

From the studies thus far reported, it appears that primary staphylococcal infections of the lung are by no means rare. Heretofore, but little interest has been devoted to the differentiation of staphylococcal pneumonia from other forms of bronchopneumonia. With further study, however, it becomes evident that certain distinct differences occur, differences as characteristic as the features which permit distinction between typhoid and paratyphoid fever or between type I and type III lobar pneumonia. The association of certain clinical features with roentgenographic and bacteriologic evidence made it possible to recognize early in the course of the infection four of the six cases the report of which follows:

REPORT OF CASES

CASE 1.—W. Z., a man, aged 30, admitted to the hospital, Aug. 17, 1931, on the tenth day of illness, complained of cough, chills and pain in the left side of the chest. He had had asthma every summer for the past six years, lasting about two months each time. August 7, the asthma became so severe that the patient had to go to bed. The next day he suffered a severe chill, followed by perspiration. Cough and blood-streaked sputum appeared the following day. A sharp pain in the left axillary region developed, which was aggravated by coughing. The pain lasted two or three days. There was no marked change in his condition until he entered the hospital.

At the time of admission he appeared to be quite ill, showed evidence of considerable loss of weight and was dyspnoic. Examination of the chest revealed decreased tactile fremitus, dullness with bronchial breath sounds and coarse râles in the left posterior part of the chest between the levels of the third and eighth vertebrae. Roentgen study (Dr. Rigler) revealed evidence of fairly dense consolidation in the entire upper portion of the left lung containing numerous rarefied areas, which may represent resolving lobar pneumonia (fig. 1). There were 9,800 leukocytes. The sputum (200 cc.) settled in three layers; thick purulent material on top was underlaid by a thin layer of pinkish fluid; at the bottom were coarse particles. Microscopically there were pus cells, detritus and numerous gram-positive cocci, predominantly staphylococci. A sputum culture revealed a pure growth of hemolytic staphylococci.

Fig. 2.—Hospital record of case 1, showing relapse on the fifty-eighth day.

For about nineteen days there were no marked changes in the clinical condition. The leukocytes increased to 15,000 and 17,000. He perspired freely, raised varying amounts of sputum and showed a remittent type of fever, as shown in figure 2. The sputum changed from pinkish to brownish, and hemolytic staphylococci in almost pure growth were again cultivated. Postural drainage did not increase the quantity of sputum. The patient appeared exhausted. A blood culture was sterile. A roentgen report, August 20, stated that the rarefied areas undoubtedly represented multiple abscesses with resolving pneumonia.

September 5 (twenty-ninth day), the physical signs indicated a spread of the process to the left base and also to the right lung. Roentgen study revealed that the cavities had increased in size in the left lung and that a definite infiltration appeared in the right upper lobe, showing beginning cavitation (fig. 3). The temperature gradually diminished and remained at the normal after September 18 (forty-second day) except for an exacerbation, October 4, lasting six days, with severe pain in the right side of the chest and an increase of sputum. At this

Fig. 3 (case 1, twenty-ninth day).—Extensive abscess formation in the left lung. At the apex of the left lower lobe is a cavity containing fluid. There is definite infiltration of the right upper lobe and a cavity at the level of the third rib.

time there were pectoriloquy, bronchial breathing and coarse râles in a small area in the right infraclavicular space. Roentgenograms revealed a marked increase in the extent of infiltration in the right upper lobe with cavity formation. There was considerable resolution in the density of the left lung, but cavities were still present (fig. 4).

The patient thereafter improved rapidly and gained 23 pounds (10.4 Kg.). At the time of his release, dulness was still present with crackling râles, and he raised from 20 to 40 cc. of sputum. A roentgenogram showed marked

resolution of the infiltration in the right lung. The left side was not markedly changed. The patient was in only fair health for a year thereafter. He complained of weakness and dyspnea on exertion, but there was no cough, sputum, fever or loss of weight. A roentgenogram showed that the entire portion of the left upper lobe was replaced by what appeared to be a large thin-walled cavity or cyst. The cavities below this area and those in the right upper lobe were apparently replaced by rather dense scar tissue.

The following case occurred during an epidemic of an influenza-like infection:

CASE 2 (courtesy of Dr. H. S. Diehl, Student Health Service).—F. S., a man, aged 22, noted a sudden onset of high fever, weakness and malaise, a sense of oppression over the chest, aching eyeballs and a stiff feeling of the throat, Feb. 15, 1932. There was no coryza or cough. He was admitted to the hospital the next day perspiring and coughing occasionally. There was evidence of beginning pneumonia in the right base by physical and roentgen examination on the second day of illness. The leukocytes numbered 7,500. Three days later there was labored breathing and evidence of consolidation over the pneumonic area and marked increase of tactile fremitus. He coughed moderately and raised a small amount of bloody sputum. The leukocytes numbered 6,300. The roentgenogram revealed coalescent pneumonia. The fever was remittent, as shown in figure 5. February 19, the fourth day of illness, the cough became worse and was accompanied by a small amount of thick, rusty sputum. Cyanosis appeared and the patient became worse with evidence of spread of the infection to the left lung. The respirations became labored and shallow. A change in position induced a paroxysm of coughing. The leukocytes increased to 13,000 and the cyanosis increased in intensity. There was but little change during the next seven days. He had a slight chill on one occasion; the cyanosis was persistent, the leukocytes varied from 15,000 to 20,000, the cough was usually unproductive and he perspired freely. Roentgen examination revealed extensive bilateral pneumonia. March 1, the fifteenth day of illness, the cough and sputum increased. Practically no organisms except staphylococci were

seen in a sputum smear. On the following day he raised 60 cc. of sputum and a roentgenogram showed rarefactions suggesting cavity formation in the pneumonic areas in both bases, especially on the right. The leukocytes numbered 24,000. The cyanosis deepened and the pulse rate increased (fig. 5). Prostration was marked. The physical signs showed evidence of consolidation in the left base; over the right base there was a decrease of the intensity of the breath sounds and a decrease of tactile fremitus. March 5, severe pain developed in the right anterior part of the chest. The sputum still showed a great predominance of staphylococci. Then, after two large swings, the temperature remained normal and the patient recovered.

In the two foregoing cases, a diagnosis of staphylococcic pneumonia was made during the second week after a consideration of the clinical course together with the bacteriologic and roentgenographic observations. Familiarity with the infection permitted an earlier diagnosis in the two following cases:

CASE 3.—C. G., a man, aged 24, "caught cold," Sept. 27, 1932. The cold became worse but did not confine him to bed. October 1, he awoke with an aching in his shoulder and left side. The following day he became worse; the pain and cough increased, accompanied by dizziness and nausea. He was admitted to the Student Health Service, October 3, with a diagnosis of acute infection of the upper respiratory tract. His temperature was 37.8 C. (100 F.); pulse, 80, and respiration rate, 18 per minute. There was slight cough but no sputum. On physical examination there was evidence of pharyngitis. Numerous râles were heard in the left lower lobe posteriorly, especially on deep respiration. There was no impairment of resonance or other abnormal signs. There were 19,000 leukocytes in the blood, 81 per cent of which were polymorphonuclear cells. A roentgen examination showed patchy areas in the left lower lobe indicative of beginning pneumonia (fig. 6).

October 4, he complained of a sharp pain in the left side of his chest, lasting perhaps three hours. He perspired quite freely. The pleuritic pain recurred at intervals for the next week. By October 6 the physical signs showed impaired resonance with suppressed breath sounds in the left lower lobe. Roentgen examination showed a spread of the process throughout the whole lower lobe. The leukocytes increased to 22,000. He began to raise 1 or 2 cc. of sputum during severe coughing spells after waking in the morning. He perspired profusely at times. October 8, blowing breath sounds and whispered pectoriloquy were noted.

The general condition remained unchanged for several days. The patient complained only of weakness, occasional chest pains and a cough. He did not appear to be very ill at any time and his appetite was good.

The fever was of the remittent type, as illustrated in figure 7. The sputum, October 11, was small in amount, thick, tenacious and greenish yellow. A smear showed staphylococci almost to the exclusion of other organisms (fig. 8). A blood agar plate culture yielded a great predominance of hemolytic staphylococcus colonies. From this finding, staphylococcic pneumonia was suspected. The patient at this time was cyanotic but otherwise did not appear to be very ill. Over the left lower lung posteriorly

Fig. 4 (case 1, fifty-eighth day).—Considerable clearing of the left side of the chest but with multiple cavities evident. Marked increase of density in the right lung with multiple cavities.

there were dulness with diminished tactile fremitus, loud, high-pitched tubular breath sounds with an amphoric quality, loud pectoriloquy and egophony, indicating cavity formation. A diagnosis of staphylococcic pneumonia with abscess and cavity formation was made and confirmed by a roentgenogram, which showed several areas of rarefaction in the previously homoge-

Fig. 5.—Complete record of case 2, from the first day of illness.

neous shadow in the left lower lobe (fig. 9). Examinations of the sputum for several days showed great masses of staphylococci. Blood cultures were sterile. The pleuritic pain persisted.

October 19 (seventeenth day) there was flatness on percussion in the left base, diminished to absent breath sounds and absent tactile fremitus. Fluid was suspected and confirmed by roentgen examination; 350 cc. of sterile, yellow, turbid fluid containing cell debris but no bacteria was removed. Thereafter, the temperature diminished and recovery was uneventful.

CASE 4 (observed at another hospital through the courtesy of Dr. B. B. Souster).—A. O., a student nurse, aged 22, awakened, April 2, 1933, with a sore throat. She went on duty but became hoarse and finally aphonic. In the afternoon she felt quite ill and her temperature was recorded as 100.4. Toward evening she went to bed and had a mild chill. She remained about the same on the following day except that severe pain, especially on breathing or coughing, developed in the right side of the chest and shoulder. The pain persisted, and on the third day impaired resonance in the right base posteriorly was detected. She raised some sputum, which contained many gram-positive cocci, singly and in clusters. A roentgenogram revealed marked infiltration in the lower half of the right side of the chest. The leukocytes numbered 12,600. On the fourth day the patient raised some blood-streaked sputum. The temperature was remittent, as shown in figure 10. Slight cyanosis and dyspnea were noted. A sample of sputum was sent to me for examination on the fifth day. It was odorless, brownish and tenacious, with flecks of fresh blood. A stained smear revealed numerous gram-positive cocci. A great predominance of nonhemolytic staphylococci and a few pneumococcus and hemolytic streptococcus colonies grew on a blood agar plate. A portion was injected intraperitoneally into a mouse, which was examined after five hours. A few gram-positive cocci were recovered from the peritoneum, and culture of the heart blood revealed a pure growth of staphylococci. Another sample of sputum received on the sixth day was more purulent and again contained a great predominance of slightly hemolytic staphylococci. A diagnosis of staphylococcic pneumonia was suggested. On examination of the patient, I found hyperresonance in the right upper anterior part of the chest, signs of fluid in the right lower part of the chest, and in a small area in the right interscapular region there were diminished

bronchial breath sounds and whispered pectoriloquy. The patient had a peculiar dusky cyanosis and appeared to be quite ill. She coughed occasionally and raised a small amount of sputum. A roentgenogram taken on the fifth day showed a spread of the process extending now into the upper lobe. There was evidence of pleural effusion and numerous small rarefied areas. By thoracentesis a small amount of blood-tinged fluid was obtained, which on smear and culture showed a pure culture of hemolytic staphylococci. An oxygen tent was used with benefit.

There was some improvement for the next few days. The pain in the chest diminished, and friction sounds were present. Herpes appeared on the upper lip. There was some perspiration, though not excessive. The leukocytes increased to 23,000. On the eleventh day I found a small area in the right intrascapular area, in which distinct amphoric breath sounds and pectoriloquy were heard, suggesting cavity formation, which was confirmed by a roentgenogram. Pleural fluid partly obscured the typical physical and roentgen observations of cavity formation. Although the patient looked considerably better, she complained of the bad taste and odor of the sputum. On the thirteenth day she raised over 30 cc. of foul sputum after a severe coughing spell and commenced having drenching sweats. Several roentgenograms during the next few days showed the development and enlargement of numerous cavities and a diminution in the amount of pleural fluid. The sputum was a foul, homogeneous, milky fluid containing myriads of staphylococci and a few other organisms, including fusiform and spiral forms. The quantity of sputum raised is shown in figure 10. Later, roentgenograms revealed the coalescence of several small cavities into larger ones, with a gradual diminution of the parenchymal infiltration. There were paroxysms of coughing. Three blood cultures taken at intervals were all sterile. On the twenty-fourth day a tender, fluctuating area appeared in the lower right posterior axillary line. This was incised and a small amount of pus drained for several days. The pus contained a pure culture of hemolytic staphylococci. Following this procedure the temperature returned to normal and uneventful recovery ensued.

CASE 4 illustrates the rapid onset of staphylococcic infection of the lung following a sore throat. Evidence of pneumonia appeared on the third day. Staphylococcic pneumonia was suggested on the fifth day because of the great predominance of staphylococci in the sputum, the type of fever and the x-ray evidence of cavity formation. The abscesses enlarged, coalesced and evidently evacuated themselves through the bronchi. The odor of the sputum was evidently from a superimposed mixed infection due to communication

Fig. 6 (case 3, first day of illness).—Patchy areas of density along the left border of the heart, suggestive of beginning pneumonia.

with the bronchi, as in true lung abscess. Empyema complicated the case. Later roentgenograms showed a diminution in the size of the cavities and their final disappearance. Curiously, this patient, as patient 3, did not appear very ill after the first few days.

The following two fatal cases were considered as primary bronchogenic staphylococcic pneumonia com-

plicating long standing conditions which presumably lowered the resistance to infection. The cases were treated in other services in this hospital and the diagnoses were made at necropsy.

CASE 5.—Mrs. M. L., aged 38, three months pregnant, was admitted to the obstetric service, Jan. 11, 1931, complaining of weakness, anorexia and fatigue. The case was essentially one

Fig. 7.—Complete record of case 3, from the first day of illness.

of chronic glomerulonephritis approaching uremia. Two days after admission spontaneous complete abortion occurred, after which the patient felt better. There was no marked change in her condition until seven days later, when the temperature rose to 37.7 C. (99.8 F.) and then dropped to normal. Two days after this there was again fever of 37.7 C., but no unusual symptoms were noted. Thereafter, the temperature fluctuated between 37.3 C. (99 F.) and 37.8 C. (100 F.) for six days, until two days before death, when it rose to 38.4 C. (101.2 F.). The day before death, sharp pain developed in the right lower axilla, accompanied by fine and coarse râles in this area. The

Fig. 8 (case 3).—Gram stain of sputum showing predominance of cocci, morphologically staphylococci. A culture of this sample of sputum revealed a great predominance of hemolytic staphylococcus colonies.

patient became worse and vomited, and the respiration rate increased until death, January 31. The right lung weighed 700 Gm. There was marked congestion and edema and a few areas of consolidation containing minute abscesses.¹⁰ The left

lung weighed 1,000 Gm. and showed numerous small abscess-like areas, especially in the upper lobe, from which pure cultures of staphylococci were obtained. Other evidence of staphylococcal infection was not found elsewhere in the body. The remaining observations were the usual changes of nephritis.

Histologic sections (Dr. J. S. McCartney) from various portions of the pneumonic area showed for the most part a coalescent pneumonia with abscess formation, as shown in figure 11. The majority of the alveoli were filled with polymorphonuclear leukocytes and erythrocytes. Some alveoli contained homogeneous, faintly stained precipitated serum and a few leukocytes. Other alveoli contained numerous threads of fibrin. Scattered irregularly throughout the sections were numerous areas of necrosis with disappearance of the alveolar septums, indicating abscess formation. In and near these abscesses were dense masses of cocci, as shown in figure 12.

CASE 6.—O. P., aged 3 months, was admitted to the pediatric service because of repeated convulsions, difficulty in feeding and loss of weight. The infant was in poor condition but on dietary regulation gained constantly in weight during fifty-three days of observation. During this time convulsions continually occurred in spite of all treatment. Suddenly, on the fifty-fourth day, the temperature rose to 40 C. (104 F.). The fever continued, though it was slightly lower until death eight days later. Pneumonia was not evident until the seventh day after the onset of fever, when a roentgenogram revealed increased density in the right upper lobe. At this time a cough developed. A smear and culture from the secretions in the throat showed a great predominance of staphylococci. Later, roentgenograms showed consolidation in the right upper lobe. Tracheal râles and cyanosis appeared. The condition became worse and the infant died.

Fig. 9 (case 3, ninth day).—Diffuse infiltration of the left base containing several areas of rarefaction suggestive of multiple abscess cavities.

At autopsy there was evidence of a pneumonic process in the whole right lung and in the lower lobe of the left lung. The bronchi contained exudate. Staphylococci were recovered in pure culture on blood agar plates from the consolidated areas and from the bronchial exudate. The remaining pathologic report bears no relation to the pneumonia and need not be cited.

The histologic sections were almost identical with those in case 5 except that atelectatic areas and purulent bronchitis were present. Consolidated areas, edema and abscesses containing large masses of cocci, morphologically staphylococci, were found.

COMMENT

These cases are presented as primary, bronchogenic, staphylococcal infections of the lung, imposed secondarily on some condition which presumably depressed the defense mechanism. There is every reason to believe, as Chickering suggests, that the staphylococci invading the lung came from those residing normally as saprophytes in the secretions of the upper respiratory tract. The possibility of exogenous infection must also be borne in mind. It is probably seldom that these organisms become pathogenic unless the soil is prepared, so to speak, by some preexisting condition. In case 1 the predisposing factor seemed to be asthmatic bronchitis; in cases 2 and 3, an influenza-like infection;

in case 4, a sore throat; in case 5, chronic nephritis, and in the last case, malnutrition and convulsions. In this connection, the recent studies of McCordock and Muckenfuss¹¹ are of interest. These observers produced multiple lung abscesses experimentally in rabbits by the injection of vaccine virus and staphylococci. Virus alone or staphylococci alone did not give rise to abscess formation in the lung. They believed that the pneumonia caused by the vaccine virus prepared the field for the growth of the injected staphylococci.

Staphylococcic pneumonia occurs more commonly than is generally assumed. In this hospital, 5 cases occurred among 110 cases diagnosed as "bronchopneumonia," including "postoperative" and "secondary" pneumonias, during the year 1931-1932. A clearer conception of the incidence was obtained from statistics covering the same period, prepared in the Student Health Service by Dr. H. S. Diehl. Among 12,000 university students, 6,200 cases of acute infections of the respiratory tract were reported. Five hundred and nine cases were severe enough to require hospitalization. Pneumonia developed in twenty-two of these, among which were two of the cases of staphylococcic

itself is only one factor in the diagnosis, since staphylococci may predominate in sputum in other conditions as well. Staphylococci were not found in the blood of any of my patients.

The usual signs of bronchopneumonia described in textbooks were present until the development of cavities large enough to produce amphoric breath

Fig. 11 (case 5).—Microscopic lung abscess.

Fig. 10.—Complete record of case 4, from the first day of illness.

pneumonia here reported. Thus, in this small series, the incidence is the same (9 per cent) as in Lyon's report and in Cole's series of 211 cases of primary atypical pneumonia.

Several features characterize staphylococcic pneumonia as an entity. The onset usually occurs during some other condition and may be sudden, with chills and high fever. In Chickering's cases the onset was usually insidious, merging into the preexisting influenza. The fever is of the remittent type characteristic of staphylococcic infection elsewhere in the body. Chills and perspiration may occur throughout the illness. Cyanosis is usually marked and may be of the peculiar reddish hue described by Chickering. The pulse and respiration rate are usually increased. The leukocyte count is variable. An early leukopenia is probably partly influenced by the preexisting infection. Later, the leukocytes increase in number. In our series, the sputum was usually odorless, thick, purulent and yellow green but occasionally pinkish. The presence of great numbers of staphylococci in the sputum served as the clue to the diagnosis of four cases. When the sputum was plated, staphylococcus colonies vastly outnumbered those of other forms of bacteria. This in

sounds, coarse râles and characteristic changes in voice sounds. The formation of abscesses large enough to be detected by physical examination or by x-rays developed at different rates in different cases. As a rule, as Fraenkel and Cole observed, abscesses develop in patients who live long enough. In case 4, large abscesses were evident by the fifth day. In case 6, diffusely scattered miliary abscesses were present on examination

Fig. 12.—Section of lung tissue stained for bacteria showing dense masses of cocci in an abscess.

of the lung twenty days after the apparent onset of infection. It is, however, not possible to date the onset of staphylococcic infection in many cases with certainty. Roentgenographic evidence indicated the complete disappearance of cavities and healing in cases 2, 3 and 4. In case 1 a single large thin walled cavity developed in one area previously involved by the infection, furnishing a potential site for chronic infection.

11. McCordock, H. A., and Muckenfuss, R. S.: The Similarity of Virus Pneumonia in Animals to Epidemic Influenza and Interstitial Bronchopneumonia in Man, *Am. J. Path.* 9: 221 (March) 1933.

A tendency to relapse is illustrated in the record of case 1. In case 4 a typical lung abscess with foul sputum developed. This suggests the possibility of staphylococcal pneumonia as the initial stage of certain cases of chronic lung abscess. Empyema developed in cases 3 and 4.

The features that distinguish staphylococcal pneumonia from other acute infections of the lung are (1) the presence of staphylococci in the lung, (2) the predominance of staphylococci in purulent sputum in smear and culture, (3) the remittent type of fever, (4) sweating, (5) the evidence of abscess formation, and (6) a high mortality rate (although four of our six patients recovered).

The question may arise in regard to nomenclature, whether to consider the cases described as "staphylococcal pneumonia" or "multiple staphylococcal lung abscesses." Much depends on the stage of the disease in question. Early in the course, the term "staphylococcal pneumonia" is acceptable. Later, "multiple staphylococcal lung abscesses" may be desirable. The latter term might better be reserved for secondary embolic or metastatic lung abscess from staphylococcal infections elsewhere in the body.

SUMMARY

Six cases of primary staphylococcal pneumonia showed well defined clinical and pathologic characteristics. The disease in sporadic cases, and probably in most epidemic cases, presumably arises as an autogenous infection, developing when the resistance is lowered by some other infection or illness. The infection behaves much like staphylococcal infection elsewhere in the body. It is characterized by gradual or sudden onset, chills or chilliness, sweats, high remittent fever, increased pulse and respiration rates, marked cyanosis and the signs and symptoms first of bronchopneumonia, later developing signs of lung abscess. Chills and sweating may recur. The sputum is yellowish green, often pinkish, purulent and odorless, and varies greatly in amount. Staphylococci are present in overwhelming numbers in smear and culture of the sputum and from the lung. The blood leukocytes vary greatly in number. The roentgenogram is of great assistance in the detection of abscess formation before it becomes extensive enough to be recognized by physical examination. The mortality rate, especially in the epidemic form, is high. Recovery took place in four of our six sporadic cases.

ABSTRACT OF DISCUSSION

DR. LEO G. RIGLER, Minneapolis: It seems strange that in the large series of serial roentgenograms of cases of pneumonia in the past years there has been failure to observe these cases. As Dr. Reimann showed in his slides, the appearance in some cases is very striking within a few days after the onset of the disease, and characteristic of cavitation. It seems possible that serial roentgenographic studies in pneumonia may give a clue to the detection of such cases and stimulate a more intensive bacteriologic search of the sputum. There are two or three things in the differential diagnosis that perhaps explain why these cases have not been observed in previous studies. In cases of resolving lobar pneumonia, the typical stage of resolution gives a picture somewhat similar to the films shown by Dr. Reimann. The clinical course of the disease under these circumstances is entirely different, but it is obvious that these small and larger areas of rarefaction in the roentgenogram, which are due to the restoration of normal lung tissue in the midst of exudative and fibrotic lung tissue, may give the appearance of cavitation. Not infrequently a type of acute lung abscess is seen which is different from what Dr. Reimann

has described. I have seen it postoperatively, and Graham has reported a number of cases in which an acute lung abscess presented the picture of consolidation with an area of rarefaction within it, which is very similar to staphylococcal pneumonia and which also clears up spontaneously in a few weeks. Multiple chronic lung abscess also has probably led observers astray. This resembles in many respects the roentgenographic appearance of the cases which Dr. Reimann showed. The clinical course is entirely different. It is possible that many of these cases of pneumonia have been mistaken for this type of chronic lung abscess.

DR. W. D. SUTLIFF, Boston: It has been possible to get together, out of a survey of 1,067 cases of pneumonia, a small number which, while not so carefully worked up, gives the incidence of this condition from another part of the country. In this large number of cases the staphylococcus was looked for particularly at the autopsy, and was found 28 times in 307 autopsies, an incidence of about 9 per cent. This is very close to what Dr. Reimann has found. In nearly every instance another organism was found in addition to the staphylococcus. This organism in two thirds of the cases was a pneumococcus and in one third a hemolytic streptococcus. In four instances the hemolytic streptococcus, staphylococcus and pneumococcus were all present. One instance occurred in a definite type 1 lobar pneumonia. The patient was treated with specific serum and did quite well but never entirely recovered. About two weeks following the return of the temperature nearly to normal the patient failed gradually and died. A pure culture of staphylococcus was found at autopsy. The staphylococcus was the only organism isolated in four cases. In three of these it was found only postmortem. In one case, staphylococci were isolated, as Dr. Reimann has isolated them, from the sputum, from the blood, and from the organs at the postmortem examination. This group of cases indicates that staphylococcal pneumonia is to a large extent a secondary condition. It may be associated with pneumococcal pneumonia and is one of the complicating factors to be reckoned with in specific therapy.

Clinical Notes, Suggestions and New Instruments

CARCINOMA OF THE STOMACH IN THE FIRST TWO DECADES OF LIFE

M. K. KING, M.D., NEW ORLEANS
Assistant Surgeon, U. S. Public Health Service

Carcinoma of the stomach is rare in patients under 30 years of age. Before the age of 20 it is so rare that those cases which have occurred in the past have usually been the subject of individual reports. However, "No age is immune and a diagnosis relying to any degree on the 'cancer age' may lead to a fatal issue."¹

Including the case herein described, I have been able to collect from the literature a total of forty cases of cancer of the stomach occurring in the first two decades of life. In 1900, Osler and McCrae² collected six cases in the first and thirteen cases in the second decade of life.

In 1924, Sullivan³ again reviewed the subject and collected a total of twenty-one cases, omitting thirteen of the cases previously collected by Osler and McCrae, possibly because of doubtful proof of their authenticity. If one accepts both of these groups, however, there were thirty-four cases reported up to 1924.

Marble,⁴ of Johns Hopkins University, in 1931, reported a case in a 17 year old girl and collected three other cases in

2. Osler, William, and McCrae, Thomas: Cancer of the Stomach. Philadelphia, P. Blakiston's Son & Co., 1900; Cancer of the Stomach in the Young, New York State J. Med. 71: 586, 1900; System of Medicine 5: 220, 1909.

3. Sullivan, R. P.: Carcinoma of the Stomach in Young People. Surg., Gynec. & Obst. 38: 283 (Sept.) 1924.

4. Marble, Alexander: Carcinoma of the Stomach in a Seventeen Year Old Girl, Bull. Johns Hopkins Hosp. 48: 39 (Jan.) 1931.

patients aged, respectively, 18, 18 and 20 years. In the past year another case was reported in a boy, aged 11 years.⁵ This group, together with the case which is here described in detail, makes a total of forty cases of cancer of the stomach reported in the first two decades of life. The review of the literature has not been exhaustive and this list may be incomplete.

The youngest patient in this group, and incidentally the one in whom the duration of illness was shortest, was an infant whose symptoms began on the tenth day of life with vomiting and obstipation. Death occurred in the fifth week and microscopic examination of a tumor found in the stomach showed cylindric cell epithelioma.⁶

In this series there were thirty-three males and seven females. Bloodgood⁷ says: "Perhaps more men have cancer of the stomach than women, because so many women get cancer of the breast and uterus first and die, that they have not the same opportunity as men have to develop cancer of the stomach." This observation is not in keeping with the even greater predominance of males seen in the younger patients.

Carcinoma of the stomach in the young is characterized by its acute onset, violent course, persistent high temperatures, early metastases and absence of cachexia.⁸ Death usually occurs in a few weeks to a few months in untreated cases. In a 17 year old girl, resection of the stomach was done with

excellent temporary results but with ultimate recurrence and death three years after the onset of symptoms. This patient lived the longest of any of those included in this group.

The result of treatment is even more discouraging than that obtained with older patients. Diagnosis comes too late for surgical intervention, and medical treatment is of necessity limited to the relief of symptoms.

Approximately 38 per cent of all cancer is cancer of the stomach, and 38,000 persons die annually in the United States from this disease.⁸ An extremely small percentage of this number occurs in patients under 20 years of age;

Fig. 1.—Negro youth, aged 20, with carcinoma of the stomach as he appeared two months before death.

yet the fact that it does occur makes it a possibility to be remembered.

In spite of the refinements in diagnosis and therapeutics, the number of five-year cures has not reached more than 10 per cent.⁷ The mortality in the younger patients has been 100 per cent. The high mortality is due largely to the failure to make early diagnoses. Long continued observation may lead to a fatal outcome, and the data which have been collected through such observation are rendered useless. When the condition is suspected, early operation is always in order. If a gumma is found, but little harm is done, and antisyphilitic treatment can be carried out with the conscience of the operator clear.

REPORT OF CASE

History.—L. N., a Negro youth, aged 20, entered the hospital, Aug. 1, 1932, complaining of pain in the stomach. Three weeks before admission he was seized with a severe burning pain in

the upper part of the abdomen, accompanied by nausea and vomiting. This attack lasted two hours and was partly relieved by an ice bag. Since that time a similar pain had recurred with increasing frequency until it had become continuous. The pain became agonizing at times and was situated in the mid-epigastrium. Food relieved the pain for from one-half to one

Fig. 2.—Outline of stomach after barium meal, showing deformity at pylorus due to carcinoma. This deformity was constant.

hour, when it recurred with great intensity and was relieved by vomiting. The vomitus contained undigested food particles and coffee ground material.

The patient had retained practically no food and he had lost 15 pounds (6.8 Kg.) during the past month. For the past few

Fig. 3.—Fluid level seen near pylorus giving the appearance of a duodenal diverticulum. This appearance was due to an enormous ulcer crater in the carcinoma mass near the pylorus, in the posterior wall of the stomach itself.

days there had been severe pain in the dorsal spine. Afternoon chills occurred with fair regularity. The bowels were sluggish.

His appetite had been poor for the past six months and he had gradually lost some weight, even previous to the time when his last illness began.

His family and personal history was negative, and he stated that he had not had syphilis.

8. Rehfuss, M. E.: *Diseases of the Stomach*, Philadelphia, W. B. Saunders Company 28: 708-764, 1927.

Examination.—The patient was emaciated and apparently in considerable pain; he weighed 102 pounds (46.3 Kg.) and was 64 inches (162.6 cm.) tall; the temperature was 37.6 C. (99.7 F.), the pulse 90 and the blood pressure 100 systolic, 80 diastolic.

The abdomen was rather flat, and there was a suggestion of fulness in the epigastric region. The whole upper part of the abdomen was acutely tender, was rigid and was difficult to examine. A hard mass, which was palpated in the right epigastrium, was difficult to outline because of the overlying rigidity.

The laboratory reported urine, feces, sputum and Kahn tests negative; hemoglobin, 85 per cent. The fasting stomach contained 40 degrees of free hydrochloric acid with 80 degrees of total acidity, and no blood, bile, mucus or lactic acid. After an Ewald test meal, 20 degrees of free hydrochloric acid was present with a total acidity of 50 degrees.

The roentgenologist reported as follows: "Fluoroscopic and radiographic examinations of the gastro-intestinal tract reveals a constant finger print deformity of the pyloric end of the stomach, and a pouch-like projection of the first portion of

The pathologic report from the biopsy specimen was: "Lymph node is partly replaced by gland cell carcinoma which is more strikingly noticeable in the afferent channel." The diagnosis was gland cell carcinoma.

Postoperative Course.—The patient stood the operation well. He appeared to improve under frequent jejunal feedings, which were begun after the second day. The operative wound healed rapidly. At times he attempted to take fluids or gruel by mouth, but this nearly always led to vomiting. After a few weeks of apparent improvement he began to lose weight rapidly. Anemia became marked, the red blood cell count falling to 2½ million. Pain was controlled by morphine, which was given freely.

Emaciation and cachexia advanced rapidly, and during the last week of life any attempt to take fluid or nourishment by mouth was followed almost immediately by vomiting. The patient died, October 8, three months after the onset of symptoms and nine weeks after admission to the hospital. The weight at death was 79 pounds (35.8 Kg.).

The condition present at autopsy was but little changed from the observations made at operation. A few neoplastic transplants

Fig. 4.—Groups of embryonal epithelial cells in a lymph gland taken from the lesser curvature of the stomach.

Fig. 5.—Same as figure 4, with higher magnification.

Fig. 6.—Section of stomach wall showing infiltration of neoplastic epithelial cells into parenchyma.

the duodenum. There is a forty-eight hour gastric retention. Conclusions: Pyloric neoplasm, probably carcinomatous, and diverticulum of the duodenum."

A barium enema showed no obstruction, and no filling defects were present in the large bowel.

The consultant on gastro-enterology considered the possibility of malignancy but was more inclined to suspect a syphilitic condition, in spite of the negative syphilitic history and Kahn reaction.

Operation.—Operation was advised, however, and was performed, August 18, two and a half weeks after the patient was admitted.

Under ethylene anesthesia the abdomen was entered through a high right rectus incision. The pyloric portion of the stomach was found to be infiltrated and bound down by a hard neoplastic growth, obstructing the outlet. The glands of the greater and lesser curvature of the stomach and of the mesentery, the retroperitoneal space and the hilus of the spleen were densely involved. The mesentery was so bound down as to make either anterior or posterior gastro-enterostomy impracticable. The liver was not involved. A number 18 French rubber catheter was placed in the upper part of the jejunum by Stamms' method and brought out through the abdominal wound. A neoplastic gland was removed from the mesentery for biopsy and the abdomen closed.

were present beneath the serosa of the liver, but the liver substance was not involved. The metastases appeared to follow a retrograde lymphatic course from the primary site in the stomach. The pylorus was found to be practically occluded by the hard ringlike mass. A deep ulceration on the posterior wall of the stomach near the pylorus measured 2 inches in length and 1 inch in diameter and probably gave rise to the appearance in one of the roentgenograms of a duodenal diverticulum.

Microscopic examination of the specimens confirmed the previous report of gland cell carcinoma.

SUMMARY

1. A case of carcinoma of the stomach is reported in a youth, aged 20. Thirty-nine other cases occurring in the first two decades of life are cited from the literature.
2. Carcinoma of the stomach in the first two decades of life is an extremely rare condition, but the fact that it does occur makes it a possibility to be borne in mind.
3. Early operation is advisable in doubtful cases, instead of therapeutic tests which consume valuable time. It is only in this way that it will be possible to lower the present 100 per cent mortality.

U. S. Marine Hospital.

TUBELIKE INFILTRATIVE MUCINOUS CARCINOMA OF
RECTUM IN A NINETEEN YEAR OLD PATIENT

CHARLES S. HIGLEY, M.D., CLEVELAND

This case is reported because of the unusual type of the tumor, which converted the rectum into a rigid firm tube as disclosed by clinical and pathologic examination. Karsner and Clark¹ in their review of the literature found only one direct reference to this form of tumor, that of Bensaude, Cain and Orléan.² They reported three cases, without information as to age, sex or special microscopic features, and stated that the condition was simply referred to by Bard. In their first case the lesion extended for 7 cm. at the rectosigmoid junction. In the second there was a vegetating cancer in the ampulla of the rectum which extended in tubelike form for 18 cm. above, involving posterior and lateral walls. The symptoms of the third case began as an acute dysentery and the lesion extended for 20 cm. in the rectosigmoid region. They used the descriptive phrase "un cylindre epais, rigide et dur comme du bois," a rigid tube, firm and hard as wood. In their case report they suggest the name "cancer infiltrant et en coulée." This means an infiltrating, sleeve-like cancer and describes the elongated annular constriction of the lumen of the rectum. They found no clinical characteristics except those found on digital examination and believed that extension along the lymphatics played an essential rôle in the production of the deformity.

REPORT OF CASE

History.—V. S., a man, aged 19, Italian, a barber, admitted to the medical department of City Hospital, Nov. 19, 1932, complained chiefly of diarrhea and pain in the left lower quadrant. The present illness dated from two weeks before admission, but on close questioning he recalled that six months before admission his stools were occasionally blood streaked. He also recalled that four months before admission there had been a decrease in the caliber of the stool and some pain on defecation. Two weeks previous to admission the patient ate some highly seasoned food and soon afterward severe abdominal cramps developed. He took several doses of saline cathartics in the next two days in an effort to relieve the abdominal symptoms and subsequently passed at frequent intervals liquid stools, which contained blood and mucus. The diarrhea gradually diminished and on admission he was having only about four stools daily. However, the pain in the left lower quadrant persisted. The past history was not significant except for gonorrheal urethritis in 1930.

Examination.—The patient was well nourished and well developed. He was intelligent and cooperative and did not seem severely ill. The pupils reacted to light and in accommodation, and the heart and lungs were apparently normal. The abdomen showed marked tenderness to palpation in the left lower quadrant, and on deep palpation several tender walnut sized masses were felt in this region. Rectal examination showed the lumen to be narrowed by a firm annular mass, which extended from about 2.5 cm. above the anus to as far as the finger could reach. It was not tender, and no bleeding resulted from the digital examination. The rectal wall felt smooth and regular. Proctoscopic examination showed a uniform narrowing of the lumen. The mucosa was gray and finely granular in appearance. There were several minute areas of ulceration, which bled easily. A biopsy of one of these areas was done.

A laboratory examination revealed: red blood count, 3,800,000; hemoglobin, 70 per cent; white blood count, 9,500; differential count, normal. The blood Wassermann reaction was negative. The feces were brown, semisolid and contained gross blood. The biopsy showed mucinous carcinoma. A roentgenographic study of the colon revealed an annular constriction about 6 cm. long just above the ampulla of the rectum.

Course.—A diagnosis of carcinoma of the rectum was made and the patient was transferred to the surgical department. December 3, an exploratory laparotomy was done under gas anesthesia by Dr. D. M. Glover. A low rectus muscle incision was made and the peritoneal cavity was opened. No free

fluid was present. There was a large mass involving the rectum and adjacent lymph nodes. The tumor was obviously inoperable and a colostomy was done. The postoperative condition of the patient was good. On the sixth day after operation the colostomy was opened. The intestinal loop was divided with a cautery at 11:15 a. m. and the patient was able to take his noon and evening meals. At 8:15 p. m. he suddenly complained of severe pain in the right side of the chest and became dyspneic and cyanotic. The respirations rose to 60 per minute, the pulse to 140 per minute and the systolic blood pressure dropped to 80 mm. of mercury. The diagnosis of pulmonary embolus was made. The patient died at 8:30 p. m.

The autopsy was performed thirteen hours after death by Dr. R. J. Williams. In the pelvis was a nodular mass, measuring 13.5 cm. in length and 10 cm. in diameter, which included the entire rectum and the distal portion of the sigmoid, as illustrated. It was firmly attached to the posterior pelvic wall and was removed with difficulty. On section, the lumen of the

Rectum and distal portion of sigmoid, showing tubelike infiltration by mucinous carcinoma.

rectum was seen to be markedly narrowed by surrounding tumor tissue, which completely encircled the rectal wall. The cut surface of the tumor mass appeared grayish white and had a gelatinous and shiny appearance. The tumor showed three well defined areas: an innermost striated layer measuring 3 to 4 mm. in width, which had striations running in the transverse diameter of the intestine; distal to this a layer measuring 2 cm. in width, which ran longitudinally and was gray and opaque; the distal layer, composed of frank tumor tissue and from 2.5 to 4 cm. in thickness and having a shiny, gelatinous appearance. Beneath the serosa on the anterior surface of the rectum and sigmoid were numerous gray-white, elevated nodules measuring up to 2 cm. in diameter.

The mucosa of the rectum and distal portion of the sigmoid showed an area of ulceration, which began 3.5 cm. from the distal portion of the rectum and extended proximally for a distance of 8 cm. This area had a gray granular appearance and the margins were irregular and elevated from 1 to 2 mm. above the surrounding rectal mucosa. The mucosa of the sigmoid proximal to the tumor was smooth and velvety. The circumference of the normal sigmoid was 8.5 cm.; the circumference of the rectum distal to the tumor, 9 cm. The involved portion of the rectum had a uniform circumference of 6 cm.

From the Departments of Pathology and Medicine, City Hospital.

2. Bensaude, Cain and Orléan: Sur une forme rare d'épithélioma colloïde rectosigmoïdien; le cancer infiltrant et en coulée. *Arch. d. mal. de l'app. digestif* 21:749 (June) 1931.

Microscopic examination of biopsy and autopsy specimens showed loss of surface epithelium with fibrosis of tunica propria, associated with infiltration of a few polymorphonuclear leukocytes, lymphocytes, plasma cells and large mononuclears. The crypts were elongated and somewhat tortuous, with goblet cell lining. There was no transition in character of epithelium or structure to tumor. In the mucosa were several masses of signet ring cells irregularly outlined, poorly defined and without acinus formation. These penetrated the muscularis and were continuous with the main tumor mass. This showed coarse and fine bands of mature connective tissue, which supported acinus-like masses of stringy, basophilic mucin. These varied greatly as to size and outline. In a few instances small masses of condensed cells were found in the acini, but many showed no cells, and numerous others contained irregular clumps of signet ring cells whose cytoplasm contained finely granular basophilic mucin. There was little necrosis and no inflammatory reaction. Several lymph nodes showed hyperplasia but no metastasis.

The tumor was a well differentiated mucinous adenocarcinoma, which in the mucosa was completely anaplastic. The lesion of the mucosa was erosion rather than deep ulceration.

The organs were otherwise normal, except that a thrombus was found in the left iliac vein, which was the only source observed for a large embolus in the right pulmonary artery.

I am indebted to Dr. H. T. Karsner, divisional chief of laboratories, for aid in the preparation of this report.

SUMMARY

A white man, aged 19, had a tubelike carcinoma of the rectum and lower sigmoid flexure. The symptoms were principally dysenteric. The tumor was a well differentiated mucinous adenocarcinoma with areas of anaplasia. Death was due to pulmonary embolism following colostomy.

3395 Scranton Road.

Committee on Foods

THE COMMITTEE HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS.

RAYMOND HERTWIG, Secretary.

NOT ACCEPTABLE

GRANDMA'S OLD FASHIONED MOLASSES

The American Molasses Company of New York submitted to the Committee on Foods a "sugarcane syrup" called Grandma's Old Fashioned Molasses.

Manufacture.—The juice is expressed from sugar cane in the West Indies Islands, sieved, and heated to 54 C.; the acidity is neutralized with calcium hydroxide, the temperature is raised to just under boiling, and a thick scum forms on the surface. The clear juice is drawn off and evaporated to a syrup. The sucrose content is partially inverted during the heating by the addition of some cane juice to prevent crystallization. The syrup is cooled and barreled for shipment to the canning plant in the United States, where it is heated to 82 C. for thirty minutes and automatically canned. That syrup which is sold in bulk in barrels is not heated.

Analysis (submitted by manufacturer).—

| | per cent |
|---|----------|
| Moisture | 22.8 |
| Ash | 1.5 |
| Insoluble ash | 0.1 |
| Reducing sugars as invert | 39.1 |
| Sucrose (copper reduction method) | 30.8 |
| Fat | none |
| Protein (N X 6.25) | 1.1 |
| Calculation (by difference) | 74.6 |
| Method (Am.) | 0.006 |
| | 0.5 |
| Sulphur dioxide | none |

Discussion of Name and Advertising.—The product is a "sugarcane syrup" and not a "molasses" according to the respective United States Department of Agriculture definitions and standards: "Sugarcane syrup is syrup made by the evaporation of the juice of the sugarcane or by the solution of sugarcane concrete, and contains not more than 30 per cent

of water and not more than 2.5 per cent of ash. . . . Molasses is the product left after separating the sugar from massecuite, melada, mush sugar, or concrete, and contains not more than 25 per cent of water and not more than 5 per cent of ash."

The label statement "The natural vegetable and mineral properties, vitamins and high sugar content make Grandma's Molasses a healthful food for all" vaguely implies the presence of all the vitamins and minerals required for proper nutrition, which is inconsistent with scientific knowledge on cane sugar syrup. Radio advertising includes the statement "It is wise to include a food made with health giving molasses such as Grandma's at each meal," which is a type of misleading specific "health food" claim. No food is "health giving"; a complete and adequate diet is necessary for health, but health depends on many other factors than nutrition. A recipe booklet, "Grandma's Old Fashioned Molasses Recipes," includes the claims "You can't feed that family of yours the valuable iron and minerals they need more economically . . . than by way of hot delicious muffins, cakes, . . . made healthful with Grandma's pure molasses," "Experiments prove that other foods digest more quickly and are more completely assimilated in the presence of molasses," "Eating sugar under such circumstances has been proved very reviving, but any highly purified food fails to give necessary minerals and vitamins, which explains why a natural sugar product like molasses exceeds sugar in food value and provides for better health," and "When taken into the stomach, all sugars are converted to fruit sugars before digestion. As a large part of the sugar in Grandma's Molasses is already in that form, it is a very easily assimilated food. Further, because of this fruit sugar content, its pleasing sweet flavor may be enjoyed without danger of overloading the system with sugar." This "molasses" does not provide all the minerals needed "by that family of yours," does not make "muffins, cakes . . . healthful" (they are wholesome without the molasses), does not give the "necessary minerals and vitamins," nor can the "molasses" be enjoyed in all cases "without danger of overloading the system with sugar"; other foods are not more "quickly and more completely assimilated and digested in the presence of molasses."

The name and claims are inappropriate, misinformative and misleading. The manufacturer was advised of the report of the Committee but has not expressed willingness to correct the name and advertising. This Grandma's Old Fashioned Molasses will therefore not be listed among the Committee's accepted foods.

REPORTS OF THE COMMITTEE

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION, AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

RAYMOND HERTWIG, Secretary.

ROUNDY'S SUPREME STRAINED PEAS,
SPINACH, CARROTS, BEETS, GREEN
BEANS, CELERY AND TOMATOES

UNSEASONED—READY FOR USE

ROUNDY'S SUPREME STRAINED VEGETABLES
WITH CEREAL AND
BEEF BROTH

UNSEASONED—READY FOR USE

ROUNDY'S SUPREME STRAINED PRUNES
FLAVORED WITH LEMON JUICE

Packer.—The Larsen Company, Green Bay, Wis.

Distributor.—Roundy, Peckham and Dexter Company, Milwaukee.

Description.—Canned sieved vegetables, fruit and cereal prepared by efficient methods for retention in high degree of the natural mineral and vitamin values of the respective products. No added salt or sugar. The same as the accepted Larsen's Strained Vegetables, Fruits and Cereals (THE JOURNAL, July 1, 1933, p. 35; July 22, 1933, pp. 282, 283).

LARSEN'S SPINACH (STRAINED-UNSEASONED)

Manufacturer.—The Larsen Company, Green Bay, Wis.

Description.—Sieved spinach prepared by efficient methods for retention in high degree of the natural mineral and vitamin values of the raw spinach. No added sugar or salt.

Manufacture.—Freshly harvested spinach is sorted and undesirable material removed, is washed, blanched in hot water until soft, strained in a steam atmosphere as described for tomatoes (THE JOURNAL, July 1, 1933, p. 35), admixed with a small amount of water to produce the desired consistency, heated to 82 C. in a closed vessel and automatically filled into washed cans, which are sealed and processed for sixty minutes at 116 C.

Analysis (submitted by manufacturer).—

| | per cent |
|--|----------|
| Moisture | 95.4 |
| Total solids | 4.6 |
| Ash | 0.8 |
| Salt (NaCl) | 0.02 |
| Fat (ether extract) | 0.4 |
| Protein (N \times 6.25) | 1.7 |
| Crude fiber | 0.4 |
| Carbohydrates other than crude fiber (by difference).... | 1.3 |

Calories.—0.2 per gram; 6 per ounce.

Vitamins and Claims of Manufacturer.—See Larsen's Strained Tomatoes Unseasoned—Ready for Use (THE JOURNAL, July 1, 1933, p. 35).

CLAPP'S ORIGINAL PUREE OF
WAX BEANS
(ADDED SALT)

Manufacturer.—Harold H. Clapp, Inc., Rochester, N. Y.

Description.—Strained cooked wax beans; a small amount of salt is added. The method of preparation is efficient for retention in high degree of the natural vitamins and minerals.

Manufacture.—Purchased canned wax beans with a small quantity of added water are strained in an atmosphere of water vapor and subsequently treated as described for Clapp's Original Baby Soup (THE JOURNAL, June 24, 1933, p. 2011).

The purchased canned wax beans are prepared from inspected graded wax beans, which are snipped, again inspected to remove unsuitable material, cut into small pieces, washed, blanched and filled into cans with hot brine. The cans are exhausted to remove absorbed air, sealed, processed under pressure and immediately cooled.

Analysis (submitted by manufacturer).—

| | per cent |
|--|----------|
| Moisture | 92.5 |
| Total solids | 7.5 |
| Ash | 1.2 |
| Salt (NaCl) | 0.5 |
| Fat (ether extract) | 0.1 |
| Protein (N \times 6.25) | 1.2 |
| Crude fiber | 0.8 |
| Carbohydrates other than crude fiber (by difference).... | 4.2 |

Calories.—0.2 per gram; 6 per ounce.

Vitamins and Claims of Manufacturer.—See Clapp's Original Baby Soup (THE JOURNAL, June 24, 1933, p. 2011).

QUIN-A-WINK SELF RISING FLOUR
(BLEACHED)

Manufacturer.—Federal Mill, Inc., Lockport, N. Y.

Description.—Self-rising flour containing soft winter wheat "short patent" flour, sodium acid pyrophosphate, salt and sodium bicarbonate; bleached.

Manufacture.—The ingredients in formula proportions are mixed in a batch mixer and automatically packed.

Claims of Manufacturer.—For cake, biscuit and pastry baking.

FORT HAMILTON BRAND CRYSTAL
WHITE TABLE SYRUP

(CORN SYRUP AND CANE SUGAR SYRUP;
FLAVORED WITH VANILLA)

Manufacturer.—Union Starch and Refining Company, Columbus, Ind.

Distributor.—E. H. Frechtling Company, Hamilton, Ohio.

Description.—This product is the same as Pennant Crystal White Table Syrup (THE JOURNAL, Jan. 30, 1932, p. 402).

STAUDT'S PARKER HOUSE ROLLS

Manufacturer.—Staudt's Bakery, Raleigh, N. C.

Description.—Rolls made by the sponge dough method (method described in THE JOURNAL, March 5, 1932, p. 817): prepared from flour, water, sucrose, lard, powdered skimmed milk, salt, yeast and a yeast food containing calcium sulphate, ammonium chloride, sodium chloride and potassium bromate.

Analysis (submitted by manufacturer).—

| | per cent |
|--|----------|
| Moisture | 28.7 |

| Carbohydrates other than crude fiber (by difference).... | 54.4 |

Calories.—3.1 per gram; 88 per ounce.

GLADIOLA SPECIAL HARD WHEAT FLOUR
(MATURED, BLEACHED)BLUEBELL EXTRA FANCY SPECIAL HARD
WHEAT FLOUR (MATURED, BLEACHED)FANT'S FAIRY SPECIAL HARD WHEAT
FLOUR (MATURED, BLEACHED)

Manufacturer.—Fant Milling Company, Sherman, Texas.

Description.—Hard wheat patent flours, bleached.

Manufacture.—Selected hard wheat is cleaned, washed, tempered, scoured and milled by essentially the same procedures as described in THE JOURNAL, June 28, 1932, page 2210. Chosen flour streams are blended and bleached with a mixture of benzoyl peroxide and calcium phosphate (1 part to 50,000 parts of flour) and nitrogen trichloride (one-ninth ounce per 196 pounds of flour).

LARSEN'S VEG-ALL—"A MAGIC GARDEN" FOR
SOUPS, SALADS, VEGETABLE DISHES

Manufacturer.—The Larsen Company, Green Bay, Wis.

Description.—Mixture of carrots, potatoes, celery, green beans, cabbage, peas, corn, lima beans, onions, sweet peppers, salt and water prepared by efficient methods for retention in high degree of the natural mineral and vitamin values of the raw vegetables.

Manufacture.—Freshly harvested vegetables are sorted, washed, mechanically peeled, inspected for removal of any undesirable material, cut or diced, and admixed in definite proportions. The mixture with water and salt is filled into cans, which are heated in an exhaust box in an atmosphere of steam at 82 C., sealed and processed for forty-five minutes at 116 C.

Analysis (submitted by manufacturer).—

| | per cent |
|--|----------|

SATURDAY, AUGUST 12, 1933

THE PHYSICIAN AND NRA

Everywhere today men talk about the National Industrial Recovery Act. Questions have poured into the headquarters of the American Medical Association relative to the relationship of the medical profession to the N R A and its stipulations. Probably the most significant of these questions concerns hours of work for physicians and hours of work and salaries to be paid to their assistants and attendants. At present it is safe to say that physicians are exempt, as are other professional men, from hours of work and payment stipulations under the N R A, and that their professional employees, such as laboratory technicians, radiologists, anesthetists and similar professional groups, are not immediately concerned. However, if a physician employs more than two persons as attendants in his office, of the class of clerical employees, accountants, laborers and similar types of help, they do come under the National Recovery Act with a minimum wage and certain maximum hours of work.

The medical profession, as far as concerns its private practice, need have no immediate concern over the stipulations of this act. The legislation is not intended to interfere with the personal relationship between physician and patient, necessary to the best type of medical care. Physicians have never had definite hours of work; they have always been subject to call at any moment for the benefit of their patients. The rights of the sick man are above hours of work or regulations of this character. It is hoped that every physician will enter wholly into the spirit of the National Recovery Act as an ideal, representing the government's point of view as to the principles and motives behind which the entire nation must unite if it is to pull itself out of the slough into which it has fallen.

In his relationship to the hospital, the physician will find himself in a somewhat more complicated situation. Because of the large number of employees involved, hospitals are definitely concerned under this act. A preliminary interview of officers of the American Hos-

pital Association with the Division of Re-Employment of the N R A developed several interesting points of view. Apparently voluntary hospitals come under the provisions of the agreement with the possibility that they might be exempted when operated largely as charities incurring deficits in their operation, and also as institutions for the care of emergencies. It was the opinion of officials in Washington that administrative, professional nursing and student staffs, dietitians, technicians and other professional employees do not come under the provisions of the agreement, but that all maids, orderlies, waitresses, laundry workers and others in the lower level of wage earners do come within this classification. As hospitals give twenty-four hour service every day during the entire week, it was pointed out to General Hammond that it would work a hardship on the hospitals to attempt to apply a forty hour week for this type of personnel. Nevertheless, he expressed the opinion that seven days a week and eight hours a day constituted too many hours of employment and that even though the majority of such employees seldom put in a total of fifty-six hours, special consideration would have to be given to the question. This matter is being carried further by the American Hospital Association.

This act concerns the American Medical Association also as an employer in its headquarters office of some five hundred people. The headquarters office, by order of the Board of Trustees, entered promptly into the spirit of the act so far as concerns payment of employees in the lower wage levels and hours of work.

Again THE JOURNAL would urge physicians in all their relationships to enter fully into the spirit of the legislation, recognizing its experimental character but realizing that the times demand experimentation by the trial and error method if a solution is to be found for what has seemed in the past a most difficult problem.

REFRIGERATION AND CANCER—A FALSE PROPAGANDA

Recently an attempt has been made to connect the apparent increase in cancer, the prevalence of dental caries and certain other less definite types of ill health with the growth in the use of mechanical refrigeration. Whenever industries are involved in propaganda in the health field, the commercial motive is naturally suspected. THE JOURNAL has no brief for any interest involved in the dissemination of such claims, nor is it concerned except from the point of view of the public health in the claims made for mechanical refrigeration as opposed to the use of ice. It does have an interest in proper interpretation of statistics concerning the public health, in order that the public may not be led into fallacious beliefs or unwarranted fears.

Inquiries have come to THE JOURNAL from physicians, health officers and better business bureaus in

widely separated parts of the country relative to the propaganda concerned. Claims are made that mechanical refrigerators devitalize the food and that this alleged devitalization of the food may be responsible for the increase in cancer, the prevalence of dental caries, and a list of ills vaguely indicated as "toxic poisoning, constipation, acidosis, pyorrhea, rectal troubles" which "plague the American people."¹ It is alleged that the "respiratory" gases from foods refrigerated in hermetically sealed chambers "as dry as Death Valley" devitalize the food and render it toxic. Some highly colored pictures of a cemetery are accompanied by statements that cancer mortality has doubled since 1900, as have deaths from appendicitis. Vague references are made to "many leading authorities," but these are not named. Acknowledgment is also made by the promoter, Mr. Teigen, to "that great international authority on refrigeration, his former associate and employer." This gentleman is not named, but information in the possession of *THE JOURNAL* indicates that the reference is to a Mr. J. M. Cattanaach of Minneapolis. *THE JOURNAL* has no evidence as to Mr. Cattanaach's scientific attainments or to those of Mr. Teigen.

A letter was addressed to Mr. Teigen asking him to elucidate certain of his claims. No answer was received, so a copy was sent again by registered mail. A return receipt for the registered communication is all the reply that has thus far been received, though six months has elapsed since the date on the return receipt.

The circular to which reference is made appears to be sent unsolicited. Mr. Teigen, however, publishes a brochure which may be had for a dollar. This is an amplification of the claims made in the circular. It is characterized by the same definiteness in quoting fragments from recognized authority, coupled with vagueness and indefiniteness in the conclusions drawn from such quoted matter. In no place is the claim definitely made that cancer, appendicitis or carious teeth are attributable to the increased use of foods mechanically refrigerated, except in the title of the booklet.² The inference, however, is drawn so that the uncritical reader will inevitably make his own deductions to that effect.

Whatever may be the motive which inspires this propaganda, it may be said definitely that there is no scientific evidence to support the claims. The circulation of such unfounded literature conjures weird phobias among its readers and is prejudicial to the public health because it diverts attention from real problems and discredits genuine health education. If there is any method by which it can be reached, it should be stopped.

2. Teigen, F. A.: *Cancer, the Potential Penalty of Electric Refrigeration*, Minneapolis, 1933.

TOBACCO ALLERGY

Nicotine may not be the dominant pathogenic agent in tobacco and many symptoms commonly attributed to this agent may in reality be chronic allergic reactions to tobacco proteins (or to bacterial proteins developed during the process of fermentation). Sulzberger¹ and his colleagues of the Montefiore Hospital, New York, have published data which do not prove that nicotine is without injurious effects but which do serve to call attention to a possibility thus far overlooked in theoretical and practical toxicological research.

Sulzberger's conclusions were drawn from a study of reactivity of the skin to various tobacco products. Tests made by the patch method on fifty-eight healthy nonsmokers, for example, showed 16 per cent with a hereditary or acquired sensitivity to tobacco extract. Similar tests with ninety-five healthy smokers showed 36 per cent with the same cutaneous sensitivity. A parallel study of seventy-three patients with cardiovascular disease exclusive of thrombo-angiitis obliterans showed 22 per cent with skin sensitivity to tobacco. This group included both smokers and nonsmokers. The same test with a group of thirteen patients suffering from thrombo-angiitis obliterans showed 77 per cent hypersensitive to tobacco, with an additional 15 per cent of these patients sensitive to other inhalant antigens. This gave a total of 92 per cent of all patients with thrombo-angiitis obliterans specifically sensitive to one or more antigenic inhalants, tobacco being by far the most common specific irritant.

In order to determine the essential factor responsible for these skin reactions, parallel tests were made with whole tobacco extract, with an aqueous extract of "denicotized" tobacco and with a 0.4 per cent nicotine sulphate solution. "In all but one of the twenty-four cases thus tested, nicotine caused no reaction. ["Denicotized"] tobacco extracts caused moderate to strong reaction in twenty-one of these cases." The general conclusion is that "many cases of thrombo-angiitis obliterans are in some way related not to a nicotine effect but to a reaction of hypersensitivity to a constituent or constituents of tobacco other than nicotine."

Evidence in support of this conclusion was obtained by a similar study of specific skin reactivity in many cases of "tobacco eczema." Here, also, cutaneous allergy was not demonstrable with the pure nicotine solution. The majority of these patients reacted to certain tobacco extracts. "We found that of the positive cases some reacted to only one of the [three] extracts [tested]; some to only two; and some to all three extracts. In other words, any given tobacco-positive patient might prove sensitive to only a given mixture of tobacco and not sensitive to any other mixture." One patient, for example, had an extremely strong reaction with a shade-grown Connecticut wrapper, whereas tests with Wisconsin filler were negative.

1. Sulzberger, M. B.: *J. Immunol.* 24: 85 (Jan.), 265 (March), 425 (May) 1932; abstr. *Bull. New York Acad. Med.* 9: 294 (May) 1933.

In another patient, "patch tests with tobacco from [a widely advertised brand of] cigarets were positive; patch tests with other brands were negative. The patient had been smoking only this brand." As soon as the patient stopped using this brand, his eczema cleared up.

The active antigenic factor in tobacco is coctostable. Little or no reduction in allergic toxicity was noted after boiling for one minute. Tobacco sensitivity, therefore, is similar to sensitivity to many other plant "proteins," many of which are coctostable.

Current Comment

FETAL CHONDRODYSSTROPHY

Although known in Egyptian times, fetal chondrodystrophy was first mentioned in medical literature by Glisson, who considered it to be fetal rickets. In the eighteenth and nineteenth centuries, much controversy developed as to the nature of this bizarre type of dwarfism. The rachitic origin of chondrodystrophy seems to have been discredited in favor of such causes as endocrine imbalance—thyroid, parathyroid, pituitary anomalies; systemic disease of the mesenchyme; reversion to a previous dwarf type; consanguinity; alcoholism, and maternal toxemia. More recently, Glisson's idea that chondrodystrophy is fetal rickets has been revived. Wilton,¹ in a recent study of the pathogenesis of the skeletal changes in four cases of fetal chondrodystrophy, applied a knowledge of modern biologic and histologic studies on cartilage and bone to this ancient disease. He points out that the development of embryonic tissues and the configuration of the skeleton are not due to external mechanical factors such as muscle activity but to internal ontogenetic causes. The rachitic factor attacks those tissues which show the greatest growth energy. The parts of the skeleton affected vary according to their state of differentiation. Wilton observed in his achondroplastic fetuses that the long bones were deformed; the ossification centers appeared late; cartilaginous bones were unusually small; the pelvis was generally contracted; the ossification zone was irregular; primary marrow spaces appeared in the cartilage; the perichondrium was thicker than normal, and the proliferation zone of cartilage was slight or entirely missing. The factor responsible for chondrodystrophy attacks the cartilage more than the bones in fetal life. Capillaries in the cartilage absorb the chondrocytes before calcification has occurred. The same factor that affects the bones and causes rickets later in life attacks the cartilage and causes fetal chondrodystrophy in fetal life. The etiologic factors of the disease are the same as in rickets: vitamin D deficiency, parathyroid hormone deficiency, and disturbances in mineral metabolism. The substances affecting the normal development of cartilage may be classified into two

groups: 1. Those substances which accelerate the biologic process of development. These substances (vitamin D, phosphorus, parathyroid hormone) Wilton calls K substances. 2. The antagonistic substances which retard this growth activity (P-factor). For normal development the ratio K/P must have a certain value. If this ratio is too small, development is delayed. Under these conditions the cartilage and cartilaginous bone are affected in fetal life (fetal rickets); at a later period the cartilaginous and membranous bones are involved (late rickets), and in adult life connective tissue, bone and teeth are affected (osteomalacia and caries of pregnancy). By means of this hypothesis Wilton expresses the various known and unknown factors in a biologic ratio which presents a concept of the biochemical equilibrium occurring in normal tissue development and demonstrates the effect of disturbed biochemical balance on the development of cartilage and bone tissue. Thus the question whether fetal chondrodystrophy is a form of rickets has been revived. It remains for further investigation to prove whether Wilton's interesting hypothesis is correct.

BERNARDINO RAMAZZINI—A TERCENTENARY

On November 5, 1633, Bernardino Ramazzini was born in Italy. His name is famous in the history of medicine as the founder of industrial and occupational medicine from both the clinical and the preventive point of view. For twenty years he occupied the chair of medicine in the school at Modena in Italy and in this period contributed works on malaria and on the results of his research in physiology. He has indeed been credited with being the first to state that mercury in a tube rises when the weather is fair and goes down when the sky is cloudy. His greatest work, however, was his treatise on "Diseases of Tradesmen,"¹ published in 1700. At that time, when he was 67 years of age, he was invited to occupy the second chair of medicine at the University of Padua. From then on he lectured regularly until November 5, 1714, the day of his eighty-first birthday, when he succumbed to an attack of apoplexy. The work entitled "De Morbis Artificum" was published and republished in the original Latin as well as in other languages in many editions. It is based on direct observation of workers in various types of industry and includes such interesting chapters as those concerning metal diggers, surgeons and others employed in frictions and inunctions in venereal cases, chemists, potters, painters, blacksmiths, "cleaners of Jakes,"² tobacconists, midwives, nurses and many others. He considered the diseases of those who stand much and of those who sit much, the diseases of wrestlers, of singers, of learned men, of those who work much with the eyes, of writers, of sailors and of innumerable others. His text reveals a rare humanitarianism, a fine quality of scientific observation, a sense of humor and the point of view of a philosopher.²

Association News

THE CLEVELAND SESSION

Eighty-Fifth Annual Session to be Held in June

The Eighty-Fifth Annual Session of the American Medical Association will be held in Cleveland, Ohio, June 11 to 15, 1934.

MEDICAL BROADCAST FOR THE WEEK

American Medical Association Health Talks

The American Medical Association broadcasts on Tuesday and Thursday from 9:15 to 9:20 a. m., Chicago daylight saving time, which is one hour faster than central standard time, over Station WBBM (770 kilocycles, or 389.4 meters).

The subjects for the week are as follows:

August 15. Physically Handicapped Children.
August 17. The Old and the New.

There is also a fifteen minute talk sponsored by the Association on Saturday morning from 9:45 to 10 o'clock over Station WBBM.

The subject for the week is as follows:

August 19. What Is Occupational Therapy?

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ARKANSAS

Society News.—Dr. Davis W. Goldstein, Fort Smith, addressed the Yell-Pope Counties Medical Society, July 13, on injection treatment of varicose veins.—The Mississippi County Medical Society was addressed in Blytheville, June 5, by Drs. Casa Collier and Robert G. Henderson, both of Memphis, Tenn., on jaundice and skin diseases, respectively.—At a meeting of the Craighead-Poinsett County Medical Society in Jonesboro, June 15, Drs. Willis C. Campbell discussed tennis elbow; Richard C. Bunting, polyneuritis, and John L. McGehee, breast tumors. The speakers were from Memphis.

CALIFORNIA

Quarantine on Mussels.—The state department of health placed a quarantine on mussels on the coast area from Monterey County to the Klamath River in Del Norte County, with the exception of San Francisco Bay, June 22, after laboratory examinations had shown mussels from these sections to be highly toxic. The sale or offering for sale of mussels gathered from these areas for the period June 22 to September 30 is prohibited. The department points out the danger of eating mussels gathered during this period of the year.

Society News.—At the regular meeting of the San Francisco County Medical Society, August 8, speakers were Drs. Raymond J. Millner, on "Methylene Blue Treatment of Cyanide Poisoning"; Edmund Butler, "Contusion of the Abdomen"; George K. Rhodes, "Treatment of Shock," and Theodore P. Schomaker, "Emergency Treatment of Fractures." The program was furnished by the emergency division of the San Francisco Department of Health.—Dr. Percy T. Magan, Los Angeles, addressed the Hollywood Academy of Medicine, July 20, on "The Making of a Doctor."

FLORIDA

Committee for Cancer Control.—Announcement has been made of the recent organization of a cancer control committee of the Florida Medical Association. Dr. Gerry R. Holden, Jacksonville, past president of the state association, was named chairman of the committee, other members of which are Drs. Joshua C. Dickinson, Tampa; Frederick K. Herpel, West Palm Beach; James M. Hoffman, Pensacola, and Gerard Raap, Miami.

Society News.—The Dade County Medical Society was addressed in Miami, July 7, by Drs. Nelson M. Black, Miami,

on "Radiant Energy, Its Characteristics, Biologic Action and Some Means of Protection Against the Harmful Effects to the Eyes"; W. Duncan Owens, Miami Beach, "Acute Appendicitis of Traumatic Origin," and Parke G. Smith, Cincinnati, "Recent Advances in Urologic Surgery."—Speakers at a meeting of the Central Florida Medical Society (Lake, Alachua and Marion counties), July 21, were Drs. William C. Blake and John C. Vinson, Tampa, on "Myocardial Ischemia" and "Treatment of Acute Epididymitis," respectively. State's Attorney A. P. Buie also addressed the meeting, on "The Doctor from the Prosecuting Attorney's Standpoint."

GEORGIA

New State Board of Health.—In accordance with a new law changing the organization of the state board of health, Gov. Eugene Talmadge has announced the new personnel. Ten members were appointed from a list submitted by the state medical association, two from a list submitted by the Georgia Pharmaceutical Association and two from a list submitted by the Georgia Dental Association. Members representing the medical association are:

| | |
|---------------------------------|-----------------------------------|
| Dr. Cleveland Thompson, Millen. | Dr. Allen R. Rozar, Macon. |
| Dr. Cyrus K. Sharp, Arlington. | Dr. Mather M. McCord, Rome. |
| Mr. R. C. Ellis, Americus. | Dr. Henry W. Clements, Adel. |
| Dr. Marvin M. Head, Zebulon. | Dr. Lisbon C. Allen, Hoschton. |
| Mr. Robert F. Maddox, Atlanta. | Dr. William A. Mulherin, Augusta. |

Members from the state at large representing the Georgia Pharmaceutical Association are Thomas C. Marshall, Atlanta, and Claude Rountree, Thomasville. Those representing the dental association are M. H. Varn, D.D.S., Atlanta, and Robert F. Sullivan, D.D.S., Savannah.

ILLINOIS

Program on Pediatrics.—Speakers at the one-day course in pediatrics held in Monmouth, July 28, for physicians of Warren County and guests from eastern Iowa and western Illinois, under the auspices of the American Academy of Pediatrics, were:

| |
|--|
| Dr. Heyworth N. Sanford, Chicago, Infant Feeding. |
| Dr. Bert I. Beverly, Chicago, Behavior Disturbances. |
| Dr. Charles K. Stulik, Chicago, General Treatment of Children. |
| Dr. Arthur H. Parmelee, Oak Park, Care of the New-Born. |
| Dr. Woodruff L. Crawford, Rockford, Allergy. |
| Dr. Robert H. Graham, Aurora, Preventive Medicine. |

Dr. Clifford G. Grulee, Chicago, secretary of the American Academy of Pediatrics, conducted a "question box."

Chicago

Fraudulent Sale of Bags and Instruments.—A report has been received that a man named Joseph Diamond has been seeking money fraudulently for a so-called credit and collection agency. This person has been obtaining money on orders for physicians' bags, instruments and other equipment from Chicago physicians, interns and students without delivering the goods. He is said to have been recently discharged from the Sharp and Smith Surgical Supply Company for dishonesty and is said to have an extensive criminal record. He is described as being about 5 feet 10 inches tall, slender, with black hair, dark skin, prominent brown eyes and a prominent nose.

Society News.—The Chicago Medical Society recently sponsored the following series of health lectures in the Hall of Science at the Century of Progress Exposition:

| |
|--|
| July 31, Dr. Philip Lewin, Infantile Paralysis. |
| August 2, Dr. John A. Wolfer, Cancer of the Breast. |
| August 3, Dr. Gilbert Fitzpatrick, Cancer. |
| August 5, Dr. George B. Lake, Mental Hygiene. |
| August 7, Dr. Fremont A. Chandler, The Crippled Child. |
| August 9, Dr. Clifford J. Barboraka, Diet in Health and Disease. |
| August 10, Dr. Francis E. Senear, Care of the Skin. |
| August 12, Dr. Max Cutler, Cancer. |

The bulletin of the society reports that 1,068 physicians have registered at its booth in the Hall of Science during June and July.

IOWA

District Meeting.—Dr. Harry H. Lamb, Davenport, was elected president of the Iowa and Illinois Central District Medical Association at its annual meeting in Davenport, July 13, succeeding Dr. Hugh A. Beam, Moline, Ill. Dr. Karl W. Wahlberg, Moline, was named vice president; Dr. John I. Marker, Davenport, secretary, and Dr. John Henry Fowler, East Moline, reelected treasurer. Speakers included Drs. Walter L. Bierring, Des Moines, President-Elect, American

Medical Association; Karl Vollmer, Davenport, president-elect, Iowa State Medical Society; George E. Decker, Davenport; Viray P. Blair, St. Louis, and James Herbert Mitchell, Morris Edward Davis and Agnes Beulah Cushman, Chicago.

MAINE

Society News.—The Washington County Medical Society was addressed at Calais, recently, among others by Drs. Albert W. Fellows on diagnosis of the eruptive fevers and Herbert E. Thompson, immunity.—At a meeting of the Aroostook County Medical Society in Houlton, June 13, the principal speakers were Drs. Edward H. Risley and John O. Piper, both of Waterville, on surgical treatment of intestinal obstruction and recent advances in the treatment of diabetes, respectively.

Ruling on Foreign Applicants for Registration.—The State of Maine Board of Registration in Medicine recently voted that no graduate of a foreign medical school will be admitted to its examinations who cannot prove that he is a graduate of a reputable foreign school, that he has at least taken out his first naturalization papers for citizenship in the United States and that he has a license to practice in the country in which his medical school is located. Dr. Adam P. Leighton, Jr., Portland, was recently reappointed a member of the board for the fourth time. He has served on the board eighteen years, for the past twelve as secretary. Other members of the board are Drs. George R. Hagerthy, Bar Harbor, chairman; Franklin A. Ferguson, Portland; William G. Chamberlain, Fort Fairfield; John G. Towne, Waterville, and Ralph D. Simons, Gardiner.

MASSACHUSETTS

Annual Meeting of State Board.—Drs. Charles P. Sylvester and Stephen Rushmore, Boston, were reelected chairman and secretary, respectively, of the Massachusetts Board of Registration in Medicine at its annual meeting, July 13. Dr. Edward A. Knowlton, Holyoke, was designated to act with these officers in the examination of chiropractors.

Dr. Osgood Honored.—The *New England Journal of Medicine* for July 13 was made up of special articles written by members of the staff of the Children's Hospital, Boston, as a tribute to Dr. Robert B. Osgood, who resigned in 1931 as chief of the orthopedic service in the institution. At the same time he resigned as the John Ball and Buckminster Brown professor of orthopedic surgery at Harvard University Medical School. The foreword in the special number was prepared by the late Sir Robert Jones, prominent British orthopedist, and most of the articles were produced from material obtained at the Children's Hospital. A large part of the work which they describe was carried on during the years Dr. Osgood was connected with the hospital.

MICHIGAN

Annual Report of Children's Fund.—The Children's Fund of Michigan, for the year May 1, 1932, to April 30, 1933, disbursed \$824,519.31 in its services to about 370,000 children, according to its fourth annual report. The program of feeding malnourished children was continued and enlarged and, at the close of the 1932 school session, sixty cafeterias were kept open for this work. A special appropriation was made for the school year 1932-1933 to provide eight emergency dental clinics for indigent children, to replace the service abandoned by the Detroit Board of Health for economic reasons. In the state-wide dental program, which is the largest single segment of the fund's health work, children in thirty-nine counties were given attention and a summer dental relief program was operated for twelve weeks. As a result of this program, three communities, Luce, Iron Mountain and Breitung township in Dickinson County, now support their own dental programs. Projects discontinued by the fund included the Menominee County Health Demonstration, infant and preschool classes and the support to child guidance clinics. This year brought to a close the fund's three year program of health education in several colleges of the state. To evolve a better plan for treating delinquent children, the fund appropriated a small sum of money to place children in boarding homes of approved environment. Since the adoption of this plan, nineteen children have been placed, two of whom failed to make good and were committed to state institutions; one was returned to his home when conditions improved, and one other passed out of the jurisdiction of the probate court handling the work. This year saw the establishment of a circulating collection of ninety-nine sets of children's books, which are lent in rotation to school districts and parent-teacher groups in communities of less than 2,000 inhabitants. Grants of the fund financed

research into causes of the decay of children's teeth; orthodontic problems, particularly dental growth and growth of bones; problems relating to childhood tuberculosis, and causative factors relating to juvenile delinquency. In addition, the fund expended \$17,240.91 on research in its own laboratory. The fund disbursed \$29,148.50 in the less prosperous sections of the northern part of the state in its program of supporting dependent children through the Michigan Children's Aid Society. At Green Pastures Camp, established two years ago by the fund for indigent Negro children, 582 children were accommodated, most of whom showed a general improvement. For the final year, a grant of \$3,000 was made to the Atlanta School of Social Work, Atlanta, for the training of Negro child welfare workers, from which Michigan draws its Negro workers. The activities of the fund are carried out in five divisions: child health, child guidance, research, dependence and miscellaneous projects.

MINNESOTA

Society News.—Members of the former Dodge County Medical Society, which had disbanded, were amalgamated into the Olmsted-Houston-Filmore Counties Medical Society, and Dodge County was added to the name of the society at a recent meeting in Rochester.—The Minnesota Dermatological Society held its annual meeting in Duluth, July 21, with clinical meetings and demonstrations at St. Mary's Hospital. Dr. Emanuel Z. Shapiro, Duluth, president of the society, was in charge of arrangements. Drs. Shapiro, Murdoch A. Nicholson, George C. Doyle, all of Duluth, and Charles W. Giesen, Superior, Wis., conducted demonstrations.—Speakers at the sixty-fifth annual meeting of the Wabasha County Medical Society, July 6, included Drs. William B. Stryker, Plainview, on "A Country Doctor's First Experience in Obstetrics"; Anson L. Clark, Rochester, "Diagnosis and Treatment of Specific Urethritis"; Rudolph C. Radabaugh, Hastings, "Use of Maggots in Osteomyelitis," and Waltman Walters, Rochester, "Advance in Surgery."

NEW YORK

Hospital News.—The cornerstone of a new \$350,000 building for the Huntington Hospital, Huntington, L. I., was laid, June 3. It was expected that the building would be placed in service, August 1.—The Buffalo General Hospital recently celebrated the seventy-fifth anniversary of its founding. The hospital now has accommodations for 462 patients.

New York City

Personal.—Mr. Reinhold Wappler, president of the American Cystoscope Makers, New York, died while traveling in Germany recently, aged 63, the *New York Times* reported, July 6. He was an honorary member of the American Urological Association.—Dr. Robert Allan Moore, instructor in pathology, Western Reserve University School of Medicine, Cleveland, has been appointed assistant professor of pathology at Cornell University Medical School.—A testimonial dinner for Dr. Daniel J. Donovan, chief surgeon of the police department, was given at the Waldorf-Astoria, July 19. Dr. Donovan recently completed forty years of service with the department.—Dr. John G. William Greeff, commissioner of the department of hospitals, since December, 1929, has announced his resignation, effective August 15.

Queens County Opens a Library.—The Medical Society of the County of Queens announces that it will open a library on a limited schedule, September 1. Periodical literature and books given by various organizations and individuals have enabled the society to make this beginning and it hopes to build up an adequate library. Classification of the material on hand was made possible by volunteer labor and the society asks members to give any time and labor possible to continue the work. It also asks those who have accumulated files of medical journals to donate those from which they are willing to part. A pathologic museum is also to be developed as an adjunct to the library, the society's bulletin announces. Here will be stored properly prepared gross pathologic specimens collected in the hospitals of the borough, with synopsis of the history of each case. The section on internal medicine and pathology is in charge of preparing the museum.

NORTH CAROLINA

Dr. Amoss Resigns at Duke University.—Dr. Harold L. Amoss, professor of medicine at Duke University School of Medicine, Durham, since the establishment of the school in 1930, has resigned to enter private practice at Greenwich, Conn., and conduct research at Rockefeller Institute for Medical Research, New York. Dr. Amoss, a native of Kentucky and

a graduate of Harvard University Medical School, was a member of the staff of Rockefeller Institute for a number of years before going to Johns Hopkins University School of Medicine in 1922 as associate professor of medicine. In 1931 he spent four months as visiting professor of medicine at Peiping Union Medical College, Peiping, China. Dr. Frederic M. Hanes, Winston-Salem, who has served as professor of neurology during the past year, has been appointed to succeed Dr. Amoss. Dr. Hanes is a graduate of Johns Hopkins University School of Medicine and has served as associate professor of pathology at Columbia for three years and as associate professor of medicine at Washington University for one year. He substituted for Dr. Amoss in the chair of medicine while the latter was in China.

OHIO

State Medical Meeting at Akron.—The eighty-seventh annual meeting of the Ohio State Medical Association will be held in Akron, September 7-8, at the Mayflower Hotel. The first day will be devoted to meetings of the house of delegates and of the sections and Friday to general sessions. At the annual banquet, Thursday night, the retiring president, Dr. Herbert M. Platter, Columbus, and his successor, Dr. Clyde L. Cummer, Cleveland, will present their official addresses and Dr. Olin West, secretary and general manager, American Medical Association, will speak on "The Need for Unity in the Medical Profession in Facing the Economic and Social Problems of the Day." Speakers at the morning general session Friday will be:

- Dr. John D. Dunham, Columbus, The Status of Peptic Ulcer in 1933.
- Dr. Chauncey W. Wyckoff, Cleveland, Throat and Ear Problems from a Pediatric Standpoint.
- Dr. Walter H. Snyder, Toledo, The Eye in Relation to Industry.
- Dr. George M. Curtis, Columbus, Newer Aspects of the Management of Hyperthyroidism.
- Dr. Harry H. Drysdale, Cleveland, Essential Factors in the Differentiation of Functional and Organic Disorders of the Central Nervous System.
- Dr. Albert H. Freiberg, Cincinnati, Sciatica in General Practice.
- Dr. Albert Graeme Mitchell, Cincinnati, Diagnosis and Prognosis of Tuberculosis in Children.

The afternoon program will be a symposium on intestinal obstruction presented by members of the faculty of Western Reserve University School of Medicine, Cleveland, as follows:

- Dr. Alan R. Moritz, Embryogenetic Basis of Congenital Obstruction.
- Dr. Harry Goldblatt, Pathology of Organic Obstructions.
- Dr. Marion A. Blankenhorn, Pathological Physiology and Symptomatology.
- Dr. Carl H. Lenhart, Surgical Management.

Dr. George Edward Follansbee, Cleveland, will address the annual organization luncheon Thursday noon on economic and social problems affecting medical practice.

PENNSYLVANIA

Society News.—Dr. Waitman F. Zinn, Baltimore, spoke on "Diagnosis and Treatment of Cancer of the Larynx" at a meeting of the York County Medical Society, June 17.—Dr. Edward A. Schumann, Philadelphia, addressed a meeting of the west section of the Fifth Councilor District Medical Society at Carlisle, July 20, on toxemias of pregnancy.

Philadelphia

Temple University News.—Announcement has been made of the appointment to the faculty of Temple University of Drs. Herman Nunberg as professor of psychoanalysis, Oliver Sturgeon English as clinical professor of psychiatry, Meyer Corff, clinical assistant in junior surgery, and Herman J. Garfield, clinical assistant in genito-urinary diseases. At the annual alumni meeting, June 14, Dr. Henry Tuttle Stull was elected president of the alumni association and members of the faculty presented graduate clinics.

TENNESSEE

State Board Election.—Dr. Benjamin L. Simmons, Nashville, was elected president of the Tennessee State Board of Medical Examiners at a meeting in Nashville, July 25. Dr. James K. P. Blackburn, Pulaski, was elected vice president, and Dr. Harley W. Qualls, Memphis, secretary. Other members are Drs. James H. Keeling, Knoxville; Thomas B. Yancey, Kingsport, and Marcus G. Spingarn, Memphis.

Personal.—Dr. Fred W. Kratz, Nashville, has been appointed health commissioner of Lincoln County, succeeding Dr. D. Dick Howser.—Dr. William H. Slaughter, who has served as head of the U. S. Marine Hospital in Memphis since October, 1930, has been transferred to Galveston, Texas, to take charge of a new hospital.—Dr. Geoffrey M. Morris, Gallatin, has resigned as health commissioner of Sumner County.

Health at Memphis.—Telegraphic reports to the U. S. Department of Commerce from eighty-five cities with a population of 37 million, for the week ended July 29, indicated that the highest mortality rate (21) appeared for Memphis and the rate for the group, 10. The mortality rate for Memphis for the corresponding week last year was exactly the same, and for the group of cities it was 9.5. The annual rate for eighty-five cities was 11.3 for the thirty weeks of 1933, as against a rate of 11.7 for the corresponding period of the previous year. Caution should be used in the interpretation of weekly figures, as they fluctuate widely. The fact that some cities are hospital centers for large areas or that they have large Negro populations may tend to increase the death rate.

WASHINGTON

State Medical Meeting at Seattle.—The forty-fourth annual meeting of the Washington State Medical Association will be held at the Olympic Hotel, Seattle, August 28-31. Guest speakers will be:

- Dr. Eldridge S. Eliason, Philadelphia, Individuality in Treatment of Fractures.
- Dr. Ralph A. Fenton, Portland, Ore., Present Trends in Treatment of Sinus Disease.
- Dr. Ralph C. Brown, Chicago, Functional Disorders of the Large Bowel.
- Dr. John V. Barrow, Los Angeles, Amebiasis in Clinical Practice.
- Dr. Herman L. Kretschmer, Chicago, Eighteen Months' Experience in Treatment of Bladder Neck Obstruction with the Resectoscope.

A special session on economics will be held Tuesday morning, August 29, with the following speakers:

- Dr. Horace Whitacre, Tacoma, Health Insurance as Applied to the State of Washington.
- Dr. Harrison Garner Wright, Seattle, Organizing and Coordinating of Service Bureaus.
- Dr. Nils A. Johanson, Seattle, Group Hospital Insurance.
- Dr. Nathan L. Thompson, Everett, Care of the Indigent Sick by the County Medical Society.
- Dr. Warren B. Penney, Tacoma, Legislative Actions and Policies.

Clinics will be held Tuesday and Wednesday mornings at Harborview Hospital. The annual golf tournament will take place Monday at the Broadmoor Country Club. Social events will include a stag dinner at which Stephen B. L. Penrose, LL.D., president of Whitman College, Walla Walla, will give an address entitled "The First Doctor on the Pacific Coast"; a dinner dance at the Olympic, and daily luncheons. The Public Health League of Washington will hold its annual luncheon meeting Tuesday, August 29, and the local health officers of the state will have their annual convention Sunday, August 27.

GENERAL

Society News.—Among speakers at the fifth annual meeting of the Aero Medical Association of the United States in Chicago, September 2-4, will be Drs. James C. Braswell, Tulsa, Okla., on "Problems of the Civilian Examiner in Aviation"; Louis H. Bauer, Hempstead, N. Y., "Examination of the Heart"; and Ralph N. Greene, Jacksonville, Fla., "Neurologic Aspects of the Examination." Afternoons will be left free for attendance at the Century of Progress Exposition.—The annual convention of the International Association of Police and Fire Surgeons and Medical Directors of Civil Service Commissions will be held in Chicago, October 12-14.—The eighty-first annual meeting of the American Pharmaceutical Association and related organizations will be held in Madison, Wis., August 22 to September 2.

Report on Psychiatric Teaching.—The final report of a two-year study of psychiatric teaching in medical schools of the United States and Canada, conducted by Drs. Franklin G. Ebaugh, Denver, and Ralph A. Noble, New York, under the auspices of the National Committee for Mental Hygiene, has been issued. Among the sixty-eight schools studied, it was found that twenty had departments of psychiatry; fifteen combined psychiatry with neurology, and thirty-two placed it in their departments of internal medicine. One had no provision for psychiatry in its curriculum. Approximately \$600,000 was expended directly each year by the twenty-four medical schools with budgets for psychiatry, it was found, but in only four were the budgets considered adequate and these four spent practically half of the amount allotted by all the sixty-eight schools. An increase in public interest has fostered the rise of what the report calls psychologic quackery. Attention was called to the fact that journals and books on popular psychology have multiplied at a tremendous rate and that there are many different cults of psychiatrists and psychologists. On the subject of specialization the report recommends the strengthening and support of university centers of graduate instruction, establishment of a qualifying board for specialists in psychiatry, and the provision of higher degrees and diplomas in psychiatry.

It emphasizes that the aim is not to train psychiatrists as such during the medical course. "It is an accepted principle that the psychiatrist must first of all be a physician and most of his special training in psychiatry must be attained after he graduates from medical school."

Trudeau Medal Awarded to Dr. Brown.—At the annual meeting of the National Tuberculosis Association in Toronto, June 26-30, the Trudeau Medal was awarded to Dr. Lawrason Brown, who has been associated with the Trudeau Sanatorium, Saranac Lake, N. Y., since 1900. Dr. Brown was president of the association in 1920 and has been president of the American Climatological and Clinical Association (1922) and the American Sanatorium Association (1919-1923). He is the author of various works on tuberculosis. Dr. Stuart Pritchard, Battle Creek, Mich., was elected president of the association and it was decided to hold the 1934 session in Cincinnati. Special guests at the meeting were Col. Stevenson Lyle Cummins, Welch National School of Medicine, Cardiff, Wales, who spoke on investigations of tuberculosis in South Africa, and Sir Humphry Rolleston, formerly regius professor of physic at Cambridge University and president of Papworth Village, who spoke on unusual manifestations of tuberculosis and also gave an address at the annual dinner on "British Pioneers in Treatment of Tuberculosis." There were symposiums on bacteriology of acid-fast strains, silicosis as an etiologic factor in production of tuberculosis, surgery of bone and joint tuberculosis in adults, and tuberculosis—a family disease. Among the speakers were:

Dr. David W. MacKenzie, Montreal, Genito-Urinary Tuberculosis.
Drs. Florence R. Sabin and Kenneth C. Smithburn, New York, Cellular Reactions to Tubereuloproteins.
Dr. James Alexander Miller, New York, Hematogenous Pulmonary Tuberculosis.
Dr. Robert I. Harris, Toronto, Surgery of Bone and Joint Tuberculosis.
Dr. Louis Hamman, Baltimore, Malignancy of the Lungs and Pleura.

Bequests and Donations.—The following bequests and donations have recently been announced:

Children's Memorial Hospital and Chicago Home for Incurables, \$50,000 each from the estate of Fred B. Jones.
Michael Reese Hospital, Chicago, \$100,000 from the estate of Abraham Meyer.
Truesdale Hospital, Fall River, Mass., \$10,000 by the will of Josephine M. Turner.
Anna Jaques Hospital, Newburyport, Mass., \$696,000 from the estate of Dr. John Marshall Hills.
Vassar Brothers Hospital, Poughkeepsie, N. Y., \$5,000 from the estate of Mrs. Ida Lansing Smith.
Dobbs Ferry Hospital, Dobbs Ferry, N. Y., \$6,700 from the estate of Rebecca Wendel Swope.
City of Cleveland, \$60,000 from the estate of John Colahan for an emergency hospital to be built in the downtown district.
Shriners' Hospital, Spokane, Wash., \$19,000 from the estate of Mrs. Elizabeth Winn.
St. Vincent's, Hamot and Zem Zem Hospital for Crippled Children, Erie, Pa., \$21,000 each from the estate of Joseph A. Stern.
Herman Knapp Memorial Hospital, New York, \$20,000, and Columbia University for the Edmund B. Wilson Fund for advancement of biologic research, \$10,000 under the will of Mrs. Ida Kämmerer.
Hayre de Grace Hospital, Hayre de Grace, Md., \$10,000 trust fund under the will of the late Benjamin Harman.
Frankford Hospital, Philadelphia, \$2,000 by the will of C. W. Merrell.
Among bequests totaling \$2,160,000, John Markle, retired coal operator who died July 10, left the following sums to New York hospitals and medical institutions: Neurological Institute and Conrad Berens Ophthalmological Foundation, \$50,000 each; New York Nursery and Child's Hospital and Broad Street Hospital, \$10,000 each. The residuary estate is bequeathed to the John and Mary R. Markle Foundation established in 1927 for the management of the Markle philanthropies.
New York Nursery and Child's Hospital, New York, \$50,000 under the will of the late Mrs. Mary Mildred Hammond Sullivan.
Montefiore and Mount Sinai hospitals, New York, \$7,500 each under the will of the late Adolph Arber.
Solomon and Betty Loeb Convalescent Home near White Plains, N. Y., \$500,000 under the will of the late James Loeb, who founded and endowed the institution in memory of his parents.
Frankford Hospital, Philadelphia, and Bryn Mawr Hospital, Bryn Mawr, \$10,000 each under the will of W. W. Fittler.

FOREIGN

Medical School Celebrates Centenary.—The University of Bristol Faculty of Medicine celebrated the hundredth anniversary of its founding, June 30-July 1. The school was opened, Oct. 14, 1833, with a faculty composed of lecturers from several schools of anatomy. It was later associated with the University college founded in 1876 and when the University of Bristol received its charter in 1909, the Bristol Medical School became the faculty of medicine of the university. Prof. Edward Fawcett, dean of the school, has occupied the chair of anatomy for forty years and has been dean since 1906. Dr. George Parker has written a history for the occasion entitled "Schola Medicinæ Bristol: Its History, Lectures and Alumni." At the centenary observances honorary degrees were conferred on Lord Dawson of Penn, Sir Holburt J. Waring and Sir Norman Walker, Sir Frank Colyer, Emeritus Professor Ernest W. Hey Groves and Prof. Miles H. Phillips, Sheffield.

Rural Health in China.—The annual report of the health program of the Ting Hsien experiment conducted by the Mass Education Movement in China in conjunction with the Milbank Memorial Fund, New York, states that the health service now functions through three divisions, the district health center in Ting Hsien, subdistrict health stations and the village health workers. The district hospital with a capacity of fifty beds was completed in the spring of 1932 and during the year cared for 224 patients for a total of 2,771 patient days; eleven free patients were hospitalized. Two epidemics occurred, scarlet fever in the spring and cholera in the summer. For the former no organized control was attempted because of social and economic conditions, but more than 6,000 vaccinations against cholera were administered. In the primary school, 26,435 treatments for trachoma were given, while in the normal school for girls, which has 567 students, 295 cases of trachoma were diagnosed, 3,776 treatments given and definite improvement indicated in 112 cases. Full time first aid service is now available in fifteen villages of the research community.

CORRECTION

Book Review.—In a book notice published in *THE JOURNAL*, July 22, page 307, referring to the book entitled "Cinquante techniques chirurgicales de Henry-Delagenière," it is stated that this surgeon began his professional career in Mons. This was in error, since the work was done in LeMans.

Government Services

Training for Reserve Officers

For the fifth year a course of training for Medical Department Reserve Officers will be offered at the Mayo Clinic, Rochester, Minn., under the supervision of Col. George A. Skinner, October 1-14. The staff and faculty of the clinic have placed their facilities at the service of the government, and medical officers of all services are invited to participate. Morning hours will be devoted to professional subjects selected by the student officers and afternoons to medicomilitary topics. Evening hours will be given over to a lyceum course of general interest. One hundred hours' credit will be given to those who take the entire course, but those whose time will not permit this may join or leave at any time and will receive credit for the hours spent in training. Uniforms are optional. Application for the course should be made to The Surgeon, Seventh Corps Area, Baird Building, Omaha, Neb.

Health in Conservation Corps

During the month ended June 24, approximately 9,000 members of the Civilian Conservation Corps were reported sick and 2,000 injured. About 1,900 illnesses were common respiratory diseases and influenza; 460 cases were measles; 247, diarrhea; 196, venereal diseases; 130, malaria, and 121, scabies. Nine cases of tuberculosis were found; three each of cerebrospinal meningitis and diphtheria; two of typhoid and one each of scarlet fever and tick fever. Twenty-seven deaths occurred.

U. S. Public Health Service

Passed Asst. Surg. George W. Bolin, relieved at marine hospital, Galveston, Texas, and assigned at the quarantine station, Marcus Hook, Pa.
Passed Asst. Surg. Hiram J. Bush, relieved at Savannah, Ga., and assigned at Ellis Island.
Surg. Marion S. Lombard, relieved at Key West, Fla., and assigned at Memphis, Tenn., in charge of the marine hospital.
Asst. Surg. Charles T. Meacham, Jr., relieved at Boston, and assigned at the marine hospital, New York.
Sr. Surg. Hermon E. Hasseltine, relieved at Washington, D. C., and assigned in charge of the Public Health Service Laboratory, San Francisco, and office of plague suppressive measures, in addition to duties as medical officer in charge of studies being conducted at the laboratory for investigation and control of psittacosis at Pasadena.
Asst. Surg. Marion K. King, relieved at New Orleans and assigned at the marine hospital, Savannah.
Surg. Clifford R. Eskey, assigned as chief quarantine officer at Honolulu, T. H.
Intern Merrill J. Reeh, relieved at Chicago, and assigned at McNeil Island, Steilacoom, Wash.
Surg. Robert W. Hart, relieved at the marine hospital, San Francisco, and assigned as medical officer in charge of marine hospital, Key West, Fla.
Carl B. DeForest, commissioned as assistant surgeon in reserve corps of the service.
Surg. Gleason C. Lake, relieved at San Francisco and assigned at Seattle.
Dr. Henry H. Duke, commissioned as assistant surgeon (reserve).

Automatic Firedamp Alarms for Coal Mines

During the last fifty years, 58,000 men have been killed in British coal mines. Every year 5,000 are seriously crippled and 170,000 temporarily disabled. The cost in workmen's compensation is over \$15,000,000 a year. Portable electric lamps have two advantages over the Davy safety lamp: they do not initiate explosions, whereas the Davy lamp may do so, and they give better illumination. But electric lamps give no warning of the pressure of gas. A miner using an electric lamp may be working in gas of explosive density without knowing it. The law requires two inspections of a mine during each working shift by a trained official, who can withdraw the men if he detects more than 2.5 per cent of gas. The Miners' Federation has objected that four hours may elapse between the two inspections and that practically every explosion happens in a place which shortly before had been pronounced safe. An automatic firedamp alarm has been invented and tested by the federation and found effective. In 1815 the Davy lamp was invented, but no further advance was made in gas detection until a few years ago. The Davy lamp enabled the miner to ascertain the presence of gas in his working place and its use in gaseous mines was made compulsory. But the federation says that the frequency of mining disasters—about fourteen a year—notwithstanding the use of the Davy lamp, shows that it is far from adequate. The federation describes gas as the greatest menace to safety in the mines. It is a direct danger as a cause of explosions and an indirect danger, because it limits the amount of lighting possible. Better lighting would reduce haulage accidents and also accidents due to falls of roofs. It would minimize the occurrence of miners' nystagmus, which is the cause of the incapacity of 10,000 men and costs the industry \$2,500,000 a year. The federation says that a mine employing 1,000 men can be equipped with automatic alarms at a cost of \$15 a week, against which could be set savings in insurance and accident compensation. The automatic alarm shows a red light when gas is present. It tests for gas automatically and continuously.

New Facilities for "Beam Therapy" with Radium

In previous letters it was reported that the Radium Commission withdrew the 4 Gm. radium bomb, used for massive radiation at the Westminster Hospital, as the results were declared unsatisfactory. Doubts were raised as to the wisdom of this decision, and a conference was called by the presidents of the Royal Colleges of Physicians and Surgeons. An expert committee was appointed to consider the subject of mass radiation, and it expressed the opinion that a unit of not less than 5 Gm. should be established. The Belgian company, the Union Minière du Haut-Katanga, which produces most of the radium used in the world today, has offered to lend 5 Gm. of radium for "beam therapy" (the new name to be used, as the misleading term "bomb" has been dropped). The new research will be controlled by a representative body of seven members, which includes Sir F. Gowland Hopkins (president of the Royal Society), who will act as chairman, the presidents of the Royal Colleges of Physicians and Surgeons, Mr. Wilfred Trotter, F.R.S., Sir George Blacker, Lord Rutherford, and Prof. Arthur Hall. An executive research committee has been set up with Prof. J. C. M'Lellan, F.R.S. (late professor of physics at Toronto) as chairman. The research will be carried on at the London Radium Institute. The loan from the Union Minière is to be free of cost excepting insurance, and a further 5 Gm.

has been promised at a later date if required for mass radiation. The period provisionally fixed for the loan is two years. The work before the radium beam therapy research will be to endeavor to discover how far the present limited field of operation for a massive radium unit in the treatment of cancer may be extended by coordinated clinical, experimental and physical research.

The Serum Treatment of Acute Poliomyelitis

The Medical Research Council announces that it will supply serum obtained from patients convalescent from acute poliomyelitis with a view to its trial in the preparalytic stage of the disease. Encouraging reports have been received on the value of this treatment from Australia and Canada, but adequate data are still needed to confirm its value, particularly in view of doubts cast by recent experience in America on the reliability of the basic data. At present the supply of serum has been deposited at the Western Fever Hospital, London, where suspected cases will be admitted for observation and treatment in the preparalytic stage and supplies of serum can be obtained by physicians. When the supply of serum becomes larger, it is hoped also to be able to send supplies to university centers in the provinces. The serum will be supplied gratuitously on condition that record forms be completed and sent to the Medical Research Council. It is considered that it should be used only by a physician or a pathologist experienced in the technic of lumbar puncture and intrathecal injection. The serum is issued in outfits of four 25 cc. ampules, sufficient for the treatment of one case. Owing to the limited stock available at present, physicians are requested to confine the treatment to the preparalytic stage or exceptionally to a pyrexial phase when the symptoms indicate rapidly progressive invasion of the cord, as shown by extension of paralysis. The serum is on no account to be used in the postfebrile stage, when the infection has become quiescent and paralysis is established.

Milk-Borne Diseases

At the International Pediatric Conference, held in London, an important discussion took place on milk-borne diseases. Dr. J. M. Hamill, medical inspector of the Ministry of Health, said that about 7 per cent of the milk samples taken at various towns in the country contained tubercle bacilli. Two thousand deaths, mostly in children, occurred annually from bovine tuberculosis, and there were a large number of persons with nontuberculous bovine tuberculosis who did not die from the disease but were sufferers throughout life. There was little likelihood that within a reasonable time it would be possible to obtain a tubercle-free milk supply. It would therefore be necessary to rely on pasteurization. But in addition to that all efforts should be made to reduce disease in cattle.

Dr. Wilburt C. Davison of Durham, N. C., suggested that there was just as much danger of infection of milk in the home from mother's fingers or flies' legs as in the dairy. The only safe sterile milk, which remained sterile, was evaporated milk unsweetened, which, with the addition of an equal quantity of water and a small amount of lactic acid, provided a perfectly pure milk, even cheaper than raw milk.

Prof. G. B. Allaria of Turin said that there was always a debatable question between those who asserted the necessity of giving children raw milk and those who upheld the necessity for bacterial purification, even at the expense of its vital properties. In the present state of the dairy industry in most countries the bacterial danger was the greater. This view was also supported by Prof. Pierre Lereboullet of Paris, who, while urging a vigorous initiative to improve the conditions of milk production and sale in all countries, so that a safe milk for all children might be available, contended that in the absence of such an elaborate and controlled organization the boiling of milk before consumption remained the sole method of protection.

Tribute to Dr. G. F. Still

Dr. G. F. Still, a pioneer in pediatrics, is about to retire from hospital engagements, and his friends have decided to recognize the occasion. In 1899 he was appointed to King's College Hospital, when no physician for diseases of children had ever been appointed to any of the teaching hospitals of London. A children's ward was in existence, but it was under the care of a gynecologist or the most junior member of the staff, who was required to hold it until he was promoted to the care of adults. But children's hospitals, including the leading one of Great Ormond Street, were already in existence. The example has been followed by many hospitals with medical schools. An influentially signed letter inviting subscriptions for the tribute to Dr. Still has been published in the medical and lay press. Among the signatures are those of Lord Beatty (chairman of King's College Hospital), Charles A. Fife (president of the American Pediatric Association), A. Dingwall Fordyce (president of the British Pediatric Association) and F. F. Tisdall (president of the Canadian Society of the Study of Diseases of Children). It is proposed that a "Dr. Still cot" will be endowed at King's College Hospital and an eminent artist, Mr. Gerald Kelly, has promised to give a portrait of Dr. Still if not less than \$2,500 is subscribed for the cot.

International Convention of Neurologists

The chief topic on the program of the thirteenth International Convention of Neurologists, recently held in Paris, was "Serous Meningitis." Professor Claude discussed the significance of this term, which he believes is inaccurate, as it includes three different types of disease: (1) internal hydrocephalus, which is a form of ventriculitis; (2) external hydrocephalus, which may be divided into several groups, one involving the dura mater, another the cerebral arachnoid, and (3) another the spinal arachnoid. The causes are various, being more commonly of infectious origin. The symptoms may be distinguished from the manifestations of cerebral tumors. The most significant symptom is headache, which may be accompanied by convulsions or coma. There is no hypertension of the cerebrospinal fluid.

Gaston Boschi of Italy read a paper on internal hydrocephalus, or ventricular serous meningitis. Hydrocephalus may be produced by reactions following irritative states within the neuraxon. They are facilitated by lymphatic plethora and by the retardation of metabolism. Finally, there is idiopathic hydrocephalus, which is to be considered the result of an infectious or toxic condition. The biologic mechanism whereby radiotherapy leads to improvement in the treatment of hydrocephalus is unknown.

Mr. Petit Dutailis discussed the surgical treatment of serous meningitis. When serous meningitis follows infectious diseases, repeated lumbar punctures may suffice. If there is a local focus of infection—often of otic origin, the focus should be carefully examined. Treatment of the hypertensive syndrome takes the form of trepanation and incision of the dura mater, according to the technic of Bourgeois. The clinical diagnosis of the subacute or chronic form is difficult to establish. Often only an operation will establish the diagnosis. Such palliative methods as punctures and decompression by trepanation act only on the intracranial hypertension. More and more, modern surgery tends to intervene directly in ependymitis of the lateral ventricles through opening up of the foramen of Monro, perforation of the septum lucidum, and in ependymitis of the fourth ventricle by opening up Magendie's foramen. Finally, the author considered the more hazardous treatment of arachnoiditis by incision, evacuation and resection of the pockets.

Clovis Vincent, Marcel David and Pierre Puech explained the indications, the technic and the accidents of ventriculography. Following Cushing, the authors use the method more and more (in 50 per cent of the cases coming to operation). They operate in the hours immediately following ventriculography, avoiding thus accidents due to the exploration. Clovis Vincent, F. Rappoport and J. H. Berdet, discussed ventriculography performed by the lumbar route, which enables the operator to make the cerebral ventricles and the subarachnoid spaces visible simultaneously. For a study of the ventricles, this method would not be equal to direct encephalography. It is sometimes used as a therapeutic intervention in disorders following cranial injuries, in which it has sometimes given good results. The technic is delicate. The problem is to withdraw the fluid only so fast as it can be replaced by sterile air, in order not to cause the pressure to vary, and then to apply radiography immediately. The authors have not had any serious accidents in sixty-five cases.

Negligence in Application of Law on Notification of Contagious Diseases

The Academy of Medicine, in a booklet published by the academy itself, complains of the negligence in the enforcement of the law pertaining to the compulsory notification of contagious diseases. Many physicians neglect to make such notifications, usually to save their patients inconvenience. Notification brings a crew of official disinfectors, who overrun the apartment or inundate it with antiseptics. The physician prefers, particularly in homes of the rich, to have the disinfection carried out by private companies that are more careful, working under his own supervision. But, since statistics are based on these notifications, the result is that they are, to a certain extent, distorted. The academy has become aroused by this state of affairs. A commission, of which Prof. Léon Bernard was chairman, reported that there has been of late some slight improvement, but only in the departments of France in which there is a health inspector. Many of the departments, however, have no health inspector. In a resolution addressed to the minister of public health, the academy calls the attention of the minister to the fact that the notification of all diseases regarded as contagious is compulsory according to law and that the responsibility for the fulfilment of such duty rests on the head of the family, the heads of institutions and the physicians in charge. The resolution adds that the law would be much better enforced if the minister would see that, in all the departments, a health inspector is installed, since the physicians are more willing to apply to a health inspector than to the offices of the prefecture.

Tincture of Iodine in Disinfection of the Skin

The method introduced in 1908 by Grossich of Trieste for the disinfection of the skin with tincture of iodine before surgical operations was rapidly adopted throughout the world. Dr. Robert Sorel of Havre, however, has for years opposed this procedure. According to Sorel, tincture of iodine has only a superficial value and does not assure a sterile operative field for more than twenty minutes, which is not sufficient. There develops a varnish-like covering composed of cauterized epidermis, in which fissures soon appear, which allow the subjacent micro-organisms to emerge, with the secretions of the cutaneous glands. The use of any other varnish would render exactly the same service, as Sorel proved experimentally. Samples taken by means of a platinum wire passed over the skin twenty minutes after painting with iodine nearly always give positive cultures. The procedure gives a false sense of security, by dispensing with thorough disinfection of the skin, as was formerly done. Sorel, at the Hôpital du Havre and in the clinic, operates without painting with iodine. The patient first takes a long bath; then, on the operating table, the operative

field is covered simply with sterile compresses. The surgeon passes over the line of incision a compress dipped in sterile soap and wipes off the surplus with a dry sterile compress. He then operates, and when the skin is closed he removes the traces of blood with a compress dipped in sterile soap and then applies a sterile compress to the wound. No antiseptic fluid is employed at any time. Sorel has used this procedure with good results for more than ten years. Tincture of iodine, he says, irritates the skin.

The Visibility of Ultraviolet Rays

Ultraviolet rays have been regarded as invisible to the human eye. That is not absolutely true; at any rate, the visibility varies with the age of the person. Mr. Jean Saidman has made a filter that absorbs completely the rays of the visible spectrum and also the beginning portion of the ultraviolet rays, while preserving good transparency up to 3,100 angstroms. With this filter he studied the visibility of the ultraviolet rays. He found that the visibility of the 3,130 region, though constant in youth, disappears between the ages 34 and 43, or thereabouts. Of the seventy-two persons who saw the ultraviolet rays with both eyes, fifty-two stated that the impression was alike for the two eyes and twenty-two saw much better with one eye than the other. The human crystalline lens is therefore not so opaque as was supposed. The disappearance of the visibility of ultraviolet rays up to 3,130 angstroms would indicate an aging of the crystalline lens, and the procedure described might, the author states, be used to detect the beginning of ocular sclerosis.

July 3, 1933.

Reorganization of Higher Schools of Learning

According to an announcement of the Prussian ministry of public instruction, plans for reorganizing the higher institutions of learning will be carried out in the near future. The reorganization is to begin with a sharp adjustment of the incomes of the head professors and the poorly compensated extraordinarii and privatdozenten. It will then be extended to the makeup of the faculties and to reshaping the courses of instruction. In an official report of the ministry for science, art and public education, the announcement is made that it would be inconsistent with the principles of the national government and the corporate character of the higher institutions of learning if private organizations such as the Verband der deutschen Hochschulen or the Rektorenkonferenz should be allowed to participate in the deliberations. The ministry reserves, however, the right in some cases to request certain of the rectors and eminent specialists to take part in the deliberations. The Hochschulverband also will continue its social tasks (supplying of aid for the families of deceased members) with the full approval of the ministry.

The minister of public instruction has informed the faculties that, in the coming months, he will depart from the customary procedure in the appointment of new professors. In a number of cases the faculties will not be requested to send in a list of the men they would like to see elected to fill vacancies, but the faculties will be given an opportunity to approve or disapprove proposals made. This simple method of deciding on new appointments is said to be necessary because otherwise the prompt filling of vacancies is endangered.

As the second measure, which is based on a law that went into effect July 1, it has been decreed that the authorities can intervene widely in the property rights of officials for the purpose of equalizing salaries, and that a reexamination by the courts is absolutely excluded. This equalization (which amounts in reality to a reduction) of salaries is to be carried out strictly, without taking account of special assurances, agreements, adjust-

ments and judicial decisions or settlements that may be of record. With regard to instructors in institutions of higher learning, it is provided that assurances given in connection with a calling to a post (which have always been customary, as regards the guaranteed income from students' lecture fees) may be altered or abolished, with the exception of those pertaining to the establishment of seniority.

For the first time since the war, there has been a decline in the last few years in attendance at German higher institutions of learning. The matriculations (after deducting the future public school teachers, who, of late, have participated in university courses) dropped from 21,525 in the summer of 1928 to 18,767 in the summer of 1932. In the summer of 1928 the number of new male students in the universities was 17,969; last summer the number dropped to 15,259. The number of new female students rose from 3,559 in the summer of 1928 to 4,664 in the summer of 1931, but in the summer of 1932 it dropped to 3,508. The decline from the summer of 1931 to the summer of 1932 amounted to 13.8 per cent.

Marriage Consultation Centers Closed

The Berlin municipal prenuptial consultation centers have been closed for the time being. Their reopening on a new basis will not be considered until the principles that are to govern the promotion of population in the new state have been established with precision.

Berlin established in 1926 its first prenuptial consultation center, following a resolution passed by the Prussian parliament demanding that persons about to be married be required to exchange health certificates. The resolution was not incorporated in a federal law, so the proponent had to be content with a voluntary health certificate issued gratis to engaged couples following a thorough physical examination. Leaflets that were given out by the bureau in charge of marriage licenses called attention to this new arrangement. The desire for an official certificate of health was regarded, in spite of attempts to explain the need of such a document, nearly always as offensive. If the physician established that either applicant was unfit for marriage, the advice of the physician was not usually followed. Almost without exception, feelings of self interest proved stronger.

The happy idea of allowing the physician in charge of a consultation center a large measure of liberty in rendering decisions led to a wide difference in the centers, of which there are hundreds in Germany. In many of these centers, consultations on marriage difficulties became the center of interest. Information on birth control gave some centers a socialistic trend.

The announcement of new regulations in this field is awaited with interest, for it is the understanding that they go far beyond the cases commonly handled in the centers and will influence the future of the German family. In any event, one can count on a federal regulation of births, having as its objective improvement in the health of the people, with emphasis on the prevention of children being born to incurable patients, weak-minded persons, and the like. The numerous opponents of present laws on the interruption of pregnancy would go even further. They have demanded for years a reform. They hope that this question, which for women is a matter of life and death, may be solved. They do not demand abolition of the paragraph of the penal code on abortion but they do demand its revision.

There is a different trend in southern Germany. The Badische Gesellschaft für Eugenik, a chapter of the Deutsche Gesellschaft für Rassenhygiene, has established in Karlsruhe a medical prenuptial consultation center for persons of moderate means, the purpose of which is to seek out the families of physical and mental superiority and to promote the propagation of children within their ranks, while endeavoring to prevent such propagation in families of inferior type.

Aims of the National-Socialist Medical League

According to an announcement at a joint session of the National-sozialistischer Deutscher Aerztebund and the Bund Deutscher Aerzte, Gau München, the agenda for the immediate future are as follows: admission of ex-service men in accordance with special regulations; measures to prevent two sources of income to one person, in order that as many persons as possible may have an opportunity to earn a living; simplification of the fee schedule; revision of the laws pertaining to physicians of the health insurance panel; regulation requiring every physician to begin his medical practice in the rural districts, a measure that is designed to promote a deepening and a broadening of medical experience, as well as the supplying of neglected regions with adequate medical service; organization of an order of federal physicians to serve as a guiding body; reforms in medical studies in the direction of a stronger emphasis on practical training and development of character.

Unfair Medical Advertising

The Prussian minister of the interior has issued an order concerning the advertising of articles, devices, remedies or procedures for the prevention or treatment of disease in man or animals. Forms of advertising in which the actions and effects ascribed to these articles are beyond their true value and deceptive advertising are prohibited. It is also forbidden to advertise devices and remedies that may be injurious to health or can be dispensed only on prescriptions issued by physicians or veterinarians. This executive order creates a uniform law in this field—at least for Prussia. It will not only check illegal traffic in certain medicines, which had become unbearable and was seriously interfering with scientific medicine, but will also suppress the fraudulent traffic in harmless remedies at exorbitant prices following fantastic therapeutic claims, causing patients to delay in consulting a physician. It will work against the "patent medicine" swindle, which advertised in the daily press and with pamphlets.

MADRID

(From a Special Correspondent)

June 10, 1933.

Seventh International Congress of Military Medicine

At the seventh International Congress of Military Medicine and Pharmacy in Madrid, May 29-June 5, twenty-six nations were represented; 1,400 conventionists, including the president of the republic, the minister of war and the minister of marine, attended the opening session, in the Teatro de la Comedia. Dr. Coca welcomed the conventionists in the name of the municipal council of Madrid.

After addresses by Lieut. Col. A. Van Baumberghen, M.D., Gen. Gonzalez Granda, president of the congress, and Lieutenant Colonel Voncken, M.D., general secretary of the permanent committee of the congress, the president of the republic, in a vigorous address, exalted the rôle of military medicine, and pointed out that international ties established by the congresses may constitute a guaranty of peace among the nations.

In the evening, the president of the republic gave a reception in the National Palace, displaying a cordiality that delighted every one. During the congress, excursions to the Escorial and to Toledo were organized. A magnificent reception was given by the government in the salons of the Hotel Ritz. Thanks are due the ladies' committee for its efforts to make the visit pleasant for the foreign ladies who attended the sessions. Several topics were discussed.

PRINCIPLES UNDERLYING SANITARY ORGANIZATION DURING WAR; APPLICATIONS OF NEW GENEVA CONVENTION

The papers on the first topic were presented by Col. Potous Martinez, M.D.; Lieut. Col. Gonzales Deleito, M.D.; Fernandez

de Rojas y Cedrun, assistant pharmaceutical inspector of the Spanish army, and Lieutenant Colonel Nordlander of the Swedish army.

The conclusions adopted were:

1. In view of the broad nature of the subject, the conclusions must take on a general character and cover the following points: (a) prevention, (b) evacuation, (c) treatment and (d) recuperation.

2. Consequently, the complex activities for the promotion of the health of the army should develop under the general supervision of the commanding officer, but with complete independence as regards everything pertaining to the use of sanitary personnel and equipment.

3. The quality of the service will be improved if the personnel of the sanitary corps has been carefully selected and has received a special military and technical training.

4. Such preparation is necessary also for the supplementary and the reserve personnel, an appeal being made to the mobilized civil practitioners in the ranks of the army.

5. In view of the constant evolution of medical science, a body of specialists of proved ability should be organized within the army medical corps.

6. The Geneva Convention, the magna charta of the army medical corps, establishes only the general principles that must be applied by all in a uniform manner. It therefore appears desirable to codify all the measures to be adopted on the subject.

PREVENTIVE VACCINATIONS IN MILITARY FORCES

The papers on the second topic were presented by Captain Sheldon, surgeon; Captain Whittingham, M.D., and Lieutenant Colonel Dawson, of the British army; Major Masaji Kitano of the Japanese marine, and Major Saéz F. Casariego, pharmacist, and Lieut. Col. Fernandez Martos, M.D., of the Spanish army.

The conclusions adopted were as follows:

1. Preventive vaccinations designed to protect the troops against infectious diseases should be given, in times of peace as well as of war, in order to combat epidemics and outbreaks. The application of this measure will vary according to the existing health conditions in the armies concerned.

2. Vaccination must not relieve one, by any means, of using all other measures to combat contagion.

3. The method of combined vaccinations is to be recommended.

4. It is desirable that, before he is assigned to a unit, the soldier shall be immunized against those infectious diseases which are amenable to vaccination. It is recommended that, in each country, an understanding should be reached between the civil and military authorities as to the best methods of vaccinating.

5. It is desirable that the methods employed in the various armies for the preparation of vaccines and other prophylactic measures be published.

TREATMENT OF URGENT SURGICAL CASES AT THE FRONT

The papers on the third topic were presented by Lieut. Col. Gomez Ulla, M.D.; Commandant Sanchez Vega, M.D.; Commandant Herre Menguijon, M.D.; Capt. Madruga Jimenez, M.D.; Capt. Martin Santos, M.D.; Campoy Irigoyen, pharmacist, of the Spanish army; Commandant Martinez Falero, M.D., and Commandant Abengoichea Laita, M.D., of the Spanish marine, and Lieut. Col. Leman, M.D., of the Belgian army.

The conclusions adopted were as follows:

1. The success of the treatment depends on the rapidity and on the manner of the evacuation to the nearest surgical center.

2. The conception of a specialized surgical unit must necessarily, in warfare, be based on the experiences of the World War.

3. Considering the nature of open warfare, the types of surgical field hospitals in the last war appear too complicated.

As a more mobile unit, the motorized, interchangeable surgical group is suggested.

4. This unit would constitute an army corps service intermediate between the services of the extreme front line, the divisions, and the more fixed services of the army.

5. For the performance of its duties, it will take up its position in the immediate vicinity of the field hospital or of requisitioned buildings, as the case may be, and must be supplied with suitable means of transportation.

6. The proposed surgical unit will be modified as much as possible in accordance with the circumstances of the war and, especially, the nature of the terrain. It must be light and mobile.

PRESERVED FOODS IN THE RATION IN PEACE AND WAR

The papers on the fourth topic were presented by Emilio Salazar Hildago, pharmaceutical assistant inspector of the second class; Juan Casas Fernandez, pharmacist of the first class; Pedro Calvo Munoz Torrero, pharmacist of the first class; Eduardo Robles Perez, commandant of the commissariat, and Lieut. Col. Victor Herrero y Diez de Ulzurum, M.D., of the Spanish army; Emilio Fernandez Espina, commanding pharmacist, of the Spanish marine, and Colonel Thomann, pharmacist, of the Swiss army.

The conclusions adopted were as follows:

Preparation and Preservation: 1. In view of the importance of preserved foods in the diet of the soldier, the first condition that such foods must fulfil is a good method of preservation.

2. To assure good preservation, it is necessary that (a) the products used (meat, flour, ground products, milk, and the like) should be of the best quality; (b) during the preparation of the preserved foods the greatest cleanliness must be observed, and the sterilization must be thorough and complete. If sterilization is not possible, desiccation (bread, soup and the like) may be sufficient.

3. With the exception of sodium chloride, and saltpeter in minimal quantities, all preservatives must be prohibited.

4. The date of manufacture must be stamped on the metal receptacle or printed on the package.

5. Since, at present, the analytic procedures vary in different countries, it is desirable to bring about uniformity in the methods of analysis in use in armies and to have these methods published either in the pharmaceutical formularies or in other documents placed in the hands of the military pharmacists.

6. The control of preserved food products in the rations of armies should be entrusted in principle (a) to a bacteriologist and to a medical hygienist, for the appraisal of the nutritive value, and (b) to specially qualified chemist-pharmacists, for the chemical aspects of the problem.

STUDY ON ORGANIZATION OF THE DENTAL SERVICES

The papers on the fifth topic were presented by Dr. Angel Vazquez of the Spanish army and the Mexican army medical corps.

The conclusions adopted were as follows:

1. The creation of an odontostomatologic service for the whole army is desirable.

2. Its activities would take the form of (a) prophylaxis, hygiene and buccodental treatment, and (b) possible cooperation with the identification services.

3. The technical personnel should be made up of professional dentists and stomatologists with legal diplomas.

4. Medicomilitary specialization on the part of odontologists should be based on a suitable preparation.

ORGANIZATION OF THE ADMINISTRATIVE SERVICES

The papers on the sixth topic were presented by Frederico Abeille y Rodriguez Fito, lieutenant colonel of the commissariat, and José Abadal y Sibila, pharmaceutical subinspector of the second class, of the Spanish army.

The conclusion adopted was that, since a good administrative management constitutes an indispensable guaranty of the correct functioning of the sanitary services, it is desirable to entrust such duties to a body of officers specially trained for the work.

OTHER TOPICS

During the congress, a number of special meetings of the chief officers of the sanitary services, in which the delegates of the association of international law and the Spanish national group of the international association of social progress participated, were held. The questions discussed included the development of international collaboration in the domain of military medicine (1) from the social point of view and (2) within the compass of international law.

The next congress will be held at Bucharest in September, 1935, under the chairmanship of Medical Inspector Butoiano, head of the Rumanian army medical corps. The following topics will be discussed: (1) principles of the organization and functioning of the sanitary services in mountain warfare, discussion to be opened by Rumania and Italy; (2) determination of the aptitude for various specialties in the land, sea and air forces, discussion opened by Rumania and France; (3) sequels of abdominal wounds, presented by Rumania and the United States; (4) research designed to make more uniform the methods of analysis of foods and beverages, discussion to be opened by Rumania and Czechoslovakia; (5) promotion of buccodental care, presented by Rumania and Lithuania, and (6) comparative study on the characteristics of the sanitary administrative services, discussion to be opened by Rumania and Chile.

The International Bureau of Bibliography of Military Medicine

The third session of the International Bureau of Bibliography of Military Medicine, in the auditorium of the university in Granada, June 5-8, 1933, was attended by more than 200 persons representing twenty-seven nations. Following is a list of the papers presented, all of which gave rise to exhaustive discussion: Functioning of the Army Medical Corps in the field, by Colonel Schickelé, M.D., of France; The Evolution of War Surgery, by Inspector General Butoiano, M.D., Rumania; Medical Inspection of the Various Classes Before and After Military Service, by Commandant Don Ricardo Murillo Ubeda, M.D., Spain; Professional Selection in the Army; Psychotechnical Recruiting, by Capt. Enrique Blasco Salas, M.D., Spain; Chemistry in the Service of Hygiene in the French Marine, by Saint Sernin, pharmaceutical chemist of the first class, France; Military Medicine and Its Relations to Modern Warfare, Especially from the Point of View of Aviation, by Lieut. Commander Julius Neuberger, United States; Cysticercosis as the Cause of Epilepsy in Soldiers, by Colonel Huszcsa, M.D., Poland; Military Medicine in the Service of the Mobilized Nations, by Captain Reynders, M.D., Belgium; Actinotherapy, Ultraviolet Rays and War Surgery, by Juan Ortega Lechuga, M.D., Spain; Role of the Military Pharmacist in the Army and Organization of This Service, by Rafael Roldan y Guerrero, pharmacist, Spain; Lesions of the Meniscus, by Captain Glorieux, M.D., Belgium; and National and International Organization of Civil Protection Against Chemical Warfare, by Captain Cambresier, M.D., Belgium.

ALLOTMENT OF A SPECIAL AREA FOR THE SANITARY SERVICES

The congress, viewing the great dangers from bombardment to which the sanitary field units and the fixed hospital establishments are exposed, adopted the following double resolution:

1. Adequate space should be reserved for the exclusive needs of the sanitary services and should be identified by the insignia of the Red Cross.

2. Regulations should be established as soon as possible covering the details of the application of the provision of

July 29, 1929, of the Geneva Convention, looking toward the amelioration of the lot of the sick and wounded of the armies in the field.

APPLICATION OF THE GENEVA CONVENTION

The congress adopted a resolution demanding that the stipulations of articles 26 and 29 of the Geneva Convention of July 27, 1929, be carried out as soon as possible by the governments that were signatories of the convention, in the following manner: 1. Military regulations shall mention the principal provisions of the Geneva Convention. 2. The codes of military justice shall establish the penalties applicable in case of violation of this convention.

The permanent committee of the congress empowered the Spanish Association of International law to draft a preliminary document to be submitted at the next meeting of the bureau, in 1934.

VIENNA

(From Our Regular Correspondent)

July 10, 1933.

The Roentgenologic Examination of Nerves, Lymphatics and Blood Vessels.

A demonstration of a new method of roentgenologic diagnosis with the aid of contrast mediums was given here at a recent session of the Gesellschaft der Aerzte, by Dr. M. Saito of Japan. To render peripheral nerves visible, Dr. Saito injected at first iodized poppy-seed oil and later a 25 per cent solution of thorium dioxide applied percutaneously, perineurally or intraneurally. He used, at the most, 1 cc. intraneurally or 20 cc. perineurally. If the nerve to be reached lies in the deeper tissues, it must first be laid bare operatively. After from three to eight days the roentgenogram can be made.

In the roentgenograms exhibited by Dr. Saito, one saw a normal nerve (injected intraneurally) whose various bundles of fibers, 20 cc. in length, were plainly visible; then a perineural injection, in which the external and the internal layers were distinctly seen, and then a nerve with traumatic adhesions following an injury (which later could be broken up operatively). Great interest was shown in an injected nerve of a leprosy patient, whereby the nodulous thickening became readily visible; likewise the roentgenogram of a neuroma. An epidural injection of an emulsion of iodized poppy-seed oil made also the lumbosacral plexus easily recognizable. Lymphatic vessels were made visible in the same manner, particularly by injection of the fluid into the larger lymphatic vessels, such as the knee joint, the peritoneal cavity or the lymph glands. One could see how the contrast medium spreads out into the lymph paths. One could see a lymph vessel along the leg, following injection of the knee; an intercostal lymph vessel following peritoneal injection (both in man), and in a dog an intrathoracic lymph vessel, likewise following a peritoneal injection. In the field of arteriography, Dr. Saito secured with this method good results. In a case in which traumatic hemorrhage within the brain was suspected, he injected a 25 per cent solution of thorium dioxide into the superior thyroid artery, and not only the cerebral arteries became visible but also the capillaries and the veins. In more than 200 cases in which, during the past two years, the author applied such injections, he saw no evidence of serious injury.

During the discussion, various authors called attention to the poisonous nature of solutions of thorium dioxide as applied to animals, but Professor Pick pointed out that it is perhaps dangerous only in myelography and encephalography (as all other colloids) and should hence not be used by way of the cisterna magna. In any event, Dr. Saito emphasized in closing that, in his experiments, no damage to speak of had occurred in human beings; not even in connection with arteriography applied to gangrenous extremities.

Prof. Viktor von Hacker's Death

The death of Prof. Dr. Viktor von Hacker, formerly famous as a surgeon, in Vienna, at the age of 81, was recently announced. With von Hacker, the last of the assistants of Theodor Billroth has passed. After thorough training in pathologic anatomy, he entered, in 1880, the clinic of Billroth, who soon recognized his ability and chose him as his assistant. From this period came his research on the antiseptic treatment of wounds after the method of Lister. He soon became the head of the surgical department of the Vienna Policlinic and in 1895 was called to Innsbruck and in 1903 to Graz, as the head of the clinic. He remained the director of the latter institution until 1924 and brought about its reorganization. The scientific activity of von Hacker and his operative technic were fundamental mile-stones in the progress of surgery, especially for gastro-intestinal diseases. Retrocolic posterior gastroenterostomy, the technic of the construction and closure of the artificial anus, operations on the stomach in carcinoma and cicatricial stenosis, and the temporary exclusion of certain portions of the intestine were the results of his research and constituted some of the most important surgical contributions of that period. Surgery of the esophagus, esophagoscopy for the location of foreign bodies, mediastinotomy, surgery of diverticula and esophagoplasty were studied by von Hacker with fruitful results. His plastic operations on the nose and face and the treatment of fractures by means of the "Hacker triangle" (upper arm fracture) are widely known. The Graz clinic, formerly directed by von Hacker, was taken over a short time ago by Denk and later by Professor Walzel.

Marriages

LEO E. BRAUNSTEIN, Schenectady, N. Y., to Miss Anne Miller of Auburn, Maine, in Albany, N. Y., July 2.

MARGARET R. MACM. DOUGHERTY to Mr. Harry Sherman Hodge, both of Mount Holly Springs, Pa., July 5.

PAUL G. HANNA to Miss Mary Alice Barber, both of St. Joseph, Mich., in South Bend, Ind., June 17.

JOSEPH ROGERS YOUNG, Washington, D. C., to Miss Anne Beverley Sinclair of Manassas, Va., July 6.

WILLIAM RODGER GILMOUR, Philadelphia, to Miss Marjorie Roach of Princeton, N. J., June 15.

WILLIAM WAUGH TURNER, JR., to Miss Ruby Christina Gaskins, both of Nashville, Ga., July 2.

THOMAS CAMPBELL HOOTON to Miss Katharine Corbin Willis, both of New York, June 28.

BERTRAND M. HART, Onida, S. D., to Miss Jennette Hoggan of Rochester, Minn., June 22.

ARTHUR NORDEN BOLZ, Walnut, Ill., to Miss Marjorie Claire Muesse of Erie, June 18.

HARVEY VAN BUREN, Statesboro, Ga., to Miss Hazel Marie Davis of Marion, Ala., in June.

LOUIS J. LEVINSON, Newark, N. J., to Miss Beatrice E. Levine of New York, June 25.

CONRAD WALL, Boston, to Miss Nell Louise Kennedy of Columbus, Miss., June 14.

JOHN W. McDOWELL, Seattle, to Miss Kathryn Witmer of San Jose, Calif., June 10.

MANUEL SPIEGEL, Chicago, to Miss Janice Gottlieb of Kenosha, Wis., June 17.

KNUT REUTERSKIOLD, Chicago, to Dr. VIRGINIA JACKOLA of Polo, Ill., June 17.

THOMAS JAMES MERAR, Quincy, Ill., to Miss Iva Russakov of Chicago, June 18.

ROBERT BRUCE NYE, Philadelphia, to Miss Alice Barrow Stone, June 15.

DAVID L. MILLIKEN to Miss Sarah Gordon, both of New York, June 26.

JOSEPH W. SHAW, Seattle, to Miss Betty Gue of Portland, Ore., June 30.

BELLA LEWINSON, New York, to Mr. Morris M. Gilbert, July 18.

Deaths

Richard Smith Dewey @ La Cañada, Calif.; University of Michigan Medical School, Ann Arbor, 1869; chairman of the Section on Nervous and Mental Diseases, American Medical Association, 1901-1902; in 1896, president of the American Psychological Society, now the American Psychiatric Association; past president of the Chicago Neurological Society; served in the Franco-Prussian War; professor of mental and nervous diseases, Chicago Post-Graduate Medical School, 1893-1909; medical superintendent of the State Hospital for Insane, Kankakee, Ill., 1879-1893, and in charge of the Milwaukee Sanitarium, Wauwatosa, Wis., 1895-1921; aged 87; died, August 4.

Isador Abrahamson @ New York; College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1894; clinical professor of neurology, University and Bellevue Hospital Medical College; member of the American Neurological Association and the Association for Research in Nervous and Mental Diseases; on the staffs of the Mount Sinai Hospital, Montefiore Hospital for Chronic Diseases, New York, the Brooklyn Hebrew Home and Hospital and the Jewish Hospital, Brooklyn; aged 61; died suddenly, July 16, at his home in Loon Lake, N. Y., of heart disease.

Henry Nelson Pulliam, Memphis, Tenn.; University of Tennessee College of Medicine, Memphis, 1919; member of the Tennessee State Medical Association, and the Radiological Society of North America; assistant in roentgenology at his alma mater; served during the World War; aged 44; on the staff of the Memphis General Hospital, where he died, July 10, of heart disease.

Samuel Browning Locker, Menard, Texas; Memphis (Tenn.) Hospital Medical College, 1909; member of the State Medical Association of Texas; president of the Mason-Menard-McCulloch County Medical Society; served during the World War; aged 57; died, March 25, in Brownwood, of hypertrophic cirrhosis of the liver.

John Franklin Kidd, Ottawa, Ont., Canada; Queen's University Faculty of Medicine, Kingston, 1883; past president of the Canadian Medical Association; fellow of the American College of Surgeons; served during the World War; consulting surgeon to the Ottawa Civic Hospital; aged 69; died, July 13.

William Watson Conger @ Major, M. C., U. S. Army, New Haven, Conn.; Jefferson Medical College of Philadelphia, 1903; served during the Spanish-American and World wars; entered the medical corps of the U. S. Army in 1920 as a major; aged 61; died, June 29, of heart disease.

Enoch David Wall, Marianna, Ark.; University of Nashville (Tenn.) Medical Department, 1905; member of the Arkansas Medical Society; served during the World War; for many years health officer of Marianna; aged 52; died, July 9, of amebiasis and cerebral hemorrhage.

Samuel Bee Woodward, Asheville, N. C.; Tulane University of Louisiana School of Medicine, New Orleans, 1920; for six years on the staff of the Veterans' Administration Home, Dayton; aged 37; died, June 18, in St. Joseph's Sanatorium, of pulmonary tuberculosis.

Harvey C. Powell @ Morgantown, W. Va.; Baltimore Medical College, 1902; served during the World War; past president of the Monongalia County Medical Society; on the staff of the Monongalia County Hospital; aged 52; died, June 30, of carcinoma of the liver.

Henry Ainsworth Yenetchi, Somerville, Mass.; University of Vermont College of Medicine, Burlington, 1879; member of the Massachusetts Medical Society; aged 76; died, June 9, in the Lawrence Memorial Hospital, Medford, of coronary thrombosis.

Rodolfo Eugene Monaco, Newport Beach, Calif.; University of Louisville (Ky.) School of Medicine, 1925; member of the Associated Anesthetists of the United States and Canada; aged 33; died, June 7, in Pasadena, Calif., of seminoma of the left testicle.

Henry Leland Noel, Lexington, Miss.; Memphis (Tenn.) Hospital Medical College, 1898; served during the World War; aged 64; died, May 14, in the U. S. Veterans' Hospital, number 63, Lake City, Fla., of pneumonia and diabetes mellitus.

Daniel Thomas O'Keefe, Boston; College of Physicians and Surgeons, Baltimore, 1892; member of the Massachusetts Medical Society; aged 66; died, June 22, in the Carney Hospital, of bronchopneumonia and cirrhosis of the liver.

Clarence Percy Burnett, Paducah, Ky.; University of Louisville School of Medicine, 1900; member of the Kentucky State Medical Association; formerly health officer of Paducah; aged 57; died, June 30, of carcinoma of the throat.

Cary F. Legge, Newark, Ohio; Ohio Medical University, Columbus, 1898; member of the Ohio State Medical Association; formerly county coroner; aged 65; died, July 8, of atrophic cirrhosis of the liver and toxemia.

Vacil Demetroff Bozovsky @ Dunkirk, N. Y.; University of Michigan Medical School, Ann Arbor, 1894; on the staff of Brook's Memorial Hospital; aged 67; died, June 24, of cerebral hemorrhage and myocarditis.

Everett Clark Moore, Brooklyn; University of Buffalo School of Medicine, 1928; aged 32; on the staffs of the New York Post-Graduate Hospital and the Bushwick Hospital, where he died, June 27, of pneumonia.

John Murdoch Pratt, National Military Home, Calif.; University of Pennsylvania School of Medicine, Philadelphia, 1908; aged 48; died, May 23, of lymphatic leukemia, chronic endocarditis and subacute pericarditis.

Charles Leland Allen, Wesleyville, Pa.; Medical Department of Western Reserve University, Cleveland, 1889; Jefferson Medical College of Philadelphia, 1892; aged 74; was found dead, July 2, of cerebral hemorrhage.

Willard Filmore Robinson @ Mars Hill, N. C.; Vanderbilt University School of Medicine, Nashville, Tenn., 1896; secretary of the Madison County Medical Society; aged 63; died, July 1, of angina pectoris.

Henry Hermann Kapp @ Winston-Salem, N. C.; Jefferson Medical College of Philadelphia, 1901; on the staff of the City Memorial Hospital; aged 53; was found dead, July 9, of a self-inflicted bullet wound.

Barney Burns Rogan, Selma, Ala.; Chattanooga (Tenn.) Medical College, 1896; member of the Medical Association of the State of Alabama; aged 57; died, July 1, in the King Memorial Hospital, of uremia.

William Hadley Parker @ Wellston, Ohio; Starling Medical College, Columbus, 1898; served during the World War; aged 61; died, June 24, in the White Cross Hospital, Columbus, of coronary thrombosis.

John B. Gordon, Stephenville, Texas; University of Georgia Medical Department, Augusta, 1880; member of the State Medical Association of Texas; aged 78; died suddenly, May 29, of heart disease.

Richard Fuller Harrell, Boulder, Colo.; Tulane University of Louisiana Medical Department, New Orleans, 1879; Gross Medical College, Denver, 1893; aged 79; died, June 27, of cerebral hemorrhage.

John Ballagi @ Homestead, Pa.; Medical Faculty of the Royal University Petrus Pázmány, Budapest, Hungary, 1881; on the staff of the Homestead Hospital; aged 75; died, April 10, of myocarditis.

Michael Mislig, New York; Cornell University Medical College, New York, 1902; member of the Medical Society of the State of New York; aged 65; died suddenly, June 28, of heart disease.

Martin Burke, New York; Bellevue Hospital Medical College, New York, 1876; member of the Medical Society of the State of New York; aged 77; died suddenly, July 10, of heart disease.

Edward Merle Frissell, Webster, Mass.; University of Vermont College of Medicine, Burlington, 1883; aged 73; died, April 11, in the Webster District Hospital, of cerebral hemorrhage.

Abraham Lincoln McIntyre, Petersburg, Ohio; Western Pennsylvania Medical College, Pittsburgh, 1896; aged 67; died, June 30, of uremia, chronic interstitial nephritis and arteriosclerosis.

Worley George Martin, Rippey, Iowa; State University of Iowa College of Medicine, Iowa City, 1909; formerly member of the school board; aged 56; died, June 13, of heart disease.

William Kilpatrick Lane, Ocala, Fla.; Jefferson Medical College of Philadelphia, 1902; member of the Florida Medical Association; aged 55; died, June 9, of pulmonary tuberculosis.

John S. Terry, Ennis, Texas; Medical College of Evansville, Ind., 1883; member of the State Medical Association of Texas; aged 72; was killed, June 3, in an automobile accident.

Charles Hardy Bailey, Gardner, Mass.; Dartmouth Medical School, Hanover, N. H., 1881; member of the Massachusetts Medical Society; aged 76; was killed, July 12, by a t.

Irene May Morse, Clinton, Mass.; Tufts College Medical School, Boston, 1906; served during the World War; aged 66; died, June 20, in the Clinton Hospital, of chronic nephritis.

Gabriel Amoros, Rio Piedras, P.R.; Bennett Medical College, Chicago, 1915; member of the Medical Association of Puerto Rico; aged 46; died, April 27, of angina pectoris.

John R. Sharp, Washington, D. C.; Hahnemann Medical College and Hospital of Philadelphia, 1901; aged 57; died, July 10, of cerebral embolus and coronary thrombosis.

Sarah Marinda Loguen Fraser, Washington, D. C.; Syracuse University College of Medicine, 1876; aged 83; died, April 9, of bronchopneumonia and fracture of the femur.

Augustine Ben Childs, Keithsburg, Ill.; Rush Medical College, Chicago, 1908; served during the World War; aged 52; died, May 28, in Evanston, of hypertension.

Leonidas Shriver Patterson, Unionville, Iowa; Medical College of Ohio, Cincinnati, 1884; aged 73; died, June 16, of chronic nephritis and cerebral hemorrhage.

Matthew C. Freilinger, Baltimore; University of Maryland School of Medicine, Baltimore, 1906; aged 59; died, July 5, of carcinoma of the right lung.

Caroline A. Stevens Frizzell, Redlands, Calif.; Woman's Medical College of Pennsylvania, Philadelphia, 1875; aged 88; died, June 7, of coronary occlusion.

Jacob Lachowski, New York; University of Vladimara, Kiev, Russia, 1894; aged 62; died, July 11, of chronic myocarditis and coronary thrombosis.

Rufus E. Mathias, Irmo, S. C.; Medical College of the State of South Carolina, Charleston, 1905; aged 54; died, July 7, of cerebral hemorrhage.

Walter H. Brissenden, Roundup, Mont.; American College of Medicine and Surgery, Chicago, 1905; aged 58; died, June 6, of coronary embolism.

John Olson, Minneapolis; College of Medicine and Surgery, Chicago, 1909; aged 53; died, June 28, of diabetes mellitus and coronary occlusion.

James Robert Harvey, Vale, Ore.; Rush Medical College, Chicago, 1889; aged 73; died, April 2, in the Eugene (Ore.) Hospital, of paracystitis.

William L. Schutter, Albany, N. Y.; Albany Medical College, 1883; aged 70; died, July 7, in St. Peter's Hospital, of carcinoma of the larynx.

Albert Decatur Barr, Cherry Valley, Ark.; Joplin (Mo.) College of Physicians and Surgeons, Joplin, 1883; aged 72; died, July 3, of nephritis.

Myron A. Martin, Chicago; Chicago Physio-Medical College, 1898; aged 64; died, July 12, of carbon monoxide poisoning, self-administered.

Thomas D. Farrer, Caldwell, Idaho; Barnes Medical College, St. Louis, 1901; aged 64; died, May 22, of acute dilatation of the heart.

William L. Rieff, Perryville, Ark.; University of Louisville (Ky.) School of Medicine, 1891; aged 73; died, June 30, of endocarditis.

Gross Scruggs Chapman, Jackson, Ala.; Medical College of Alabama, Mobile, 1879; aged 77; died, June 25, of valvular heart disease.

Alonzo White, Palmyra, Mo.; Jefferson Medical College of Philadelphia, 1865; aged 91; died, June 25, of hepatic carcinoma.

William Claiborne Graves, Borger, Texas; Missouri Medical College, St. Louis, 1897; aged 65; died, July 1, of pneumonia.

Coyle J. Tracy, Pasadena, Calif.; Baltimore Medical College, 1897; aged 65; died, June 17, of hemorrhage from the duodenum.

James M. Webb, Ooltewah, Tenn.; Chattanooga (Tenn.) Medical College, 1900; aged 63; died, June 15, of chronic arthritis.

Sandy A. Moir, Francisco, N. C.; College of Physicians and Surgeons, Baltimore, 1886; aged 70; died, May 29, of pellagra.

Clarence D. Harris, Morley, Mo.; Missouri Medical College, St. Louis, 1895; aged 58; died, July 4, of heart disease.

William O. Thomas, Irving, Texas (licensed, Texas, under the Act of 1907); aged 52; died, June 21, of acute pellagra.

Cecil R. Price, Starks, La.; Memphis (Tenn.) Hospital Medical College, 1912; aged 50; died, June 3, of heart disease.

Samuel D. Hodge, Bald Knob, Ark. (licensed, Arkansas, 1903); aged 65; died suddenly, June 28, of heart disease.

Bureau of Investigation

MISBRANDED "PATENT MEDICINES"

Abstracts of Notices of Judgment Issued by the Food and Drug Administration of the United States Department of Agriculture

[EDITORIAL NOTE: The abstracts that follow are given in the briefest possible form: (1) the name of the product; (2) the name of the manufacturer, shipper or consigner; (3) the composition; (4) the type of nostrum; (5) the reason for the charge of misbranding and (6) the date of issuance of the Notice of Judgment—which may be considerably later than the date of the seizure of the product.]

Mul-So-Lax.—Mul-So-Lax Laboratories, Inc., Kalamazoo, Mich. Composition: Petroleum oil (34 per cent) and phenolphthalein, emulsified with water. For chronic appendicitis, "liver troubles," colitis, etc. Fraudulent therapeutic claims.—[N. J. 18742; May, 1932.]

Mag-Net-O Balm.—Magneto Balm, Inc., Baltimore. Composition: Tar, red pepper, mustard oil, turpentine oil and methyl salicylate incorporated in petrolatum. For rheumatism, headaches, etc. Fraudulent therapeutic claims.—[N. J. 18744; May, 1932.]

Brown's Bronchial Troches.—John I. Brown and Son, Boston. Composition: Extracts of licorice and cubeb, sugar, starch and a gum such as acacia. Fraudulent therapeutic claims.—[N. J. 18747; May, 1932.]

Lavodin.—Lavodin Co., Oakland, Calif. Composition: Small quantities of potassium iodide, common salt, horax, oil of cinnamon and glycerin together with 7.9 per cent of alcohol, and water. Falsely claimed to be antiseptic. Fraudulent therapeutic claims.—[N. J. 18928; June, 1932.]

Minton's Asthma, Hay Fever and Catarrh Remedy.—D. L. Minton, Sidney, Ohio. Composition: Potassium iodide, a trace of plant extractives and water. Fraudulent therapeutic claims.—[N. J. 18930; June, 1932.]

Wilson's Chloro-Inhaler.—Western Pacific Chemical Co., Seattle, Wash. Composition: A glass inhaler containing a cloth impregnated with menthol, a small quantity of a chlorine-yielding compound, a calcium salt, chloride and carbouate. For hay fever, influenza, headaches, etc. Fraudulent therapeutic claims.—[N. J. 18931; June, 1932.]

Davies' Geng-Seng.—Davies' Geng-Seng Co., Los Angeles. Composition: Powdered ginseng root, aloe, epsom salt, baking soda and sugar. For indigestion, bleeding gums, catarrh, asthma, etc. Fraudulent therapeutic claims.—[N. J. 18932; June, 1932.]

Mason's Cream of Olives Ointment.—Aschenbach and Miller, Inc., Philadelphia. Composition: Essentially camphor in a fatty ointment base. For catarrh, sore throat, skin eruptions, etc. Fraudulent therapeutic claims.—[N. J. 18933; June, 1932.]

Dr. Jones' Formula Grip and Cold Tablets.—J. F. Stras, LaCrosse, Wis. Composition: Acetanilid, camphor and extract of a laxative drug, red pepper and starch. Fraudulent therapeutic claims.—[N. J. 18935; June, 1932.]

Norwesco Laxative Cold Tablets.—Blumauer Frank Drug Co., Portland, Ore. Composition: Acetanilid, quinine, camphor, red pepper, a bromide and a laxative plant drug extract. Fraudulent therapeutic claims.—[N. J. 18936; June, 1932.]

Page's Cru-Mo Salve.—W. H. King Drug Co., Raleigh, N. C. Composition: Essentially volatile oils, including methyl salicylate, menthol, camphor, eucalyptus and pine oil in an ointment base of petrolatum, paraffin and wool fat. For croup, neuralgia, rheumatism, etc. Fraudulent therapeutic claims.—[N. J. 18937; June, 1932.]

Pheno-Septol.—Pheno-Septol Co., Inc., Rochester, N. Y. Composition: Small quantities of carbolic acid, a salicylate, a borate, alcohol, a potassium salt, flavoring and coloring, with water. Falsely claimed to be germicidal. For tonsillitis, laryngitis, catarrh, piles, typhoid fever, etc. Fraudulent therapeutic claims.—[N. J. 18938; June, 1932.]

Phen-Amy-Caps.—Franklin Laboratory, Portland, Maine. Composition: Capsules containing phenacetine, amidopyrine, caffeine and an extract of a mydriatic drug, such as hyoscyamus. Misbranded because phenacetine not properly declared and because of fraudulent therapeutic claims. Claims to relieve pain, etc.—[N. J. 18939; June, 1932.]

B-J-C Capsules.—Cline Medicine Co., Poplar Bluff, Mo. Composition: Salo (2.6 grains per capsule), copaiba, santal oil and sulphur. For cystitis, gonorrhea, etc. Fraudulent therapeutic claims.—[N. J. 18941; June, 1932.]

Angell's Cough Syrup.—James R. Angell, New Orleans. Composition: Sugar, alcohol, water and a small quantity of plant drug extract including tannin. Fraudulent therapeutic claims.—[N. J. 18942; June, 1932.]

Kitchel's (S. B.) Liniment.—S. B. Kitchel Co., Coldwater, Mich. Composition: Ammonia (4 per cent), sodium and potassium carbonates (1 per cent), traces of iron sulphate and tannin, with approximately 95 per cent of water. Fraudulent therapeutic claims.—[N. J. 18944; June, 1932.]

Servex.—Burnham-Snow Products Co., Hollywood, Cal. Composition: Essentially boric acid (86 per cent), oxyquinoline sulphate and quinine sulphate. A "vaginal protective powder." Fraudulent therapeutic claims.—[N. J. 18946; June, 1932.]

Hy-Ko.—Hy-Ko Co., Longview, Wash. Composition: Essentially benzoic acid (5.9 per cent), alcohol (11.4 per cent by volume), sugar and water. For influenza, hay fever, chills, etc. Misbranded because alcohol content not declared and because of fraudulent therapeutic claims.—[N. J. 18956; June, 1932.]

Melo.—McKesson Western Wholesale Drug Co., Ltd., Los Angeles. Composition: Essentially zinc chloride and iodide, glycerine, alcohol (6 per cent) and water. Falsely claimed to be antiseptic. For mouth, nose and throat disorders. Fraudulent therapeutic claims.—[N. J. 18958; June, 1932.]

Lithiated Sorghum Compound.—Sharp & Dohme, Inc., Philadelphia. Composition: Lithium benzoate, lithium citrate, alcohol, sugar and water, with extracts of plant drugs, including hydrangea. For cystitis, rheumatism, etc. Fraudulent therapeutic claims.—[N. J. 18961; June, 1932.]

Best's Vaginal Cones.—Best Cone Co., New York. Composition: Boric acid and quinine sulphate in a cocoa butter base. "Uterine tonic," etc. Fraudulent therapeutic claims.—[N. J. 18962; June, 1932.]

Denn's Compound.—Denn's Rheumatic Cure Co., Columbus, Ohio. Composition: Essentially extracts of plant drugs, including a laxative such as cascara sagrada, with sodium benzoate, sugar, alcohol and water. For kidney and liver disorders, rheumatism, etc. Fraudulent therapeutic claims.—[N. J. 18968; June, 1932.]

Hick's Epsom Salts Compound Tablets.—Charles M. Hick & Co., Chicago. Composition: Essentially epsom salt (4 grains per tablet) and aloe. Adulterated and misbranded because below professed standard of strength.—[N. J. 18969; June, 1932.]

Co-Liv-Ol.—Silmo Chemical Co., Inc., Vineland, N. J. Composition: Essentially a fish oil, calcium and magnesium carbonates, small quantities of iron and aluminum compounds, and water. Contained no vitamin D. Fraudulent therapeutic claims.—[N. J. 18972; June, 1932.]

Harding's 444.—Harding Drug Co., Jackson, Miss. Composition: Essentially potassium iodide, mercuric chloride, laxatives such as cascara sagrada, alcohol (4.6 per cent by volume), glycerine and water. For blood disorders, rheumatism, etc. False declaration of alcohol content. Fraudulent therapeutic claims.—[N. J. 18973; June, 1932.]

Vilane Powder.—Blackburn Products Co., Dayton, Ohio. Composition: Essentially borax, salt, baking soda and small quantities of thymol, menthol, methyl salicylate and eucalyptol. For catarrh, cystitis, diarrhea, etc. Falsely claimed to be a disinfectant. Fraudulent therapeutic claims.—[N. J. 18974; June, 1932.]

Angeline.—Angeline Corporation, Hamilton, Ohio. Composition: Extracts of plant drugs (including laxatives), sodium salicylate, flavoring material, alcohol and water. For rheumatism, neuralgia, etc. Fraudulent therapeutic claims.—[N. J. 19026; July, 1932.]

Magle Salve Heal-Al.—Ericka Mfg. Co., Inc., Springfield, Mass. Composition: Essentially petrolatum with 6 per cent of peppermint oil. For skin disorders, piles, catarrh, pneumonia, asthma, etc. Fraudulent therapeutic claims.—[N. J. 19027; July, 1932.]

Steketee's Neuralgia Drops.—Hazelton & Perkins Drug Co., Grand Rapids, Mich. Composition: Essentially balsam of Peru, alcohol (45.6 per cent), water, and a small quantity of volatile oils. Fraudulent therapeutic claims.—[N. J. 19028; July, 1932.]

Grafanol Ointment.—R. F. Grafa & Sons, Durant, Okla. Composition: Petroleum products (61.5 per cent), mineral matter (8 per cent) and water (30.5 per cent). For skin cancers, sore throat, nasal catarrh, piles, rheumatism, etc. Fraudulent therapeutic claims.—[N. J. 19029; July, 1932.]

Kojene.—Kojene Products Corporation, Buffalo, N. Y. Composition: Essentially oxyquinoline sulphate and water, flavored with methyl salicylate. For skin and mouth disorders, catarrh, eczema, and as a "preventive." Fraudulent therapeutic claims.—[N. J. 19032; July, 1932.]

Kojenol.—Kojene Products Corporation, Buffalo, N. Y. Composition: Essentially oxyquinoline sulphate, a small quantity of resinous material and water. For pyorrhea. Fraudulent therapeutic claims.—[N. J. 19032; July, 1932.]

Marvel Ointment.—White & Kleppinger, Inc., Chicago. Composition: Essentially volatile oils (35 per cent, mostly methyl salicylate) in an ointment base (65 per cent) of petrolatum and paraffin. For rheumatic pains, asthma, catarrh, pneumonia, etc. Fraudulent therapeutic claims.—[N. J. 19034; July, 1932.]

Mother's Joy Rice's Salve.—Rice Chemical Co., Greensboro, N. C. Composition: Essentially kerosene, methyl salicylate, camphor, menthol and eucalyptol, in a petrolatum base. For sore throat, bronchitis, pneumonia, catarrh, asthma, skin eruptions, etc. Fraudulent therapeutic claims.—[N. J. 19037; July, 1932.]

Kelpor (H. H. Brooten's Mineral).—P. A. Tucker, Portland, Oregon. Composition: Mainly aluminum silicate and iron oxide, with a small quantity of other iron and magnesium compounds, including sulphate and phosphate, with traces of calcium compounds and sulphate. For diabetes, anemia, gastritis, etc. Fraudulent therapeutic claims.—[N. J. 19045; July, 1932.]

Jenkins' Rheumatic Medicine.—McKesson Parker Blake Co., New Orleans. Composition: Salicylic acid (about 1½ grains to the tablespoonful), a small quantity of a plant drug, alcohol (32 per cent by volume), and water, flavored with anise oil. Misbranded because of fraudulent therapeutic claims and false statement of alcohol content.—[N. J. 19048; July, 1932.]

Taylor's Royal Brand Green Seal Pills.—Horace B. Taylor Co., Philadelphia. Composition: Essentially iron (ferrous) sulphate (0.26 grain each), ginger, licorice, aloe and a small quantity of soap. For "menstrual disorders." Fraudulent therapeutic claims.—[N. J. 19053; July, 1932.]

STATISTICAL STUDIES OF DIABETES

To the Editor:—I have recently come across some interesting figures, which throw light on the value of statistical studies based solely on official mortality figures.

Godias J. Drolet in *THE JOURNAL*, March 11, reported diabetes mortality in New York City during the thirty year period 1901-1931. The curves which he showed apparently proved an increase in the number of females as opposed to males, in whom diabetes is given as the primary cause of death. I obtained from Mr. Drolet the original figures reported by the New York department of health and have compared them with the figures which are officially reported by the Census Bureau for New York City.

Mr. Drolet in the *New York Times* of May 21 states that he understands that the local practice in the New York City

Deaths and Death Rates per Hundred Thousand from Diabetes Mellitus by Sex, 1901 to 1931

| Year | Males | | Females | | Total | | Death Rate | | Difference, per Cent |

department of health, where several associated causes of death have been listed, has been to give preference to a medical determination of the more likely primary cause rather than to follow mechanically the rules of the Manual of Joint Causes of Death, and states that this practice has been maintained under the direction of Dr. William H. Guilfooy, just retired after forty years of service in charge of the New York bureau of records.

The official mortality figures for New York City which are reported by the Census Bureau, on the other hand, it may be assumed, are reported after the classification as to primary and secondary causes, which is made in Washington according to the Manual of Joint Causes, this being the standard procedure employed by the Census Bureau itself.

It is therefore of considerable interest to compare over a period of thirty years two different methods of classifying these mortality figures for diabetes, bearing in mind that discrepancies are bound to occur when different methods of classification are in use, and are particularly apt to be marked in mortality figures for diabetes and for cancer.

The accompanying table shows for each year the number of males and females and total deaths as reported by the New

York department and by the Census Bureau, marked "N. Y." and "U. S.," respectively. Another column shows the difference in the death rate figured on the total number of deaths in each case, and the last column shows the percentage of discrepancy which these two systems of practice have shown.

It would seem that there are many personal factors entering into the classification of primary and secondary causes of death, for in no other way could two systems get such irregularly distributed differences in coding the same certificates.

Physicians object to crediting to diabetes a death which is due to a perforated appendix or to lobar pneumonia just because the patient is known to have had mild, though thoroughly cared for, diabetes. This occurs as a routine in the use of the Manual of Joint Causes and constitutes an injustice to modern diabetes therapy.

It has been my contention that the increase in hospitalization and its attendant increase in accuracy of diagnosis, coupled with the use of the Manual of Joint Causes, are responsible for official figures the significance of which is doubtful.

JAMES RAGLAN MILLER, M.D., Hartford, Conn.

PRECIPITATION TESTS FOR SYPHILIS

To the Editor:—On visiting the venereal disease exhibit of the United States Public Health Service at the Chicago Century of Progress Exposition I saw a statement which, in my opinion, is not alone incorrect but, in addition, does a grave injustice to American science. I refer to the statement which lists Meinicke as the originator of the precipitation test for syphilis.

Ten years before Meinicke began to write on precipitation with syphilitic serums, Michaelis (1907) published his "Precipitinreaktion bei Syphilis." In 1910, Jacobstahl reported a precipitation test which required the dark field microscope to read the results. In 1911, Bruck and Hidaka showed that, by modifying the technic, the use of the microscope was not necessary. In 1915, Hecht published a precipitation method of his own. In 1917, Meinicke published a "water and salt solution" method based on precipitation. In 1918, Sachs and Georgi published a precipitation test which bears their names. In the same year, Meinicke abandoned the "water and salt solution" method and published what he called the "third modification." Then came Dold in 1921 with his "turbidity test" for syphilis, and in 1922 Meinicke's "third modification" was discarded in favor of a "turbidity test" with cholesterol. But this test, too, was short lived, for in 1923 Meinicke discarded this test in favor of a turbidity test with the use of balsam instead of cholesterol. (Balsam was also used in a precipitation test suggested by de la Riviere and Gallerand.)

It was this last turbidity test with a special microprocedure as a check method that Meinicke employed at the League of Nations conference at Copenhagen in 1928. As is well known, the Kahn test was more sensitive than the Meinicke method in syphilitic cases, while in the nonsyphilitic group the Meinicke test gave nine false positive reactions and the Kahn test none. The results of this conference led Meinicke to abandon the "turbidity test" and develop the so-called clarification test—a precipitation method in which the precipitate settles out after overnight incubation, giving a clear supernatant fluid. But at the Montevideo conference of the League of Nations Health Committee in 1930, the Kahn reaction was again more sensitive than Meinicke's clarification test in syphilitic cases, while in the nonsyphilitic group the clarification test gave seven false positive reactions and again the Kahn test gave no false positives. Meinicke's latest method is clarification test II.

In the face of these facts one cannot help but wonder how Meinicke can be listed as the originator of the precipitation test for syphilis by so important a scientific body as the U. S. Public Health Service. Credit for the very first work along the lines

of precipitation tests should obviously go to Michaelis or to Jacobstahl or to both. But credit for the first practical method that has stood the test of time during an entire decade, a test that is universally acknowledged to be based on outstanding studies governing the phenomenon of precipitation in syphilis, a test that proved its superiority at two international competitive conferences sponsored by the League of Nations Health Committee, one that has forced improved modifications of numerous Wassermann tests all over the world and has been the forerunner of practically all precipitation tests during the past decade is obviously the American developed Kahn reaction. I say "American developed" advisedly, for in a recent issue of the *Medizinische Klinik* Dr. Meinicke himself points out that there is no reason for German physicians to use the American developed Kahn test when German-Austrian methods are available.

ISRAEL WEINSTEIN, M.D., New York.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

EFFECT OF SPORTS ON COMPENSATED HEART DISEASE

To the Editor:—Is there any good evidence that strenuous sports such as football and basketball are harmful to boys with well compensated valvular lesions of the heart? A rapidly growing boy with mitral stenosis and hypertrophy played both football and basketball, contrary to my advice, throughout his high school course, without any apparent injury. I have now under observation two high school boys with slight mitral stenosis, with no enlargement of the heart, who have never suffered from any cardiac symptoms and have perfect compensation. In one case there have been several attacks of rheumatic fever, in the other case scarlet fever and some vague "growing pains." One of these boys plays both football and basketball; the other plays basketball and is a star gymnast. In both cases, athletic sports seem to improve the boys' general condition and have no demonstrable bad effects on the heart. On the other hand, I once had a patient with combined aortic and mitral lesions of rheumatic origin who died of heart failure at the age of 23; he had always been active in athletics and I thought his athletic activities had probably contributed to his early death. If you answer this question in *THE JOURNAL* please omit name and address.

M.D., Pennsylvania.

ANSWER.—There have been published no satisfactory statistical studies to show whether or not strenuous sports such as football and basketball are harmful to boys with "well compensated" valvular lesions of the heart. The experience has been a common one that strenuous sports seem sometimes to harm and sometimes to benefit growing boys with valvular disease. Undoubtedly several factors enter in besides the mere existence of the heart trouble; among these factors the two most important are the degree of valvular involvement and the occurrence of infection, particularly of the rheumatic type. The more marked the valve lesions and the more valves involved, the more likely is the heart to be affected unfavorably by strenuous exertion; heart size, which may also be used as a prognostic aid (the larger the heart, the worse the prognosis), is in these youths with chronic valvular disease primarily dependent on the degree and number of valve lesions. Relatively slight involvement of the mitral valve is only a slight handicap for the heart, and the possessor of such a heart may live practically a normal life and respond to exercise with favorable effect like a normal person, while marked mitral stenosis, marked aortic regurgitation, and especially the combinations of the two are considerable burdens which may prove too much for a heart when it is subjected to exhausting physical effort. Severe rheumatic fever, through its effect on the heart muscle as well as on the endocardium and pericardium, may precipitate heart failure in an individual with or without valvular heart disease; the occurrence of such infection is favored by catching a cold, which in turn is more apt to come with exhaustion and exposure to cold and wet.

It is in general wise to advise that any youth with any degree of rheumatic valvular heart disease be protected from the extreme exertion incident to the most strenuous sports, such as football, basketball and hockey, but that the less strenuous sports, such as baseball, tennis and golf, be permitted when the heart disease is only slight or moderate. Exercise in moderation is more likely to be helpful than harmful except when the

valvular disease is extreme, when only the mildest exercise, such as walking, should be allowed. These general rules are safe to follow; but there are always exceptions and each case must be judged individually on its merits because of the complexity of the factors involved, which include rapidity of growth, general health, temperament, familial health and longevity, and family resources.

SENSITIZATION TO GRASSES

To the Editor:—Will you kindly give me an opinion as to the following case and treatment you would suggest? Recently I tested a hay fever patient for susceptibility, using a Parke Davis diagnostic outfit containing groups 28 to 31 inclusive (Gramineae, Chenopodiaceae, Ambrosiaceae and Artemisia). She showed some reaction to each of the groups, apparently, particularly to group 31. Later I repeated the test more carefully and on this occasion she reacted to groups 28 and 31. I had not supposed there were any of the artemisia grasses about, but the reaction was definite in each case. Is there a combination of these groups available or would you suggest the Parke Davis group 31 alone? Please omit name.

M.D., Massachusetts.

ANSWER.—In the district cited the Artemisia family of plants is not present; hence they cannot be a factor in hay fever and there is no necessity for treating the patient with any pollen of this group. The Artemisia are, however, fairly closely related to the ragweeds, so that many ragweed-sensitive patients also give a positive skin test to the sages (Artemisiae). This may explain the reaction of the patient to the latter. It should also be ascertained whether the patient has not formerly lived in western parts of the United States, where she may have acquired a sensitiveness to the Artemisia pollen.

Presumably the patient resides in the locality mentioned. The seasons in which the symptoms occur are not stated. At any rate, the patient should have tests with the tree pollens (probably cottonwood, maple, oak, elm and ash), grass pollens (probably timothy, June grass and orchard grass) and ragweed pollen (short ragweed). The latter is the only important fall hay fever plant in the district. These tests should be made with the individual pollen extracts and not with groups. Group testing may result in weak or negative reactions, whereas one of the pollens of the group may give a strong reaction by individual testing.

After tests are made and treatment is considered, it should be remembered that before any pollen is used in treatment it must fulfil all the following requirements:

1. The season of pollination of the plants must correspond to the time when the patient has symptoms.
2. The plant must be wind pollinated.
3. It must be present in the district in which the patient lives.
4. The plant must be abundant and must be a good pollinator.
5. The patient must evidence a positive test with the pollen.

If these rules are adhered to, many of the pollens may be left out of consideration in treatment. If the patient is sensitive to more than one pollen of the same group and of the same season (the grasses, for example) they may be combined in one treatment mixture. Under no circumstances should shotgun mixtures of the type which the inquirer describes be used as a routine in diagnosis and especially in treatment.

"RADIO DEATH FIGHTERS" OR HYPERPYREXIA IN DEMENTIA PARALYTICA AND SYPHILIS

To the Editor:—A patient of mine suffering from locomotor ataxia brings to me an article published in the April, 1933, issue of the *Country Gentleman*, entitled "Radio Death Fighters," by Paul de Kruif. This is some sort of electrical treatment recommended for his condition and he wants my advice as to his trying it. A letter from the editor of that magazine states that he thinks that they will be able to install their machine in hospitals within the near future at a figure which will enable hospitals to go in for it. I have never heard of the treatment before and would like any information you may be able to give me about it. Please omit name.

M.D., Pennsylvania.

ANSWER.—The fever-producing apparatus referred to by de Kruif is a 1 kilowatt short wave radio transmitter, developed by Willis R. Whitney of the General Electric Company. The essential difference between a transmitter used for transoceanic broadcasting and the apparatus used for therapeutic fever production is that the energy is concentrated between two large condenser plates instead of being directed from an aerial. The name "radiotherm" has been applied to the altered radio transmitter. The heating effect is produced by a vacuum tube oscillator, composed of two 500 watt radiotrons, producing a high frequency field of approximately 10,000,000 cycles per second (30 meter waves) between the condenser plates. The patient lies on a stretcher between the plates. No contact electrodes are used.

Many other methods have been used for artificial fever production, such as diathermy, hot baths, hot air and electric blankets, as well as inoculations with malaria, rat bite fever and relapsing fever. The purpose of experimentation with fever production by physical methods has been to provide a suitable substitute for inoculation methods. The few reports that have appeared in medical literature seem to indicate that the therapeutic value of fever induced by physical methods is comparable to the results that have been obtained with malaria inoculations. The development of the various forms of apparatus is still in the experimental stage. The employment of the various types of electrical apparatus for fever production should be restricted to institutions, under the direct supervision of physicians who have thoroughly familiarized themselves with the physical and technical principles involved.

The following references will provide further information regarding the various methods employed and the results that have been obtained:

TREATMENT OF SYPHILIS

To the Editor:—I have been treating a young man for syphilis since July, 1928. He came in the early secondary stage. He had gone to another doctor at first, as he did not want me to know that he had it, I being the family physician. Here he had local treatment for his chancre for about a month. The Wassermann (Kolmer technic) was 4 4 4 4 4. I treated him with nearsphenamine, giving him six or eight weekly injections, then gave him a rest period (for which I am now sorry) and then put him on mercury by inunction, mercurial ointment, which he rubbed in faithfully. In September, 1928, the Wassermann reaction was 3 4 4 2 0. In April, 1929, it was 3 3 3 0 0. In June, 1929, it was 2 2 2 0 0. In September, 1929, it was 2 2 0 0 0. I then gave him an ampule of "Biliposol" every week for fifteen weeks and then changed him to inunctions with small doses of potassium iodide. Following this it was negative in all dilutions. I then did not see how I could keep him on bismuth indefinitely, and no longer trusted the nearsphenamine, so I got some arsphenamine and gave him ten weekly intravenous injections of 0.4 Gm. Following this his reading was 4 4 4 1 0. I then realized that he did better on bismuth than on arsenic, and put him back on the Biliposol, of which he has had fifteen intramuscular injections and one of iodobismutol. The negative Wassermann reaction was in March, 1932. I have been unable to get him to go to any one else, cannot refer him to an expert, and am rapidly learning that I do not come in that category myself. He has no neurologic symptoms, and I have never had his spinal fluid examined. His general condition seems good. I rather think he will be negative now, after this last series of Biliposol, preceded by a thorough course of mercurial inunctions with mercurial ointment and potassium iodide, 10 grains (0.65 Gm.) twice daily. If you can give me any help, please do so. When I first began to treat him he developed a slight to moderate albuminuria. He had had tonsillitis and after I removed the tonsils the albuminuria cleared up and has never returned. He seems to stand the arsenic, bismuth and iodide perfectly well. Please omit name and address.

M.D., Texas.

ANSWER.—It would appear that the patient is tolerant to all the drugs commonly employed in the treatment of early syphilis. Therefore there can be no objection to systematic treatment according to the methods commonly accepted in modern syphilotherapy. Measured by these standards, the treatment has unfortunately not been adequate during the early years of the infection. Since there has apparently been no tendency to symptomatic relapse, the case can now be regarded as being in the latent stage with a tendency to persistent serologic positivity. Since the patient has not received any of the arsenicals for some time, two courses, preferably of arsphenamine, are indicated, if well tolerated. A course should consist of six

injections at weekly intervals, 0.4 Gm. to the dose. After a four months rest interval, such a course should be repeated. This would give the patient a total of thirty injections of arsphenamine, including the eight doses of neoarsphenamine, a fairly good average total amount of the drug.

During the four months rest interval a course of bismuth injections (sodium potassium bismuth tartrate, 0.2 Gm. once a week or its equivalent) should be given. In order not to produce toxic manifestations, a rest period of about a month before and after the course of bismuth is desirable.

Following the second course of arsphenamine, a rest period of a month and then more injections of bismuth preparations until he has received a total of about sixty are indicated. Experience has shown that this amount of treatment in a healthy young adult is not excessive and should be given irrespective of the behavior of the blood Wassermann, but with due regard to the tolerance of the patient. If there are no clinical complications, an examination of the spinal fluid may be deferred until the full series of treatments has been completed. After that the test should by all means be done, as it is then of far greater prognostic significance than the blood Wassermann. In the event that the fluid is positive, further routine treatment is undesirable and such measures as intraspinal injections, trypanamide, or even malaria treatment must be considered. Should examination of the spinal fluid prove negative, short courses of bismuth preparations, about ten injections to the course, should be given twice a year for two more years. Barring any tendency to symptomatic relapse, it is wise to examine the patient once a year for many years to come.

OBESITY AND MENSTRUAL DISTURBANCES

To the Editor:—A woman, aged 25, suffers with intermittent attacks of amenorrhea and menorrhagia. She was married five years ago and has had no children or, as far as she knows, pregnancies. Up to the time of her marriage the menstrual function was normal, starting at 13, occurring every twenty-eight days, and lasting five days. This kept up until she was married one year. She then missed four successive periods, started flowing, and flowed for six weeks. She was curetted at the end of that time and the flow ceased. The surgeon naturally thought she was pregnant and had a miscarriage. But the uterine scrapings sent to the laboratory showed only normal scrapings, without evidence of retained secundines. This condition has kept up off and on for the past four years, during which time she has increased in weight from 136 to 210 pounds (from 61.7 to 95 Kg.). During this time she has had three separate curettages by three different surgeons to stop bleeding. All the scrapings were examined and all were normal. The last curettage was done in September, 1932, after she had flowed for two months. Previous to this, I prescribed ovarian residue tablets, and she was regular for twelve months. This was the longest period that she had been regular during the four years. The last curettage was one in Newport, R. I., where she was spending the summer. This last bleeding came on in spite of the fact that she was still taking the tablets, so I do not think that they had anything to do with helping her condition. After the curettage in September, she did not menstruate until six weeks ago, when she started, and she is still flowing. She never has any pains with the periods but passes clots, especially when on her feet for any length of time. An interesting part of this case is the fact that she gains weight and her blood pressure increases while flowing. Yesterday it was 160/90. She has a normal pressure of 124/80. She has no kidney disturbance, and her pelvis is absolutely normal. This has been checked up on by five different surgeons. I should like to know your impression of this case. I am sure she has an ovarian disturbance of some kind and would appreciate it if you would recommend a form of treatment. I have thought of giving her some injections of theelin or possibly the extract of corpus luteum. I had also considered the use of radium in this case but dismissed it from my mind on account of bringing on an artificial menopause. Do you think that removal of the uterus would be indicated? I had thought of that but, on account of her age, decided to hold off.

M.D., District of Columbia.

ANSWER.—The development of marked obesity associated with menstrual disturbances and a spastic type of hypertension is most easily explained on an endocrine basis. Determination of the basal metabolic rate is in order to evaluate the influence of the thyroid in this condition. Sugar tolerance tests might point more especially to a pituitary gland disturbance. The picture is suggestive of pituitary dysfunction with secondary ovarian changes. There have been reported instances of beneficial results in cases of functional amenorrhea and menorrhagia from the intramuscular administration of some of the female sex hormone preparations, especially those obtained by the extraction of the urine of pregnant women. "Antuitrin S" and "Follutin" are of this type. If the basal metabolic rate is below normal, thyroid extract may be administered orally in addition. Dietary restriction is also advisable. If these measures fail, one might consider roentgen therapy of the hypophysis. It would be well, in addition, to consider the possibility of the presence of a masculinizing tumor of the ovary (Meyer) before employing radium or hysterectomy—a last resort.

INTRAVENOUS INJECTIONS—LOESER'S PRODUCTS

To the Editor:—On page 7 of the enclosed pamphlet, attention is drawn to the use of hydrochloric acid by intravenous injection for various conditions, among which asthma is mentioned. My information on this subject is nil and I would appreciate your opinion concerning intravenous therapy with hydrochloric acid. I have a patient with asthma who is willing to take a chance at almost anything. Would I be justified in attempting such medication? I might state that the patient has been in the hands of one of our best asthma specialists for over a year, and in spite of extensive operations and vaccine treatment I see little if any improvement.

M.D., New York.

ANSWER.—The so-called literature on the intravenous use of hydrochloric acid in the pamphlet referred to by the correspondent is the commercial propaganda of the Loeser Laboratory, whose exploitation of unscientific intravenous medicaments has been previously noted. Reports on products of the Loeser Laboratory have appeared from time to time:

Loeser's Intravenous Solution of Calcium Chloride, *THE JOURNAL*, March 21, 1925, p. 914; Jan. 16, 1926, p. 217.

Loeser's Intravenous Solution of Hydrochloric Acid, *THE JOURNAL*, March 21, 1925, p. 914; Jan. 16, 1926, p. 217.

Loeser's Intravenous Solution of Sodium Iodide, *THE JOURNAL*, April 16, 1931, p. 1120.

Loeser's Intravenous Solution of Sodium Thiosulphate, *THE JOURNAL*, April 28, 1925, p. 1289; Jan. 16, 1926, p. 217.

In the "literature" on the intravenous use of hydrochloric acid, the testimonials for the use of the acid mention nearly all the disorders known to medicine as being benefited, without adequate evidence of any kind. The alleged relationship between causes of disease and therapeutic effects is an earmark of pure invention. Contrary to the implications in this propaganda, the intravenous use of hydrochloric acid is far from harmless; the acidity of the solution advocated is more than a million times that of the blood.

The intravenous injection of the recommended quantities of hydrochloric acid would utilize something like 16 to 24 mg. of base as bicarbonate, which exists in from 6 to 8 cc. of blood. The damaging effect on the blood of such utilization of base is well stated by Burns in his book "An Introduction to Bio-Physics," 1921, p. 417: "Erythrocytes are easily damaged by acid. This will lead to agglutination and hemolysis on the addition of acid as soon as the reserve of base has been used up." There would be other disturbances caused by such injection; for instance, those caused by invoking the intravenous reflexes, which could hardly be regarded as beneficial. From this it follows that the intravenous injection of hydrochloric acid is capable of doing more harm than good, especially with repeated injections, and therefore this procedure has no justifiable place in the therapeutic armamentarium. Physicians should unreservedly condemn the advocacy of such crude and dangerous experimentation.

PANCREATIC AND HYPOPHYSEAL DIABETES—ACROMEGALY

To the Editor:—Given an acromegalic patient with hyperglycemia and glycosuria, how is one to distinguish between pancreatic and hypophyseal diabetes? Do acromegalic and pituitary gigantic individuals excrete the anterior pituitary growth hormone? If so, how may one detect this hormone? Please omit name.

M.D., California.

ANSWER.—The hyperglycemia and the glycosuria that may accompany acromegaly are essentially similar to those which occur in ordinary diabetes mellitus. It is impossible to distinguish between "pancreatic diabetes" and "hypophyseal diabetes" on the basis of the metabolic manifestations alone. The fact that such a patient has signs and symptoms of acromegaly is therefore the primary reason for considering his diabetes of hypophyseal origin. The more recent physiologic investigations are making it increasingly evident that the anterior lobe of the pituitary gland occupies an important place in the normal carbohydrate metabolism. It is not improbable, therefore, that it may play a part in all cases of diabetes. In other words, the distinction between "hypophyseal" and "pancreatic" diabetes may be quantitative rather than qualitative. However, diabetic patients in whom there is a manifest pituitary abnormality, such as acromegaly, may differ from ordinary diabetic patients in one respect; namely, that their metabolic manifestations may be fluctuating in character. They may show spontaneous, temporary or permanent improvement or even "cure" of their diabetes, associated with evidences of change in pituitary activity.

There appear to be no references in the literature regarding the determination of the anterior pituitary growth hormone in the urine of acromegalic and pituitary gigantic individuals. Parhon, Balli and Stirbu (*Compt. rend. Soc. de biol.* 104: 227 [May 16] 1930) made daily injections of from 1 to 2 cc. of blood serum from a young acromegalic woman into two

growing guinea-pigs for a period of about three months. During that period the experimental animals increased their weight by 145.5 per cent, while similar control animals injected with normal human serum increased their weight by 135.5 per cent. This is suggestive but not especially convincing evidence of the presence of an increased amount of anterior pituitary growth hormone in the circulation of acromegalic patients.

That the hormone would be found in the urine if it were present in increased amounts in the blood is indicated by the work of Wehefritz and Gierhake (*Arch. f. Gynäk.* 149:377, 1932; abstr. *Klin. Wchschr.* 11:1106 [June 25] 1932), who obtained the growth hormone from the urine of pregnant women by adsorbing it on animal charcoal, after a preliminary purification of the urine. Young growing rats in which this charcoal was subcutaneously implanted showed a definitely increased rate of growth as compared to their controls.

HYPERESTHETIC OR VASOMOTOR RHINITIS

To the Editor:—A married woman, aged 33, for the past nine years, for two to four hours arising, has sneezed continually, with a marked watery discharge from nose. The turbinates have been removed, making the air passages clear. The tonsils have been removed. She has two children aged 6 and 3. She has tried various otolaryngologists, without relief. The menstrual periods are usually a week late but are otherwise normal. However, during her two full term pregnancies this condition leaves her. Would ovarian treatment help this? I should appreciate any information that may help this condition.

N. C. Ritsjorn, M.D., Highwood, Ill.

ANSWER.—The patient evidently has a hyperesthetic rhinitis or vasomotor rhinitis probably caused by an allergic reaction to one or more proteins. The fact that the patient sneezes shortly after arising indicates that probably house dust is the offending factor to which the patient is sensitive. House dust as a rule settles during the night when the air of a room is still, but after the patient rises and walks about, the air is stirred and the dust rises, is inhaled and causes sneezing. It cannot be said whether ovarian treatments of any sort would be of benefit in this condition. On the other hand, the patient may be sensitive to various types of proteins, and in order to learn to which ones, skin tests with different groups of proteins should be made.

SODIUM THIOSULPHATE WITH ARSPHENAMINE— SODIUM DEHYDROCHOLATE

To the Editor:—Please advise me regarding the following: Do you believe or know that it is safe, as is reported in some recent articles, to use sodium thiosulphate 4 per cent solution to dissolve neoarsphenamine in 10 cc. of distilled water and use intravenously for treating syphilis, also to prevent nausea, vomiting and liver reactions, also possibly skin reaction? Do you advise the use of sodium dehydrocholate 5 per cent solution to dissolve neoarsphenamine by adding 10 cc. of distilled water and using this for treating syphilis and the prevention as above (given intravenously)? May I also ask for the name of a company which may make the sodium dehydrocholate 5 per cent solution ready to use for intravenous injection?

M.D., Iowa.

ANSWER.—The use of sodium thiosulphate with arsphenamine has been recommended (Iwakiri: *J. Orient. Med.* 17:25 [Sept.] 1932), but experience with this mixture has not been sufficiently extensive to warrant conclusions as to clinical usefulness at this time. Iwakiri used a 5 to 10 per cent solution of sodium thiosulphate as a solvent. He apparently substituted a sodium thiosulphate solution for distilled water in equivalent quantities. The Council on Pharmacy and Chemistry has not recognized the use of sodium dehydrocholate (Decholin-N. N. R., manufactured by Riedel de Haen, Inc., New York) to diminish reactions from arsphenamine preparations. Sufficient information is not available to make any definite statement as to its usefulness in this connection.

SUNLIGHT IN GLANDULAR TUBERCULOSIS

To the Editor:—In a case of active adult glandular tuberculosis in the chest, it is desired to give increasing doses of sunlight to the maximum. At what dosage should one start, to be safe and conservative, and how rapidly may one increase it? It is intended to expose the entire body to slanting rays from an open window. What is the maximum dose? Please state whether dosage should change with the month, and time of day exposure is made; also give any other information you consider pertinent. Please omit name and address.

M.D., New York.

ANSWER.—Taking it for granted that the diagnosis of adult lymph node tuberculosis is certain, if high fever exists one would sacrifice solar exposures for complete bed rest under circumstances in which it is necessary to leave the bed to reach the sun rays.

Otherwise, solar exposures vary greatly, depending on many factors, such as location, altitude, humidity, season of year,

time of day, general condition of patient, presence of complicating pulmonary tuberculosis and whether the patient is of marked blonde or brunette type. The rate of increase of dosage will vary with skin reactions as well as constitutional ones.

In temperate zones, during the spring, adult patients not acutely progressively ill may be exposed in a room not chilly between 10 a. m. and noon and between 2 and 4 p. m. In hotter months, one should avoid the depressing heat between 11 a. m. and 2:30 to 3 p. m.

One should aim for a mild skin redness at the start and expose daily or every other day, depending on the reactions. The patient should feel as well during and after exposures as before. Reaction of depression, irritability, fatigue or undue prolonged elevation of temperature indicates stopping exposures for a while at least.

Recognizing these factors, one may start safely with five or ten minutes' exposure front and back morning and afternoon. The reaction should be studied and the exposure increased by five minutes daily up to two hours daily. The exposures should be broken up into morning and afternoon periods.

If marked pigmentation results and the patient thrives, an exposure of three hours should be the maximum.

COMMUNED FRACTURES OF PHALANGES

To the Editor:—A man, aged about 60, had a comminuted fracture of the distal phalanges, the ungual portion of the middle and ring fingers of the left hand. I put his fingers up in tongue depressor splints five weeks ago with biweekly change of splints, infra-red rays and massage as the treatment. Up to now there has been no change in the roentgenographic appearance—that is, no callus formation—and there is slight pain at the tips. The patient is quite well otherwise. What further treatment would you suggest? Please omit name.

M.D., New York.

ANSWER.—Five weeks in splints would ordinarily be considered ample time, and might even be longer than is advisable. Cases of this kind should be considered similarly to fracture into joints, and early active motion is desirable. The most important consideration at present would be active use in order to obtain flexion of the distal interphalangeal joints.

Physical therapy, including radiant heat, massage, active motions and passive movements, should speed up recovery of function. Contrast sprays will help the local circulation and nerve supply. The affected hand should be sprayed for one minute with cool water and one minute with warm water alternately. This should be done for ten minutes and the procedure carried out twice daily. The whirlpool bath and hot paraffin bath should be tried if they are available.

Occupational therapy in these cases is even more valuable than physical therapy. The patient's other hand is more beneficial than physical therapy because it is always available for massage and gentle manipulation.

POSSIBILITY OF CEREBROSPINAL SYPHILIS OR DEMENTIA PARALYTICA

To the Editor:—In 1926, while a student, I had some sinus trouble and the doctor advised a Wassermann test. It came back four plus. I had three others taken at different laboratories. They were all four plus. Immediately I started treatment, using arsphenamine, mercury and potassium bismuth tartrate alternately. The treatment lasted nearly a year. The Wassermann test remained four plus. My physician finally dismissed me, saying that I was Wassermann fast. I have taken some iodides, but the Wassermann remains four plus. My mother died with general paralysis or, as some called it, creeping paralysis. She lingered nine years. A short time before she died her Wassermann reaction was four plus. Two of her sisters died insane. Can't you see what a dreadful sword of Damocles is hanging over my head? While I am young it may not matter much but isn't there a danger of insanity later? I would take malaria or anything to get rid of this. I have remained single because of it and am in constant dread. Is the malarial treatment recognized by the American Medical Association? If so, where can I go to be treated? Please omit name, address and state.

M.D.

ANSWER.—The treatment of syphilis by malaria is indicated only in cases in which there is involvement of the central nervous system, and this in turn can be ascertained only by a complete spinal fluid examination, which includes a Wassermann test, cell count, globulin test and colloidal gold test. Malaria is of unquestionable value, especially in the parenchymatous types of central nervous system syphilis, particularly dementia paralytica, but it is a method of treatment which requires bed care and frequently hospitalization and has largely been replaced by the intravenous use of tryparsamide, which is an office procedure and, under proper control, is attendant with fewer complications and reactions. Certainly, malarial therapy should not be instituted without clear-cut indications for its use, and a competent syphilologist should be consulted before any such method of therapy is undertaken. The mere fact that insanity is present in the family does not necessarily predicate a

nervous system involvement from syphilis, and, furthermore, malarial treatment has no preventive value under such conditions. Neither will it protect against inherited psychoses. The Wassermann-fastness in this patient, while it may be an evidence of central nervous system involvement, may as well be an expression of inadequate treatment or possible cardiovascular damage, and the suggestions and further advice of a competent syphilologist are indispensable to the subsequent management of the case.

HEADACHES IN BEAUTY PARLOR OPERATOR

To the Editor.—A young woman, a beauty parlor operator, complains of severe occipital headaches, lately almost constantly present. She states that she gives many "permanent waves," and her constant presence in the room with the fumes of the "permanent wave solution" seems to make this much worse. She does not know what the solution contains, nor am I familiar with it. No sensitivity tests have been made, but we do know that the patient is properly fitted with glasses. Please omit name and town.

M.D., Iowa.

ANSWER.—The number of "permanent wave solutions" is legion. The following three formulas are indicative of their dissimilarity:

- Four per cent hydrazine hydrochloride.
- Fifteen per cent each of potassium carbonate and borax, aqueous ammonia and glycerin in low percentage, together with rose, elder, and orange water to make 100 parts.
- Borax, 3.75 parts; sodium bicarbonate, 3.5 parts; linseed oil, 0.17 part; starch, 0.4 part; water to make 100 parts.

Manifestly, more information as to the particular variety of solution in use is prerequisite to any opinion as to a possible relationship between headaches and wave solutions.

Other agents in use in some beauty parlors are equally likely causes of headaches.

TOXICITY OF HYDRAZOIC ACID

To the Editor.—In my locality there is an explosives plant where the workers are exposed to the fumes of hydrazoic acid. They complain of headaches and temporal throbbing. They feel as if an iron band were tightened round the head. It thus appears that it has a vasomotor property somewhat similar to amyl nitrite and glycyl trinitrate. Could continuous exposure to this acid cause any ill effect? Any information concerning this matter will be most welcome. (The formula of hydrazoic acid is HN_3).

A. R. Côté, M.D., Brownsburg, Quebec.

ANSWER.—It appears that this substance possesses toxic properties akin to the oxides of nitrogen and also to the nitrites. Extensive exposure may be expected to lead to pulmonary edema. Trivial exposure may occasion inflammation along the respiratory tract, particularly in its upper portion. This is the characteristic action of various oxides of nitrogen. In addition there may arise headache, vasomotor disturbances, lowered blood pressure and rapid heart, which are common manifestations of the action of nitrites. It is probable that hydrazoic acid is not highly stable or, at least, that it may be associated with other nitrogen compounds. It is a possibility that the damage that may be done to exposed workmen may not be the direct result of the hydrazoic acid but to associated compounds, particularly oxidation products. Actual cases are rare.

The following articles will furnish detailed information as to cases and experimental work:

- Kocher, Z.: A Case of Hydrazoic Acid Poisoning, *Klin. Wchnschr.* 9: 2160 (Nov. 15) 1930.
Stern, Rudolf: Ueber Toxische Wirkungen der Stickstoffwasserstoffsäure, *Klin. Wchnschr.* 6: 304 (Feb. 12) 1927.
Biehler: The Pharmacology of Hydrazoic Acid, *Knolls. Mitt. f. Aerzte* 21, 1927.
Biehler: The Pharmacology of Hydrazoic Acid, *Arch. f. exper. Path. u. Pharmacol.* 126: 1, 1927.
Kobert: Lehrbuch der Intoxikationen, 1906.

From the experimental work of Biehler, hydrazoic acid was found to be an irrespirable gas, leading to pulmonary edema, respiratory paralysis, diminished blood pressure and rapid heart.

In the articles cited, additional articles in literature are referred to.

USE OF GLYCINE IN MYASTHENIA GRAVIS

To the Editor.—What, if any, untoward actions might be anticipated from the administration of glycine in a case of myasthenia gravis? What is the pharmacologic action of this chemical substance?

K. F. Weiss, M.D., Visalia, Calif.

ANSWER.—Glycine (also known as glycolic) or aminoacetic acid, must be distinguished from the photographic developer parahydroxyphenyl amino-acetic acid, unfortunately marketed under the trade name "Glycin." The latter is a poisonous substance, partaking of the toxic properties of this class of reducing compounds.

The amino acid glycine is, of course, a normal constituent of protein, being present to the extent of about 25 per cent in

gelatin, for instance. The latter is one of the commercial sources of aminoacetic acid. No untoward effects might be expected, then, from the administration of moderate amounts of glycine. In the cases of myasthenia gravis studied by Boothby (*Proc. Staff Meet., Mayo Clin.*, Sept. 28, 1932) 15 Gm. of glycine twice daily apparently produced no ill effects.

Physiologically, glycine has been found to increase the excretion of creatine, being more effective in this respect than any other amino acid tried. Since it appeared that some deficiency in creatine metabolism (which has been found to be involved in the physiology of muscular activity) may be a factor in progressive muscular dystrophy and in myasthenia gravis, glycine was tried apparently with promising results in a few patients. It is, of course, too early to make any definite statement as to the eventual rôle of glycine in the treatment of such conditions.

Following is a bibliography of the recent literature on this subject:

Thomas, Milhorat and Technor: *Ztschr. f. physiol. Chem.* 205: 93, 1932.
Milhorat, Technor and Thomas: *Proc. Soc. Exper. Biol. & Med.* 29: 609 (Feb.) 1932.
Rose, W. C.: Annual Review of Biochemistry, J. M. Luck, editor, Stanford University Press 2: 195, 1933.

MAPLE SYRUP AND URTICARIA

To the Editor.—Is maple sap or freshly made maple syrup a common causative factor in urticaria? I have recently seen five cases of urticaria in children and in every instance the offending substance ingested seems definitely to have been maple sap, freshly made maple syrup and in one instance (a 3 year old girl) freshly made maple sugar. As no other maple sap season has ever been accompanied by characteristic urticaria, I am wondering whether the maple products are a cause or a coincidence. Please omit name.

M.D., Wisconsin.

ANSWER.—The sap from which maple sugar and similar products are made contains a material to which patients can become sensitive in the same sense that honey or cane sugar occasionally contains substances from the sap of plants which can sensitize and cause allergy in human beings. The offending substance is contained in exceedingly minute amounts—in fact, so minute that it is not possible to get hold of the offending substance. The condition is analogous to a case in which a young man was sensitive to an extract from corn silk, corn shuck and leaves of corn (reported by W. W. Duke in *THE JOURNAL*, Aug. 6, 1932). This patient did not react to the pollen, the grain or the fungus that grows on corn but did react to the sap. It is analogous also to honey sensitiveness reported in Duke's monograph on allergy (St. Louis, C. V. Mosby Company, 1925) in persons reacting to certain types of honey, in one instance only to wild honey.

The treatment of these cases should be primarily one of avoidance, but if the occupation of necessity brings the patient in contact with maple sap, an attempt at desensitization might seem advisable.

DEFICIENCY OF GROWTH HORMONE

To the Editor.—Would you advise me regarding the probable cause and outline treatment for the following case, and give prognosis: A girl, aged 19, has never yet menstruated. She is the third of seven children, all living and well and apparently normal except that the next older brother is below par mentally. The father and mother are living and well. The patient's personal history is negative except for menstruation. She is 57½ inches (145 cm.) tall and weighs 86½ pounds (39 Kg.). The span is 57 inches. There is no axillary or pubic hair. The mammae are very small. The nipples are small and inverted. The areola of the nipple is almost imperceptible. The patient bites off her fingernails close. Please omit name.

M.D., Kansas.

ANSWER.—The patient's short stature indicates that she probably has suffered a lack of the growth hormone of the anterior lobe of the pituitary. However, as this is not the only cause of a lack of growth, nonendocrine conditions should first be ruled out, such as diseases in the parents, childhood infections in the patient and her exposure to various toxins. If no nonendocrine cause for her lack of growth can be discovered, it can with reasonable certainty be ascribed to a lack of the growth hormone of the anterior pituitary.

The absence of pubic and axillary hair and the lack of development of the mammae might also be attributed to a lack of pituitary function, a failure of the sex hormone of the anterior lobe. Whether each of these deficiencies, that is, the deficient growth and the failure of the menstrual function and sexual development, should be ascribed to failure of a separate hormone, as is now indicated by recent experimental work, or whether all should be attributed merely to a breakdown in the anterior

lobe is in this connection of only academic interest. Her stature, the relationship of the upper to the lower measurement, and the absence, presumably since they are not mentioned, of gastrointestinal upsets, tend to rule out a primary ovarian failure as the cause of the amenorrhea.

The prognosis in such cases is fair. Treatment may include experimentally anterior lobe by mouth in doses of from 0.3 to 1 Gm. three times a day in enteric coated tablets. Preparations of the growth and sex hormone should be given in doses of one ampule each three times a week. Administration of theelin experimentally may also be of value.

PARAPHENYLENEDIAMINE DERMATITIS

To the Editor:—A man, aged 21, is engaged in the cutting of furs and making them up into wearing apparel. During the last year he has had a marked dermatitis when engaged in the work. When the patient is given treatment and remains away from furs, the condition clears up; but on reengaging in the work, he notices itching and reddening of the skin in from eighteen to thirty-six hours, associated with intense itching. I should appreciate it if you would send me any suggestions relative to what to do with this patient so that he may continue his work. It is well paid and he is extremely anxious to keep on working at the present time. Please omit name.

M.D., Iowa.

ANSWER.—This dermatitis, in all likelihood, is due to contact with paraphenylenediamine or other fur dye. A lesser possibility is that the worker is sensitized to fur itself rather than to any fur dye or other chemical employed in the tanning and preserving of furs.

It is desirable that patch tests be carried out to determine the substance to which the worker is sensitive. The technic for patch testing may be found in an article entitled "The Contact or Patch Test in Dermatology: Its Uses, Advantages and Limitations," by M. B. Sulzberger and Fred Wise (*Arch. Dermat. & Syph.* 23:519 [March] 1931).

The prospects of continuation in this trade without recurrences of the dermatitis are not good. Desensitization is not promising. The general upbuilding of health will provide some expectation of betterment; protective garments will bring about a small amount of additional security; after years of exposure, natural immunity may develop, but this is not assured. If patch tests indicate a well established sensitivity, and if the dermatitis is severe, probably it would be to the advantage of this youthful workman to change occupation at an early time.

P. J. Hanzlik (*J. Indust. Hyg.* 4:386 [Jan.], 448 [Feb.] 1923) and R. Williamson (*ibid.* 4:507 [April] 1923) have presented an extensive discussion of paraphenylenediamine toxicity.

A. L. A.

To the Editor:—Enclosed please find pamphlet of A. L. A., supposedly a superior local anesthetic. Please give your opinion of its value as a local anesthetic.

M. J. SCHWARTZ, M.D., Chicago.

ANSWER.—"A. L. A." is the unscientific proprietary name for a local anesthetic which is being exploited to the medical profession by Sutliff & Case Company, Inc., Peoria, Ill. According to the advertising literature the product has the following formula:

| | per cent |
|-------------------------------------|----------|
| P-Aminobenzoic Acid Ethylester..... | 3 |
| Phenethylol | 5 |
| Ether | 10 |
| Olive Oil | 82 |

P-Aminobenzoic Acid Ethylester is the cumbersome name for ethyl aminobenzoate-U. S. P. (Anaesthesine). Phenethylol is a name for a product which is better known under the designation benzyl alcohol. If the firm had wanted to be absolutely candid about the composition of its product it would not have been necessary to hide the composition under the noninforming initials A. L. A.; the statement of composition could have been given in the chemical terms easily understood by the medical profession rather than those terms which, in effect, hide the identity of the product. Naturally, the product does not stand accepted by the Council on Pharmacy and Chemistry.

MOST RAPID HEART BEAT

To the Editor:—In the Heart Rate, by Boas and Goldschmidt, the statement is made that "the highest rate that we have seen reported is 246, after thirty minutes of exhausting exercise which resulted in collapse." Will you kindly advise whether this is the highest rate ever recorded, and if not, what is the highest on record?

M. C. SILIN, Boston.

ANSWER.—A survey of recent literature indicates a report of 300 beats per minute maintained without intermission for several days in a case reported by Russell and Ellison (*Lancet* 2:546 [Sept. 10] 1927). In this case the number of beats was

recorded by the electrocardiograph and the polygraph. There are numerous instances on record of from 270 to 290 beats per minute, checked by the electrocardiogram. Previous to the development of these devices it was necessary to depend on auscultation, which, obviously, could not yield so accurate a count of the rate as is accomplished by the mechanical methods mentioned.

Council on Medical Education and Hospitals

COMING EXAMINATIONS

ALASKA: Juneau, Sept. 5. Sec., Dr. Harry C. DeVighne, Juneau.
AMERICAN BOARD OF DERMATOLOGY AND SYPHILOLOGY: *Written*. Boston, Chicago, Cleveland, New York, Philadelphia, St. Louis and San Francisco, Oct. 28. *Oral*. New York, Dec. 15-16. Application must be filed before Sept. 1. Sec., Dr. C. Guy Lane, 416 Marlboro St., Boston.
AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY: The examinations will be held in various cities of the United States and Canada, Dec. 9. Sec., Dr. Paul Titus, 1015 Highland Bldg., Pittsburgh.
AMERICAN BOARD OF OTOLARYNGOLOGY: Boston, Sept. 16. Sec., Dr. W. P. Wherry, 1500 Medical Arts Bldg., Omaha.
NATIONAL BOARD OF MEDICAL EXAMINERS: *Paris I and II*. The examinations will be held at centers where there are five or more candidates, Sept. 13-15. Ex. Sec., Mr. Everett S. Elwood, 225 S. 15th St., Philadelphia.
NEW HAMPSHIRE: Concord, Sept. 14-15. Sec., Dr. Charles Duncan, State House, Concord.
NEW YORK: Albany, Buffalo, New York and Syracuse, Sept. 25-28. Chiel, Professional Examinations Bureau, Mr. Herbert J. Hamilton, Room 315 Education Bldg., Albany.
OKLAHOMA: Oklahoma City, Sept. 12-13. Sec., Dr. J. M. Byrum, Mammoth Bldg., Shawnee.
PUERTO RICO: San Juan, Sept. 5. Sec., Dr. O. Costa Mandry, Box 536, San Juan.
WISCONSIN: *Basic Science*. Madison, Sept. 23. Sec., Prof. Robert N. Bauer, 3414 W. Wisconsin Ave., Milwaukee.

Arizona January Report

Dr. J. H. Patterson, secretary, Arizona Board of Medical Examiners, reports the written examination held in Phoenix, Jan. 10-11, 1933. The examination covered 10 subjects and included 100 questions. An average of 75 per cent was required to pass. Four candidates were examined, 3 of whom passed and 1 failed. One physician was licensed by reciprocity. The following colleges were represented:

| College | PASSED | Year Grad. | Per Cent |
|--|--------|------------|----------|
| Harvard University Medical School..... | (1930) | | 86.2 |
| Jefferson Medical College of Philadelphia..... | (1930) | | 79.3 |

Book Notices

Lymphatics, Lymph and Tissue Fluid. By Cecil K. Drinker, B.S., M.D., Professor of Physiology, Harvard School of Public Health, and Madeleine E. Field, A.B., Ph.D., Instructor in Physiology, Harvard School of Public Health. Cloth. Price, \$3. Pp. 254, with 14 illustrations. Baltimore: Williams & Wilkins Company, 1933.

Much information on lymph and tissue fluid appears as isolated articles in journals of physiology, immunology, anatomy and pathology. The authors of this monograph have attempted to correlate such data and present their views on the subject. The first chapter deals with the embryology and anatomy of the lymphatic system. Sabin's conception of the origin of lymphatics is held by the authors as opposed to the view of Huntington, McClure, Kampmier and others who believe that the earliest lymphatic trunks are established by progressive coalescence of originally discontinuous mesenchymal spaces. The latter view deserves more than passing notice in spite of the authors' preference. This chapter on the whole is, however, a well summarized introduction. The chapters on physiology of lymph and tissue fluid are excellently written and present a vast amount of data in readily available form. The chapters on the entrance of foreign particles and colloidal solutions into the lymphatics and on the permeability of the blood capillaries are especially well organized. Chapters on the flow of lymph, composition of lymph and a consideration of tissue fluid complete the expository phase of the monograph. The authors then point out the practical considerations of the subject. While they are distinctly limited by a lack of complete data, this chapter is well done and should serve a useful purpose for those interested in a practical application of facts. The authors are to be commended for their attempt to present a working conception of the lymphatics. The monograph will be of special interest to the physiologist, anatomist and pathologist, but the internist also should find in it stimulation as well as a number of workable facts.

Vorbeugung und Bekämpfung der Operationsgefahren. Von Professor Dr. M. Kappis. Paper. Price, 17 marks. Pp. 382, with 12 illustrations. Leipzig: Georg Thieme, 1933.

This monograph, by Kappis of Hanover, deals with precautions to be taken and methods of combating operative dangers. Operations have become standardized and there is little to be expected in the way of improvement in technic. At present the surgeon's chief efforts are directed toward determining in advance the patient's ability to withstand operation, to decrease the dangers of operation by special and general preoperative measures, and to increase the chances of cure by careful post-operative management. It is with these subjects that this volume is concerned. Special consideration is given to the newer concepts of normal and pathologic physiology and to the latest developments in the other biologic and natural sciences. Whenever these can be made use of, they are applied to the patient about to be operated on, during the course of the operation, and postoperatively. The chief value of the volume is in the application of this new knowledge in surgery. The author points out that a study of the causes of death following operation in his clinic shows that 55 per cent were the result of the condition for the relief of which the operation was undertaken, and that, obviously, practitioners are limited in their ability to help extremely sick patients, such as those suffering from cancer, suppurative peritonitis, or severe injury. On the other hand, many of the other causes of death are more or less preventable. These include pulmonary complications (pneumonia, lung abscess, bronchitis), which constituted 7.5 per cent; thrombosis and embolism, which constituted 1.6 per cent in 1923, over 8.6 per cent in 1930, and 6.5 per cent in 1931; the general condition of the patient, 14 per cent. patients in whom operation was hazarded as the last and only hope; operative infection, often unavoidable, as in operations on the stomach and intestine for cancer or ileus; mistakes in diagnosis, improperly selected time of operation, or improperly planned operative technic, and special postoperative complications, as cerebral hemorrhage and the like, which accounted for 1 per cent. It is possible to decrease many of these by attention to the nervous system, the organs of circulation, the metabolism and the important viscera, including the endocrine glands. The aim of the author has been to collect this infor-

mation in one volume, so that the experienced as well as the inexperienced surgeon can evaluate, as well as present knowledge allows, the ability of a particular patient to withstand operation, and his limits. The material is divided into three parts. Part I, of 150 pages, considers preoperative precautions and preoperative preparation. Each of the organs and systems is considered separately with discussions on the methods of determining whether they are functioning normally or not, and the means of correcting them, so far as is possible, before operation. Part II, of 50 pages, discusses the dangers that occur during the time of operation and immediately following, with the appropriate treatment. Part III discusses postoperative care. This comprises 180 pages, or almost half of the volume. It is divided into two parts, general and special, the former comprising two thirds of this portion of the work, the latter about one third. Under the latter the special post-operative care is grouped under operations on the various systems and organs. The directions are explicit as to the care following these special operations and even include elaborate diet lists, planned by days. The work is strictly down to date, is based on modern thought, and source references to the literature are given at the bottom of the pages. It is a valuable book for all surgeons able to read German and for all others who are responsible for the care of patients requiring operation.

Laboratory Manual: Methods of Analysis of Milk and Its Products. Compiled by International Association of Milk Dealers. Fabrhold. Price, \$5. Pp. 462, with 140 illustrations. Chicago: The Association, 1933.

The Laboratory Committees on Research and Methods of the International Association of Milk Dealers have collected in this comprehensive laboratory handbook the practical data of the literature of their industry, including methods of bacteriologic and chemical examination of dairy products and products used in the dairy industry, such as fruits, flavors and gelatin. The testing of washing solutions, brines, sterilizing solutions, and sterility of milk bottles and cans are included. Practically all laboratory tests used in large or small milk or dairy products plants are presented in detail. The manual makes scattered data readily available and will tend to standardize laboratory procedures which are prime essentials to a still greater perfection of methods, greater efficiency in the technical control of the industry, and improvement in the quality and health safety of the tremendous output of dairy products. Sections are devoted to the organization of a dairy laboratory, bacteriologic control methods, chemical and physical control methods for dairy products, bacteriologic, chemical and physical tests for nondairy products, and the preparation of bacteriologic mediums, standard solutions and indicators. The appendix is notably complete in conversion tables, engineering data and tables, legal standards, authoritative analyses and properties of dairy and related products, and other practical plant information. The arrangement and classification of the material are excellent.

La transfusion du sang de cadavre à l'homme. Par Serge Judine, professeur, chirurgien en chef du service de chirurgie à l'Institut de Traumatologie et de chirurgie d'urgence. Préface du professeur A. Gosset. Paper. Price, 24 francs. Pp. 144. Paris: Masson & Cie, 1933.

In this monograph, Serge Judine reports his interesting experiences and experiments in performing the first hundred transfusions in which cadavers were used as donors. The author is the chief of the Emergency Hospital in Moscow, a city of more than three million inhabitants, which cares for street accidents, industrial accidents and emergencies of all sorts. It has an operative activity unequaled in the whole world. In such a center, emergency transfusions are often necessary. Not being able always to have desirable donors at his disposal, Judine sought a solution of this difficult problem. He knew the experimental work of Schamoff, who bled dogs as completely as possible, washed physiologic solution of sodium chloride through their veins, and then revived them by transfusing into them blood from cadaver dogs killed several hours previously. Judine decided to apply this method to human patients.

After experimenting on dogs himself and determining the innocuousness and efficiency of these transfusions, particularly if the blood is removed within less than eight hours post mortem, the first opportunity to try it on a man presented

itself. The first case in which Judine used the blood of a cadaver was that of a young man who attempted suicide by cutting the veins of the cubital fossa with a razor. The patient was in an agonal condition, extremely pale, pulseless, hardly breathing, and with dilated pupils. A transfusion was indicated, but it was the middle of the night and there was no donor obtainable. Judine had in the institute the cadaver of an arteriosclerotic patient, aged 60, who had died six hours previously and whose blood was of the same group. He decided to act. He opened the abdomen of the deceased, and from the vena cava withdrew 450 cc. of blood, which he injected immediately into the patient. A veritable resurrection occurred. No toxic reaction followed, and four days later the patient left the hospital. Since then he has used this method successfully in more than one hundred cases.

He used the blood from intact cadavers who died of suicide, heart disease or skull fracture. Blood is drawn under aseptic precautions through a cannula in the jugular vein, with the cadaver in an exaggerated Trendelenburg position. From 1 to 1.5 liters may be obtained in a minute or two. The blood is collected in sterile flasks, preserved with sodium citrate, 2 Gm. to 500 cc. of blood, stoppered with cotton, and placed in the icebox, where it is kept at a temperature of from 1 to 2 C. and where it may remain in good condition until used, or as long as twenty-eight days. It is best, however, to use it during the first eight days. The blood group is determined and a Wassermann test is performed in each case, either before or after death. Cadaver blood and refrigerated blood can be grouped without any abnormality. His indications for transfusion, the technic and the amount of cadaver blood used are the same as when living donors are used. The results have been satisfactory, at times striking, and are not associated with any greater percentage of reactions, particularly if the blood used has been taken from a cadaver dead less than twelve hours. These researches of Judine must be recognized as extraordinary. The idea of transfusing cadaver blood, however, cannot fail to offend and will probably not be accepted universally for a long time.

Group Payment for Medical Care: The Stanocola Employees' Medical and Hospital Association, Baton Rouge, Louisiana. Financial and Administrative Features. By C. Rufus Rorem, Ph.D. Quality of the Professional Services. By John H. Musser, M.D., Paper. Pp. 40. Chicago: Julius Rosenwald Fund, 1932.

Since 1924 a group of employees of the Standard Oil Company of Louisiana have operated the Stanocola Employees' Medical and Hospital Association, an organization maintained to furnish medical and hospital services to themselves and their dependents. The report of this project is a brief in favor of the insurance principle by the distribution of the burden of cost over a considerable number of persons. The beneficiaries of the plan pay \$36 annually, an amount which, it is stated, represents about 2.5 per cent of family income. For the year 1931 the total costs to the association for medical services were \$92,245.80. Of this amount, \$41,175.00 was paid for the services of seven physicians. It is claimed that these physicians received more than they would have been able to collect in independent practice among the same group. A value of the amount of service rendered by the medical staff may be estimated by multiplying the volume of services by the average fees for each type of service. It is found that this amount reaches approximately \$200,000. This seems to be ample reason for the statement that the association has been an economic success in the savings to its members. It ought to be added, however, that the medical staff has contributed services equivalent to about \$160,000 to the success of the project.

Although it is implied that a free choice of physician is available, it is obvious that this free choice is limited to the seven physicians on the staff. The authors refer to the work of the physicians employed by the Standard Oil Company as group practice. It is possible that the organization of the physicians resembles independent group practice; however, it would appear that all these physicians who receive full time salaries from the Standard Oil Company are contract group physicians in the ordinary sense of the term.

It is claimed that the members of the Stanocola Employees' Medical and Hospital Association appear to receive a type of medical service that is remarkable, considering the financial outlay. It is admitted that definite limitations are placed on the

character of the medical service and that some of the physicians have too large a group to care for. It is claimed that the physicians have certain advantages in this organization, such as freedom from financial worries, the daily contact with other physicians who maintain a constant contact with medical advances, no fear of losing a patient to another physician and certain time off each week in addition to a vacation period without loss of income. Nothing is said concerning the attitude of the county or state medical societies relative to this or similar projects. The report leaves the reader with the impression that the plan is considered a model one which should be adopted elsewhere.

Les tachycardies paroxystiques ventriculaires. Par Roger Froment. Préface du Docteur L. Gallavardin. Paper. Price, 50 francs. Pp. 541, with 47 illustrations. Paris: Masson & Cie, 1932.

On approaching this book, one wonders how 500 pages can be used in a discussion of ventricular tachycardia. One discovers that the author does it exceedingly well and without unnecessary circumlocution. Ninety-nine cases are reported which illustrate all possible forms of this disorder and one suspects that these cases represent all that are to be found in the literature to date. The book is opened by a general consideration of the subject. Here are considered the importance of this disorder, some historical facts in connection with it, and the diagnostic criteria, both clinical and electrocardiographic. The author then divides the cases into two main groups, the grave type (*les tachycardies ventriculaires pré-fibrillatoires*), and a benign type. It is with the former type that a large part of the book is concerned. A consideration of the causes of this disorder includes diseases of the coronary artery, chloroform intoxication, certain drugs, diphtheria toxin, pulmonary embolism, the rôle played by the extracardiac nerves, and electrical irritation of the myocardium. Among the drugs that are given a place in the discussion are digitalis and its allies, whose danger in this condition should be well known. Quinine is mentioned as a dangerous drug to use in cases in which the heart appears damaged. This fact does not seem so well known and this portion of the work is worthy of serious study. It seems probable that the author somewhat exaggerates the dangers of morphine in this connection. A clinical consideration of the subject follows, which includes electrocardiographic studies of the various types of the disorder and is concluded by a discussion of treatment. A bibliography of 426 references introduces a somewhat novel feature: the references are classified in accordance with the author's idea of their importance. Some references are labeled "fundamental," others "important," still others "of average importance," while the remainder carry no special mark. The book is excellently done and is clearly the result of long and painstaking study of the subject. To all who are interested in this disorder the book is highly recommended.

Slums, Large-Scale Housing and Decentralization. Edited by John M. Gries and James Ford. Reports of the Committees on Blighted Areas and Slums, Abram Garfield, Chairman. Large-Scale Operations, Alfred K. Stern, Chairman. Business and Housing, Harry A. Wheeler, Chairman. Industrial Decentralization and Housing, Stuart W. Cramer, Chairman. Cloth. Price, \$1.15. Pp. 245, with illustrations. Washington, D. C.: President's Conference on Home Building and Home Ownership, 1932.

Reports of four committees of President Hoover's Conference on Home Building and Home Ownership are presented in this volume. The Committee on Blighted Areas and Slums discusses the economic, social and health aspects of slums, and their prevalence in America in smaller cities as well as in metropolitan centers. This report is followed by appendixes representing individual opinions supplementing the committee's report. These seem to be more in the nature of amplification and by way of advocating individual recommendations than minority reports. The Committee on Large-Scale Operations for the eradication of slums makes a report in which is discussed the importance of capital in the provision of housing, and the unsound condition of the present social structure, in which adequate housing is, at least in urban centers, a luxury product and is unadapted to improvement. Large-scale operations for slum improvement are held to be essential, and a few are cited, with emphasis on the fact that there are few to cite. It is pointed out that philanthropy has given impetus to many of these projects. It is also pointed out that large-scale operations need not imply the apartment house type of residence but

may be expressed in groups of individual houses. There are six appendixes to this report. The third committee deals with housing and business. The sum of its deliberations is that housing must be provided on a business and not a philanthropic basis, and that it is time business got at the problem before government swallows the opportunity. This is not the only report which intimates, sometimes bluntly, that, unless slums are cleared out by private initiative, government will do it, a threat which history should lead one to believe is not idle. This chapter has two appendixes. The last report is one devoted to industrial decentralization and housing, distribution of wage earners, and location tendencies of industries, setting forth the advantages of small industrial-agricultural communities as compared with the great population centers that now exist. The report is an interesting and valuable collection of facts, useful especially to those who are concerned with the slum and its influence on community health, morals, progress and economics.

The Legal and Ethical Aspects of Medical Quackery. By Leonard La Marchant Minty, Ph.D., B.Sc., B.Com., South Eastern Circuit and Central Criminal Court, Barrister-at-Law. Cloth. Price, 7/6. Pp. 262. London: William Heinemann, Ltd., 1932.

This is an interesting and informative little book, in which the author, an English barrister, discusses the irregular practice of medicine, herbalists, bonesetters, chiropractors, osteopaths, homeopaths, abortionists, peripatetic opticians, "patent medicine" quackery and religious quackery. Much of the book is written from the standpoint of English law and custom, but the conditions described do not seem to differ widely from analogous conditions in the United States. Although the author's discussion of affairs in this country is in some respects out of date and in others erroneous, American readers are hardly likely to be misled. To any one who is interested in the broader aspects of quackery as related to the art of healing, the book is worth while.

The Effect of Sunlight and Other Factors on the Strength and Color of Cotton Fabrics. By Mary Anna Grimes. Division of Rural Home Research, Texas Agricultural Experiment Station, Bulletin No. 474. Paper. Pp. 56, with 27 illustrations. College Station, Texas: Agricultural and Mechanical College of Texas, 1933.

This pamphlet contains a review of the literature and also a report on the original work carried out at the Texas Agricultural Experiment Station on twenty-two cotton fabrics, which were exposed to sunlight from 25 to 375 hours in 25-hour periods. It was found that, in general, an increase of time of exposure resulted in a greater color fading and also in a reduced strength. The loss in breaking strength was not to the same extent in all fabrics. The average loss in the breaking strength of the cotton fabrics after 375 hours of exposure ranged from approximately 8 to 47 per cent in the warp and from 18 to 58 per cent in the filling. Spectrophotometric analysis of the color of each fabric before and after exposure to sunlight revealed that all fabrics, whether white or dyed, underwent some change in color. Unbleached fabrics became lighter, and bleached undyed fabrics became grayer and more yellow.

Die Blutgruppen und ihre Anwendungsgebiete. Von Dr. Fritz Schiff, Abteilungsdirektor am Städtischen Krankenhaus im Friedrichshain, Berlin. Mit einem Beitrag: Indikationen und Technik der Bluttransfusion. Von Professor Dr. Ernst Unger, Dir. Arzt am Rudolf Virchow-Krankenhaus, Berlin. Paper. Price, 18.60 marks. Pp. 267, with 96 illustrations. Berlin: Julius Springer, 1933.

Here is one more book on the blood groups and their applications in transfusion and otherwise. It is divided into the following chapters: the human blood groups; blood transfusion, with a section on indication and technic by Ernst Unger; blood groups in criminology; heredity in blood differences; the examination of biologic descent (parentage); the importance of the blood groups in certain problems of heredity; blood groups and anthropology; blood grouping in the animal kingdom. The book does not deal with the details of the technic of practical blood grouping; for technical instructions the reader is referred to the author's *Die Technik der Blutgruppenuntersuchung*, the second edition of which was published in 1929. Fortunately these two books are published in the same handy format by the same publisher. In the book now under review the section formed by pages 72 to 79, on the methods used in certain large cities to secure adequate supplies of healthy

donors for therapeutic transfusion, will be of especial interest to those who are directly concerned with this important problem. The book is comprehensive, reliable, handy. It is provided with an extensive bibliography arranged alphabetically according to the names of authors. With its sister volume on technic it constitutes a third standard recent work on blood grouping. The other two are Lattes' *Individuality of the Blood*, Oxford University Press, 1932, and *Handbuch der Blutgruppenkunde*, edited by Paul Steffan, Munich, J. F. Lehmann, 1932.

Accounting and Business Procedure for Hospitals. Prepared by New York Conference on Hospital Accounting. Herbert R. Sands, Consulting Accountant. Cloth. Pp. 185. New York: United Hospital Fund of New York, 1933.

This is not a textbook on bookkeeping—it is not a treatise on the theory and practice of accounting, as such. It is a presentation of the principles on which hospital financing, accounting and management are based. Among the subjects of valuable chapters are the proper handling of endowment and other funds, the determination of rates, the purchasing, storing and issuing of supplies, and the handling of payrolls and budgets. Attention is given to statistical reports in addition to the financial statements, and brief suggestions are made regarding medical statistics, including analyses of case histories. The book does not present a system, or a set of forms, that can be taken over by hospitals, but it should be a valuable help to any one who is concerned with the administration of a hospital. Incidentally, it suggests an approach to a greater uniformity in financial and medical statistics.

Wissenschaftliche Forschungsberichte, naturwissenschaftliche Reihe. Herausgegeben von Dr. Raphael Ed. Liesegang. Band XXX: Fortschritte der Serologie. Von Hans Schmidt, Dr. med. a. o. Prof. für Hygiene. Institut für exper. Therapie "Emil v. Behring," Marburg a. L. Paper. Price, 12 marks. Pp. 191, with 20 illustrations. Dresden & Leipzig: Theodor Steinkopf, 1933.

This book reviews the progress of serology during the last few years and up to July, 1932. The word serology is used in a strictly limited sense and includes only such immune phenomena as may be studied in the test tube. In other words, the book does not deal with the biologic problems of immunity, infectious and otherwise, or of anaphylaxis. An enumeration of the main topics will indicate better the exact scope of the book: antigen and haptens, agglutination, hemagglutination, specific precipitation, complement, hemolysis, complement fixation and deviation, the Wassermann reaction, inhibition zones in serologic reactions, phagocytosis, bactericidal and bacteriolytic antibodies, toxins and antitoxins, the lipoids in serologic reactions, and the formation of antibody. The book gives an authoritative, more or less critical, instructive review of the progress of investigation of the problems just indicated.

Pediatric Nursing: A Text-Book for Nurses. By Abraham Levinson, B.S., M.D., Associate in Pediatrics, Northwestern University Medical School. Second edition. Cloth. Price, \$2.75. Pp. 282, with 29 illustrations. Philadelphia: Lea & Febiger, 1933.

The chief duty of the nurse is to carry out the treatment prescribed by the physician and to render aid in prophylaxis so far as she is able. The nurse who understands the essentials of the disease from which her patient is suffering is likely to be more efficient in caring for that patient than one who understands only nursing technic. However, the knowledge of nursing technic is of first importance for the nurse. In this book, special emphasis is placed on these subjects. Enough information on the anatomy and physiology of the infant is included to give the nurse a background on which to base intelligent care of the baby. Unlike many other books written for the nurse, this one is dedicated to her. In other words, it is prepared in language that she can understand. It discusses all problems from her standpoint, and not from that of the physician. As a textbook for nurses interested in pediatrics, this book should find its place.

A Surgeon's Pocket Book. By H. S. Souttar, D.M., M.Ch., F.R.C.S., Surgeon, London Hospital. Cloth. Price, 7/6. Pp. 285. London: William Heinemann, 1933.

This is a small, pocket sized compend of surgery, actually an abstract of the author's textbook "The Art of Surgery." It is written in skeleton outline form and in itself is insufficient. As a companion to the regular textbook it may prove helpful to the student for study and review.

Medicolegal

Sponge Left in Abdomen: Physician, Not Nurse, Responsible.—The appellant left a sponge in his patient's abdomen after an operation. She sued him. The trial court gave judgment in the patient's favor, and the physician appealed to the Supreme Court of Indiana. He admitted that he put the sponge into his patient's abdomen and that he relied, as was the custom, on the report of a nurse that all sponges used in the operation had been accounted for. The nurses who assisted were provided by the hospital. Their mistakes, he contended, could not be imputed to him.

A physician who is performing an operation in the abdomen, said the Supreme Court, cannot assign details of it to persons who are to assist him, unknown to the patient, and escape liability by relying on them to perform duties that he himself is obliged to perform. Although the evidence supported the physician's contention that good surgical practice left it to nurses to account for instruments and sponges used, that evidence, the court held, did not exonerate him as a matter of law; a jury might consider it in determining whether he was or was not negligent, but the determination rested exclusively with the jury.

The physician-appellant objected because his patient, the appellee, introduced no expert testimony to prove negligence. The introduction of expert testimony, said the court, was a matter of defense. The rule of *res ipsa loquitur* applied and it put on the appellant the burden of proving that he was not negligent. Of the many expert witnesses who testified for the appellant, not one testified that it was in any way beneficial or useful to leave a sponge in a patient's abdomen. The sponge in this case had a tape attached, to which, according to the expert testimony, forceps were to be attached. The tape and forceps should have hung outside the body as long as the sponge was in the abdomen, for the very purpose of preventing a loss of the sponge after it had served its purpose. The appellant, said the court, offered no testimony to show that the requirements of good surgical practice had been met and that forceps attached to the sponge had been left hanging outside the patient's body. If this had been done, it seemed to the court, the incision would not have been closed without finding the tape protruding through the opening.

The decision of the issue in a case such as this, said the court, cannot rest entirely on expert testimony, as the appellant would have it do. Such a practice would invade the province of a jury and take from it its duty of deciding whether a given set of facts does or does not constitute negligence. The propriety of placing sponges in the abdomen may be a matter to be proved by expert testimony, but the propriety of removing them after they have been so placed is not. To leave a sponge in the abdomen knowingly might give rise to a question on which expert testimony would be competent, but no such question is presented here; the appellant did not knowingly leave the sponge in his patient's abdomen. The inference that this sponge should have been removed before the completion of the operation is supported by abundant evidence.

The judgment of the trial court against the physician-appellant was affirmed.—*Funk v. Bonham (Ind.)*, 183 N. E. 312.

When Is a Child Born Alive.—Stuertz died without leaving a will. Sept. 19, 1929. On May 23, 1930, his widow, after a prolonged and difficult labor, gave birth to a child. At birth the child showed signs of asphyxiation. The child made no effort to breathe nor any other movement, but the umbilical cord pulsed. The cord was ligated, injections of lobelia were given to stimulate breathing, and artificial respiration and other usual methods to revive newly born infants were employed, but without success. After a half hour or so these efforts were discontinued and the child was regarded as dead. The birth certificate reported the child as stillborn and stated the cause of death as toxemia.

On the hypothesis that the child was born dead, the parents of the deceased instituted a suit to enforce their supposed rights of inheritance in the estate. Pursuant to the directions of the trial court, the jury found that the child was born alive, and

the widow and child were therefore the heirs to the estate. The parents of the deceased then appealed to the Supreme Court of Nebraska.

In *Brock v. Kellock*, 30 L. J. (N. S.) 498, it was held that proof of breathing was not necessary to prove live birth, the pulsation of the umbilical cord being sufficient evidence. In *Goff v. Anderson*, 91 Ky. 303, 15 S. W. 866, 11 L. R. A. 825, it was held that a child was born alive when it made an effort to breathe after independent circulation and delivery, "independent circulation" meaning circulation maintained by the child independent of the mother. In *Doe ex dem. Cannon v. Killen*, 5 Houst. (Del.) 14, it was held that a baby was born alive when the pulsation of the umbilical cord was strong and the heart continued to beat for five minutes after the cord was cut. "A child never heard to cry, and who did not live, but whose heart beats were perceptible and could be heard, though no respiration could be induced, was 'born alive,' and was 'issue,' within a will." *Matter of Union Trust Co.*, 89 Misc. 69, 151 N. Y. S. 246. See also *Fleming v. Sexton*, 172 N. C. 250, 90 S. E. 247.

The evidence in the present case, said the Supreme Court of Nebraska, proves that the child at no time voluntarily breathed; that it made no sound; that it made no movement of any muscle of its own volition. It proves also that the child was well developed, that its heart sounds were discernible before delivery and that they were heard after the child was born, for twenty or thirty minutes according to the physician's evidence and for ten minutes according to the hospital record. The umbilical cord pulsated for fifteen or twenty minutes after it was cut. The court held that for every legal purpose the child was alive at birth. The judgment of the court below was affirmed.—*In re Stuerts' Estate (Neb.)*, 245 N. W. 412.

Sterility Not Due to Nervous Shock.—The plaintiff, a married woman, was injured in an accident. A jury awarded her \$2,500 as compensation for her injuries and suffering and \$5,000 as compensation for her supposed inability to bear children. The defendant appealed to the Supreme Court of Michigan, asking that the award for sterility be set aside. Her attending physician testified that in the accident the plaintiff received no cuts, no visible bruises and no objective signs of injury whatever. A roentgenogram taken four months after the accident showed "no pathology," no fracture, no dislocation and nothing to account for the pains in the plaintiff's neck, which her physician then concluded were due to "torn ligaments in the cervical region." Some months after the accident, he found that the plaintiff had uterine tumors, not attributed to the accident, which rendered her permanently sterile. Five months after the accident, however, he had examined her, found her physically capable of having children and advised her to do so. No children had been born to her since the accident, although at the time of the accident she had one child 8 months old, so he concluded that the plaintiff must have been made sterile by the extreme shock of her nervous system caused by the accident. "This kind of testimony," said the Supreme Court of Michigan, "is sterile." The testimony did not disclose evidentiary facts. The expert had but a theory, that the plaintiff was sterile, since she did not become pregnant; that she did not become pregnant, because of lack of ovulation; that the lack of ovulation was due to shock to her nervous system. Probative evidence must be something more tangible than a mere pyramiding of theories. The sterility here alleged was too remote and speculative, considering the nature of the injuries, to warrant the verdict rendered. The judgment of the court below awarding \$5,000 for sterility was reversed.—*Ford v. Nicol (Mich.)*, 246 N. W. 130.

Damages: Dentist's Loss of Earnings Because of Injury An Element.—The plaintiff, a dentist, was injured in an automobile accident. He sued and as an element of damages alleged the loss of earnings during absence from business. The trial court refused to allow this, and the dentist appealed to the court of appeals of Louisiana, Orleans. There is no doubt, said the court of appeals, that plaintiff's income was affected as a result of his injury. Counsel for the defendant, however, contended that loss of profits should not be allowed as damages because they were too remote, uncertain and speculative. If, said the court of appeals, the plaintiff had been employed on a

salary basis and had lost a part of his salary during his disability, there would be no question of his right to recover that loss as an element of damages. The courts are constantly awarding damages on this account to laborers who are paid by the day, week or month, and without objection as to the propriety of the awards. In what respects then does the claim of the plaintiff differ from salary or wages? The determining factor, said the court, is the certainty with which the loss has been established. When it has been definitely proved that a decrease in earnings has resulted from inability to exercise personal efforts or skill toward the production of income and the amount of such loss has been established with reasonable certainty, an award should be made. On the other hand, when the claim for profit is interwoven with other factors, such as invested capital and the industry and skill of others whose ability and zeal contribute to the result, such profits may not be the subject of an award. In the present case the record shows the gross and net income of the plaintiff for the years 1928, 1929, 1930 and 1931, and a comparison of these figures indicated that during the year of his injury, 1930, his income was less by \$2,211.67 than the average for the other three years. The appellate court concluded that the plaintiff had shown with sufficient certainty a loss of earnings attributable to his accident, in the sum stated.—*Crozat v. Toye Bros. Yellow Cab Co. (La.)*, 145 So. 60.

Recoverability of Medical Expense in Personal Injury Suit.—A court may authorize the jury, in awarding damages, to consider reasonable charges or expenses incurred or paid by the plaintiff for medical, surgical, hospital or nursing services and for medicines. To justify an instruction on this subject, such expense must be claimed in the petition, and the evidence must show not only that expenses were incurred or paid, and the amount thereof, but also that they were reasonable and necessary in view of the nature of the injury and the attending circumstances.—*Mrs. Baird's Bakery v. Davis (Texas)*, 54 S. W. (2d) 1031.

COMING MEETINGS

- American Academy of Ophthalmology and Otolaryngology, Boston, September 18-22. Dr. William P. Wherry, 1500 Medical Arts Building, Omaha, Executive Secretary.
- American Association of Obstetricians, Gynecologists and Abdominal Surgeons, Lucerne-in-Quebec, Canada, September 11-14. Dr. Magnus A. Tate, 19 West Seventh Street, Cincinnati, Secretary.
- American Congress of Physical Therapy, Chicago, September 11-15. Dr. F. B. Balmer, 185 North Wahash Avenue, Chicago, Secretary.
- American Roentgen Ray Society, Chicago, September 25-30. Dr. Eugene P. Pendergrass, 3400 Spruce Street, Philadelphia, Secretary.
- Association of Military Surgeons of the United States, Chicago, September 25-27. Dr. J. R. Kean, Army Medical Museum, Washington, D. C., Secretary.
- Colorado State Medical Society, Colorado Springs, September 14-16. Mr. Harvey T. Sethman, 537 Republic Building, Denver, Executive Secretary.
- Delaware, Medical Society of, Wilmington, September 26-27. Dr. W. O. La Motte, 604 Medical Arts Building, Wilmington, Secretary.
- Idaho State Medical Association, Twin Falls, September 18-19. Dr. Harold W. Stone, 105 North Eighth Street, Boise, Secretary.
- Indiana State Medical Association, French Lick, September 25-27. Mr. T. A. Hendricks, 23 East Ohio Street, Indianapolis, Executive Secretary.
- Kentucky State Medical Association, Murray, September 11-14. Dr. A. T. McCormack, 532 West Main Street, Louisville, Secretary.
- Michigan State Medical Society, Grand Rapids, September 12-14. Dr. F. C. Warnshuis, 148 Monroe Avenue, Grand Rapids, Secretary.
- National Medical Association, Chicago, August 13-14. Dr. Walter G. Alexander, 136 West Kinney Street, Newark, New Jersey, General Secretary.
- Nevada State Medical Association, Las Vegas, September 29-30. Dr. Horace J. Brown, 120 North Virginia Street, Reno, Secretary.
- New England Surgical Society, Boston, September 29-30. Dr. J. M. Birnie, 14 Chestnut Street, Springfield, Mass., Secretary.
- Ohio State Medical Association, Akron, September 7-8. Mr. Don K. Martin, 131 East State Street, Columbus, Executive Secretary.
- Pennsylvania, Medical Society of the State of, Philadelphia, October 2-5. Dr. Walter F. Donaldson, 500 Penn Avenue, Pittsburgh, Secretary.
- Utah State Medical Association, Salt Lake City, September 14-16. Dr. L. R. Cowan, 305 Medical Arts Building, Salt Lake City, Secretary.
- Vermont State Medical Society, Barre, October 5-6. Dr. W. G. Ricker, 31 Main Street, St. Johnsbury, Secretary.
- Washington State Medical Association, Seattle, August 28-30. Dr. Curtis H. Thomson, 1305 Fourth Avenue, Seattle, Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to *THE JOURNAL* in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Streptococcus in Trichomonas Vaginalis Vaginitis.—Hibbert divided the 103 cases that he observed into four groups. The first group consisted of sixty-one patients who presented a typical picture of Trichomonas vaginalis vaginitis, in which the protozoon was demonstrated under the microscope in every case. The gram-positive streptococcus was the predominating organism in fifty-three cases, Doederlein's bacillus in six, and no particular organism predominated in two. The second group represented twenty-one patients in whom Trichomonas vaginalis was present but no associated growth of the streptococcus was observed. The third group of sixteen patients suffered from an acute vaginitis presenting no Trichomonas vaginalis. The fourth group of five patients presented neither organism. In these five patients the author took the responsibility of introducing the two organisms separately and together into the

vaginal canal in order to be convinced that the streptococcus was actually capable of producing a vaginitis either associated with or independent of Trichomonas vaginalis. The author's method of treating these patients was by the vaginal application of streptococcal bouillon filtrate produced from the organisms isolated from the patients. All other methods of treatment were suspended, all douches forbidden, and the patient was allowed only one tub bath daily. In indicated cases, repeated cauterization of the cervix was resorted to when cervicitis was present. The vaginal canal was dried with sterile cotton pledgets, and a large cotton tampon saturated with the bouillon filtrate was packed against the cervix and allowed to remain in place for twelve hours, during which time the patient was advised to remain off her feet to aid in retaining the fluid vaginally. This treatment was repeated from two to three times a week until the vaginitis disappeared. The author concludes that Trichomonas vaginalis may be found in the vaginal secretions of many women for long periods of time without producing an acute vaginitis. In a large percentage of the cases of acute vaginitis in which Trichomonas vaginalis existed there was an associated predominant growth of a gram-positive, nonhemolytic, short chain streptococcus, which is capable of producing an active vaginitis when not associated with Trichomonas vaginalis. By repeated vaginal application of a specific streptococcus bouillon filtrate the active growth of the organisms in the vagina dies out and the vaginitis subsides in spite of the persistence of the protozoon in the secretions.

Roentgen Treatment in Amenorrhea and Sterility.

Edeiken used small doses of x-rays to the ovaries and pituitary body in fifty-six cases of functional amenorrhea, with the result that menstruation returned to normal in forty. There was an associated sterility in thirty-three. The following plan of treatment and technic has given the author the best results: Two treatments are given weekly at intervals of three days. The first is given over the anterior pelvis through a field large enough to include both ovaries. The second is given over the pituitary body through a small field. The central ray enters just above and posterior to the middle point of a line drawn between the outer canthus and the external auditory canal. These treatments are continued for three weeks. In the patient of average size, the technical factors are 127 kilovolts, 5 milliamperes, 14 inch distance, and 5 mm. of aluminum filter for from three to five minutes. This is equivalent to from 7.5 to 12.5 per cent of the skin erythema dose, or from 50 to 80 roentgen units. The author varies this dosage according to the size of the abdomen and the thickness of the abdominal wall. He concludes that small doses of x-rays directed to the pituitary gland and ovaries are of proved value in patients with functional amenorrhea. It is of definite value in properly selected cases of female sterility. Before irradiation is undertaken, all pathologic lesions in the pelvis which may be a possible cause of amenorrhea or sterility must be excluded by a competent gynecologic examination. This form of treatment is not attended by any reaction or discomfort to the patient and, when properly administered, has no ill effects on the patients or the subsequent offspring. Cooperation is essential between the gynecologist and the radiologist.

Cesarean Sections.—Although cesarean section is on the increase, in Daichman and Pomerance's series the percentage of patients thus delivered in recent years shows a slight decrease. Of 733 cesarean sections, 25 mothers died, giving a maternal mortality of 3.4 per cent. This, the authors believe, compares favorably with similar series reported from other institutions. Any patient with a temperature of more than 100 F. by mouth for more than seventy-two hours was classified as morbid. With this as a standard, 46.8 per cent of their patients showed morbidity. The gross fetal mortality was 6.5 per cent and, corrected for prematurity and monstrosity, it was 3.7 per cent. They obtained the best results in the group of 152 elective sections. The maternal mortality was 1.9 per cent, the corrected fetal mortality 1.9 per cent, and the average number of days of elevated temperature 3.5. Although there were only 57 low flap sections in their series, the maternal mortality and morbidity are not any higher than for the non-elective classic cases, in spite of a much longer test of labor and a greater period of ruptured membranes. This can justly be used as an argument for the low flap section in the so-called potentially infected cases.

Administration of Sodium Amytal in Labor.—Van Del states that the oral administration of sodium amytal in labor has been satisfactory in the majority of the 215 cases of his study and that the oral dosage can be more definitely controlled than that by the intravenous method. Labor has not been prolonged and no deleterious effects have been noted on the babies. No idiosyncrasy to the drug has occurred. The degree of analgesia depends on the amount and time of administration of the drug. Sodium amytal is not a complete analgesic; hence it cannot be depended on in all cases. The best results have been obtained with an initial dose of 15 grains (1 Gm.), which may be increased to 20 grains (1.3 Gm.) during the course of labor. The combination of amytal and morphine gave excellent results, which were probably due to the synergistic action of the latter. During labor, careful nursing supervision was necessary, since some of the patients became restless. Sodium amytal has a definite value as an adjuvant analgesic combined with morphine and a local anesthetic in laparotrachelotomy before or during labor.

Cancer Modifying Course of Epilepsy.—Hodskins and Guthrie present data which seem to indicate that acidosis and alkalosis are not immediate factors in controlling and precipitating seizures, although they may act indirectly by favoring dehydration and hydration, respectively. The influence of oxygen tension on the capillary permeability and the effect of oxygen administration on cerebral functions have been suggested as important factors in controlling convulsions. Attention has been directed to the relation of vasomotor activity to brain metabolism and other, equally obscure, physicochemical processes. In a review of fifty-five patients suffering from malignant conditions complicating epilepsy it was shown that the number of seizures decreased as the malignant condition progressed. Only eight of the fifty-five patients showed an increase in seizures during the progress of the malignant growth. In the others there was either no change or a decrease in seizures. There was a definite decrease in the frequency of seizures in thirty-two of the fifty-five patients. Alkalosis, which may be associated with cancer, obviously does not induce seizures in epileptic patients. Cachexia and dehydration incident to malignant neoplasms probably raise the convulsion threshold, which accounts for the decrease in seizures.

Hereditary Factors in Epilepsy.—The results of Stein's study of 1,000 epileptic patients and 1,115 nonepileptic controls do not justify the conclusion that the symptom complex known as epilepsy, either alone or as migraine, or as any other neuropsychiatric disorder, is an inherited condition. However, the higher incidence of neuropsychiatric disorders in the families of epileptic patients may well be explained on the basis of an existing potential or latent germ plasm defect. It is likely that this defect or vulnerability furnishes more than usually fertile ground for the production of epilepsy by such known contributing factors as trauma, infection, birth injury and alcoholism. In other words, it may be that this potential or latent germ plasm defect, whatever it may be, requires a less severe blow

than usual from these contributory or exciting factors in order to activate it into the clinical condition known as epilepsy. It is difficult to escape the conclusion that this germ plasm defect or vulnerability appears in too large a proportion in the family histories of the patients, when compared with those of the controls, to be entirely accidental.

Sodium Amytal and Sodium Thiocyanate in Mental Disorders.—Harris and Katz made a comparative study of the action of sodium thiocyanate as compared with that of sodium amytal in a group of seventeen patients presenting various psychopathologic manifestations. They observed that the intravenous injection of from 1 to 1.5 cc. of sodium amytal may produce marked transient ameliorating effects in some psychotic patients. The temporary improvement with sodium amytal seen in some of the authors' patients occurred without the induction of narcosis. The oral administration of sodium amytal, even in hypnotic doses, was not as effective as the intravenous in producing the transient ameliorating manifestations seen in some of the patients. Sodium thiocyanate was without any noticeable therapeutic effect in the same patients. Some toxic manifestations were observed in several cases following the oral administration of sodium thiocyanate. No contrasting effects were observed between sodium amytal and sodium thiocyanate which could be of diagnostic value.

Annular Stricture of Rectum and Anus.—Keller advocates and describes an operation which applies only to the common varieties of troublesome annular strictures seen in the distal 3 or 4 inches of the rectum and in anal strictures. Full thickness grafts are taken from a hair-free area and thinned down as desired. If the tubular type is to be used, it is sewed with catgut in that shape around a trocar. A long ligature of black silk thread is sewed at each end. The same type of ligature is inserted when flat grafts are used. The stricture proper is exposed with a rectal speculum or retractors. A trocar and cannula are then passed under the stricture, and

the trocar is withdrawn, leaving the cannula in place under the stricture and mucous membrane. A U-shaped carrier having a long and short arm is now passed into the rectum above the stricture. The point of the short arm of the carrier is pressed through the mucosa into the open end of the underlying cannula and drawn down into it. The cannula is withdrawn, leaving the carrier beneath the stricture with its end presenting through the original point of puncture. The graft with its black silk ligature is threaded on the end of the carrier. The carrier is passed back beneath the stricture, withdrawn from the rectum, and the ligature detached. The graft is drawn into proper position by exerting a pull on the ligature presented through the stricture. The ligature ends are tied and allowed to remain as a marker until the roof of the tunnel graft is finally removed. Usually three or four grafts are placed at equidistant points. It is imperative that there be accurate coaptation of the graft throughout the area to be covered with epithelium. A water-distended Hagner or Pilscher bag not only insures proper coaptation of the opposing surfaces but also presses out clots and secretions. It also diminishes the danger of passive congestion, which usually appears about the third day. Precautions are taken to prevent defecation for seven days, and at the end of this period the bag is removed and the bowels are freely moved. The bag is again introduced and defecation discouraged for another seven days. The bag is removed and the bowels are evacuated. The rectum is cleansed with irrigations of compound solution of cresol. The roof of the tunnel over each graft is then divided. Irrigations with compound solution of cresol or 1:500 silver nitrate solution are continued for at least one week.

Ganglionectomy.—According to Zollinger, the removal of one or more of the lumbar ganglions in dogs hastened the regeneration of bone in fifteen of seventeen animals. This acceleration of bone repair was slight in eleven animals, it was definite in four, and there was more regeneration on the side opposite the ganglionectomy in two. Bone injury in the upper and middle thirds of the fibula seemed to be repaired faster than that in the lower third. The regeneration of bone was accelerated in three animals in which the sympathetic chain was interrupted nine, thirteen and thirty-four days before the bone injury. The removal of one lower lumbar ganglion in seven dogs was apparently as effective in hastening the repair of bone as a more complete resection of the chain. There was no anatomic increase in the size of the arterial bed following lumbar ganglionectomy in nine dogs in which the arterial bed was visualized by mercury. The injections were made from 19 to 114 days after the ganglionectomy.

Silk Seton.—Hiller reports a case of communicating hydrocephalus in which silk setons were inserted into the spinal canal by a simple technic, which is as follows: Under aseptic precautions, three knots overlying one another were tied at the end of a piece of number 3 black waxed silk. The patient was placed on the operating table, the head of the table lowered, and a spinal puncture between the third and fourth lumbar vertebrae made with a number 17 spinal puncture needle. The depth of the spinal canal from the skin surface was noted and the piece of silk cut to be about half an inch shorter than this distance. The stylet of the needle was then withdrawn and the knotted end of the silk forced into the shaft of the needle ahead of a number 9 wire, twice the length of the spinal puncture needle. When the bulbous end of the silk was felt to pass the end of the spinal puncture needle, the wire was held in place by a hemostat and the needle withdrawn. The wire was then withdrawn and the operation was completed. No anesthesia was required.

Puerperal Infections.—Robinson points out that pathogenic bacteria do not multiply in the blood stream of human beings (except in the most fulminant types, or as an antemortem phenomenon) but in the septic focus, from which they are discharged into the lymph and blood streams in larger or smaller quantities and at longer or shorter intervals, according to the direct or the indirect anatomic relation between the septic focus and the circulation. The course and outcome of a bacterial infection are determined far more conclusively by the location of the septic focus and by the depth and extent of the bacterial invasion than by the type of the pathogenic micro-organism causing it. Every bacterial infection is associated with a greater

or lesser invasion of the blood stream; therefore, every puerperal infection is a bacteremia of a varying degree of severity. A single entry of pathogenic bacteria into the blood stream does not constitute a severe or a fatal sepsis. The failure to recover bacteria from the blood in outspoken cases of bacteremia is due to the abstraction of the blood during or immediately after the chill, instead of from three to five hours before its occurrence, and to the neglect of making anaerobic cultures as well as aerobic. The septic focus forms an integral part of every bacterial infection, and its removal or deviation from the blood stream constitutes the only effective remedy in the treatment of puerperal sepsis. The only contraindication of this procedure is inaccessibility, or its location within an organ whose removal may cause immediate death. Septic endometritis should be treated by curettage, as long as the septic focus is limited to the endometrium, septic myometritis by hysterectomy, and pelvic thrombophlebitis by early ligation of the affected vessels and excision of the ligated part with or without a hysterectomy, depending on the condition of the uterus. Pelvic cellulitis should be incised early, as soon as the induration becomes accessible, and fluctuation should not be waited for. The best avenue of approach is the extraperitoneal, suprapubic or lateral, depending on the location of the induration. Lateral vaginal incisions should be avoided, owing to the danger of injuring the ureter or the uterine artery.

Insulin-Inhibiting Substance in Urine.—The experiments of Watson and Dick point to the presence of a substance in the urine which causes partial inactivation of insulin when the latter is added to the urine, incubated and the effect of the insulin on the blood sugar of the rabbit noted following subcutaneous injection of the mixture. The urine of diabetic patients appears to possess the insulin-inhibiting property to a slightly greater degree than does the urine of nondiabetic hospital patients and normal persons. The difference is most marked in patients with severe diabetes. This insulin-inhibiting factor is destroyed by heating the urine at 60 C. (140 F.) for several hours or by boiling the urine for a few minutes previous to the addition of the insulin. The authors assume that this substance enters the urine from the blood stream by elimination through the kidneys. Whether or not it is identical with the insulin-inhibiting substance which is believed to exist in the blood of diabetic and of nondiabetic patients is undetermined. They discuss the possible significance of the phenomenon relative to the pathogenesis of diabetes mellitus. While they cannot make a definite statement concerning the nature of the insulin-inactivating principle in the urine, its behavior with regard to heat suggests an enzyme-like character.

Bacteriophage Therapy in Bacillary Dysentery of Flexner Type.—Kessel and Rose present a study of bacteriophage therapy in sixty-eight cases of bacillary dysentery from which *Shigella paradysenteriae* of the Flexner type was isolated. Thirty-three of the patients not receiving bacteriophage were used as controls. Twelve of the treated cases appeared in the 1930 season when a specific bacteriophage was prepared for each case. The bacteriophage was administered by mouth, on an average of four days after admission to the hospital.

The average number of days of hospitalization of this group was 11.9 days, while in the control group the average was 10.1 days. No deaths were recorded in either series during this season. Twenty-three patients in the 1931 series received a bacteriophage which was later tested for lytic properties. The bacteriophage was administered by mouth within a few hours after admission to the hospital. The average number of days of hospitalization of this group was eleven days, while in the corresponding control group the average period of hospitalization was 12.1 days. There were four deaths in the series treated with bacteriophage and three in the control series during this season. These results indicate that the oral administration of bacteriophage, as used in this study, produces no marked clinical benefit over the recognized symptomatic care and treatment.

Lipemia Retinalis.—Jaffe and Schonfeld report the case of a diabetic patient with lipemia retinalis, aged 30, who began to show changes in the fundus oculi toward normal after twenty-four hours of vigorous antidiabetic coma therapy. A determination of the blood fat was made on the third day after admission, when the visual degree of lipemia was somewhat less. The total blood lipoids amounted to 21.7 per cent. On a high carbohydrate and low fat content diet and adequate insulin, the lipemia retinalis disappeared rapidly. The fundus was normal when the total blood lipoids were 16.3 per cent. The blood, however, still had a slight creamy color. The authors made an attempt to reproduce the original lipemia retinalis by means of a diet having a high fat and low carbohydrate content and no insulin for several days. The blood lipoids, instead of rising, fell to 9.3 per cent. Newburgh and Marsh attributed this phenomenon to the ability of the body to utilize the carbohydrate and, as a result, to the deposition of fat in the body depots. Parker and Cullen observed that, with the onset of acidosis, the lipemia retinalis returned. The authors did not subject their patient to excessive acidosis because of complicating pulmonary tuberculosis.

Sympathetic Ophthalmia.—Samuels studied, by microscopic section, the condition of the uvea at the site of the wound of 101 eyes in which the specific infiltration of sympathetic ophthalmia was found. The principal feature of his study was the finding of two cases of primary lesions in sympathetic ophthalmia. To these he added nine cases in which the infiltration was overwhelmingly greater in the region of the wound than elsewhere. Fliri denied the existence of a primary lesion in sympathetic ophthalmia, arguing that the appearances thus interpreted by Redslob were but the signs of a localization of microorganisms that were already circulating in the blood before the injury took place. To this one may reply that the uveal tissue is often severely damaged in contusions and yet no local specific infiltration develops afterward. The essential thing is that the globe must first be opened. The failure to find a primary lesion proves nothing, whereas the discovery of a single primary lesion is of the greatest significance. The author states that the infiltration in the anterior part of the uvea which appears to be older than that in the posterior part is suggestive of a primary lesion. In certain cases the path of the infiltration from the site of the wound to the choroid could be traced by continuity with as much certainty as that from the choroid to the emissaria. The author

believes that the establishment of the existence of primary lesions strengthens the original theory, and weakens all others, that sympathetic ophthalmia is caused by a bacterium whose port of entrance is an opening in the eyeball.

Diathermy Test.—For the past six months, Kimble, in testing the urine for albumin, has been using a simple device that consists of two specially constructed plates, insulated from each other and connected through a suitable shaft and cord to the terminals of a diathermy machine. The instrument is inserted in a test tube one third full of urine to which has been added a few drops of acetic acid. About 2,000 milliamperes of current is turned on. The albumin present is quickly coagulated. A white line appears between the two plates in from two to five seconds. The solution below the plates remains clear and is used for comparison with the "ring" above. The instrument is removed, 1 cc. of alkaline bismuth subnitrate is added, and the instrument is replaced. The same amount of current is again turned on. In a few seconds the solution between the two plates boils. It is allowed to boil for half a minute. If any sugar is present, a black ring appears between the plates.

Traumatic Osteomyelitis of Cranial Vault.—Adelstein and Courville state that traumatic osteomyelitis of the flat bones of the skull is a somewhat uncommon complication. It can be prevented in many cases by suitable treatment of the original wounds of the scalp. The diploic spaces between the tables, together with the enclosed venous system, favor dissemination of the infection, although early local reaction usually

prevents this from taking place. A suggestive classification of the lesion is based on the pathologic changes and the roentgenographic appearance of the lesion: (1) localized osteomyelitis, (2) spreading osteomyelitis, and (3) infectious necrosis of fragments in comminuted fracture of the skull. Cases of localized osteomyelitis may be subdivided into sclerosing osteitis following local injury with an opened or intact scalp, and circumscribed osteomyelitis in which infection is implanted directly into the diploe after abrasion of the outer table of the skull. The type of lesion may be anticipated by recognition of the mode and time of entrance of the infecting organism. The authors discuss the pathogenesis of the formation of sequestrums and the mode of invasion and spread of the infection, together with the probable pathologic change in each type of osteomyelitis. They present a series of six cases illustrating the various clinical types of the disease. The course of the disease is followed roentgenologically in each case. Their plan of treatment has been essentially conservative, consisting of daily dressings with balsam of peru. This substance favors the subsidence of infection and the development of granulation tissue. It is necessary to keep draining sinuses open by controlling the growth of granulations, using a silver nitrate stick when necessary. Surgical intervention is limited to the removal of sequestrums that cannot be discharged through draining sinuses.

Snapping Scapula and Humerus Varus.—Milch and Burman point out that the frequency with which snapping scapula sounds have been observed appears to vary within a wide range. From a study of the cases reported in the literature and their six cases, in which either unusually loud scapular noises or snapping was found, it appears that the causes of these sounds may be divided into three main groups: (1) those due to changes in the bony structure of the undersurface of the scapula or of the wall of the chest; (2) those due to changes in the musculature intervening between the scapula and the wall of the chest, and (3) those due to changes in bursae normally or abnormally present between the scapula and the wall of the chest. To these may be added two other groups: cases in which no reason could be assigned for the production of scapular snapping, and cases associated with certain occupational activities, such as dressmaking, needle working, piano playing and baking. Conservative treatment has been of value only in those cases in which changes in the soft structures were suspected. In some cases, simple counterirritation, as by vesication, has given satisfactory results. In others, physical therapy and massage have been of value. When definitely demonstrable bony changes are present, an effort should be made to remove the cause. In some patients the superior and in others the inferior angle of the scapula has been resected. In one of the authors' cases and in several others reported in the literature, the upper margin of the scapula was amputated, while angulated portions of the ribs or scapula were removed with some success in others. The authors have recently reexamined one of their patients with a snapping scapula who was suffering from Gaucher's disease and in whom marked changes in the skeletal system were observed. During the course of the roentgenographic examination they observed extreme downward bending of the heads of the humeri. The heads appeared in no way malformed, but the glenoid appeared to be definitely smaller than normal and to project outward like a nipple. The neck appeared markedly shorter and its angle with the head and shaft of the humerus much decreased. The plane of the anatomic neck, instead of being oblique, became almost vertical and, on the left side, the level of the upper edge of the great tuberosity was definitely higher than the head of the humerus. The authors believe that this is the first case in which a humerus varus has been observed in Gaucher's splenomegaly.

Malignant Conditions of the Rectum.—Kallet and Saltstein report seven cases of unusual rectal tumors, three sarcomas, three melanomas and one leukosarcoma. Both sarcoma and melanotic growths arise beneath the mucosa, ordinarily either in the anal canal or in the lowest part of the ampulla. It is often stated that these growths generally originate in the posterior wall. However, six of the authors' cases were on the anterior wall. When located anteriorly, the first symptoms may be due to pressure on the structures at the neck of the

bladder. In several of the histories, pain was a prominent early symptom. In one case it radiated to the penis. In another it radiated along the left sciatic nerve and was so excruciating that the patient could not sleep. In one case there were terrific tenesmus and rectal spasm out of all proportion to that seen in early rectal cancer. Another patient also had severe rectal pain. The first objective manifestation is the mass beneath the mucosa, which may be confused with a benign polyp or hemorrhoid. The first manifestation in one of the authors' cases was a small mass which was extruded with each bowel movement. In another a bulging gangrenous rectal polyp proved to be melanoma. The growth often develops locally, forming a mass almost indistinguishable from carcinoma. In sarcoma the mucosa tends to remain intact longer, and ulceration occurs late. In the melanoma cases there was little distinguishable difference between the clinical course of melanoma and of sarcoma. The metastatic deposits, on the contrary, usually exhibit heavy pigmentation, as may older tumors. One of the patients with spindle cell sarcoma is well and free from recurrence eight months after local resection, implantation of radon seeds and high voltage roentgen therapy, and another suffering from melanoma is alive seven months after resection and high voltage roentgen therapy but is rapidly failing. The other patients died from six weeks after the onset of symptoms to five years after treatment.

Thyroid Hyperplasia.—According to the experiments of Hibbard, white rats fed on a diet low in iodine in a relatively nonendemic region failed to have thyroid hyperplasia. Changes in the thyroid did not occur in rats fed on a diet poor in vitamins and leafy vegetables. A 2 per cent solution of calcium chloride, combined with a diet low in iodine, produced a definite thyroid hyperplasia in a large percentage of the experimental animals. Hyperplasia was not observed in the rats fed on a diet high in calcium lactate and low in iodine. Definite changes in the thyroid, similar to those obtained by a diet high in calcium chloride and low in iodine, were found in rats fed on a diet high in sodium chloride and low in iodine. This suggests that chlorine (or the halogens as a group) may act as a positive factor in the production of thyroid hyperplasia.

Effect of Insulin and Dextrose on Intestine.—Gage and his associates observed that, experimentally, dextrose and insulin either alone or in various combinations produced marked changes in the activity of the normal and the obstructed intestine. The changes were more marked in the normal intestine and that which had been obstructed for twenty-four hours than in the intestine obstructed for longer periods of time (forty-eight, seventy-two and ninety-six hours). Insulin alone produced an increase in intestinal activity (both in the normal and in the obstructed intestine) in 55.5 per cent of the cases, the average increases in tone and amplitude being 7.2 and 3.8 mm., respectively. Dextrose alone caused an inhibition of intestinal activity (both in the normal and in the obstructed intestine) in every instance (100 per cent), the average decreases in tone and amplitude being 22.9 and 6.9 mm., respectively. Dextrose and insulin combined resulted in an increase in intestinal activity in 44.5 per cent and no change in 55.4 per cent. Insulin preceded by dextrose produced an increase in intestinal activity in 70 per cent and no change in 30 per cent. The average increases in tone and amplitude were 12.3 and 3.3 mm., respectively. Dextrose solution preceded by insulin produced an increase in intestinal activity in 70 per cent, with average increases in tone and amplitude of 27 and 8.5 mm., respectively. In 19 per cent there was no change, and in 10.8 per cent there was a decrease in activity. The experimental results indicate that dextrose solution exerts an inhibiting effect on both the normal and the obstructed intestine which can be largely obviated by the use of insulin. The authors suggest that, clinically, dextrose alone should be used cautiously, and that it should be combined with insulin in order to minimize the inhibiting effect it may have on the intestine.

Treatment of Compound Fractures.—Gurd describes a specific technic for the treatment of severe compound fractures with extensive laceration and contamination of tissue, which is a modification of the procedure suggested by Morison in 1916, the essential features of which are: (1) immediate operative intervention and reduction of the fracture; (2) conservative excision and radical incision of tissues; (3) proper treatment of the wound with bismuth iodoform paraffin paste, following dehydration; (4) obliteration of dead spaces and prevention of adhesion of opposing wound surfaces by means of firm packing with relatively large, petrolatum soaked, packs of bismuth iodoform paraffin paste; (5) avoidance, so far as possible, of ligatures and sutures; (6) application of a plaster-of-paris cast over a thin layer of padding with no window; (7) infrequent

dressings, the first approximately eighteen days after the injury, done in the operating room under an anesthetic, with a secondary suture and packing when indicated; (8) application of an unpadded plaster cast and felt heel as soon as union commences. Although by means of the technic that he suggests phlegmonous inflammation in even severe compound fractures is almost completely eliminated, the author's experience in cases in which diffuse cellulitis and tissue necrosis has already occurred has proved that the technic is of value. He has employed approximately the same method in the treatment of acute infective osteomyelitis with satisfactory results.

Splenic Extract in Bone and Joint Tuberculosis.—Wheeldon treated seventeen patients suffering from bone and joint tuberculosis with splenic extract. He observed that this treatment was beneficial, as improvement was noted in the patients' febrile condition, local reactions, growth, weight, color, appetite, blood composition, deformity, complications, roentgenograms, and permissible activity, and in the dispensing with support. The author's method of administration has been to give the aqueous extract of spleen orally. The patient is given a teaspoonful three times a day for a week, or until it is found that he can and will tolerate the material. After that a table-spoonful is given three times a day. This dosage contains the active principle from 1½ pounds of raw spleen. The extract is best tolerated in a sandwich, hot bouillon, tomato or orange juice or gravy. From this study the author concludes that improvement from splenic extract treatment probably will be more apparent to those who are unable to enforce a strict compliance with the accepted ideal treatment, i. e., support, recumbency, heliotherapy, proper feeding and proper aeration. The production of splenic extract is possible and the distribution is practicable. It is possible to obtain the cooperation of patients in adopting the splenic extract diet, even of those in remote sections. Splenic extract treatment has also produced improvement in osteomyelitis (acute and chronic) and in ununited fractures. Enough improvement has been shown in the blood composition to stimulate further study of this phase.

Aseptic Necrosis of Head of Femur.—Stewart reports a case of aseptic necrosis of the head of the femur following traumatic dislocation of the hip joint. The chronic arthritis of the hip appeared to be secondary to the necrosis. The picture is somewhat similar to that sometimes seen in intracapsular fracture of the neck of the femur with necrosis of the head, in which bony union occurs but the head subsequently breaks down as a result of weight bearing before bony transformation has taken place. When it becomes evident from roentgenograms that aseptic necrosis has occurred in the femoral head, weight bearing should be avoided during the period of repair. A study of the late results of hip dislocation might reveal similar cases. The author attempted to reproduce this condition in dogs and rabbits by cutting the ligamentum teres and, in some cases, also the vessels in the periosteum of the femoral neck. The experiments were only partially successful. A part of the bone died in some experiments and was transformed; but in no instance was collapse of the head and necrosis of its articular cartilage observed. The divided ligamentum teres showed a distinct tendency to unite. It appeared that the vascular supply of the head of the femur by way of vessels within the femoral neck of the animals was usually sufficient to preserve the vitality of the head. There was no regularity in the process of transformation of the femoral heads following operative circulatory interference. Apparently, the variability of the blood supply to the head of the femur is such that, by interrupting identical portions of it in a series of experimental animals, identical and progressive stages of aseptic necrosis, followed by transformation of the femoral heads, could not be demonstrated. There is a certain individual reaction of each head in a series of similar operative procedures. No head in the animals with open epiphyseal lines showed changes similar to Legg-Calvé-Perthés disease.

Intermittent Hydrarthrosis of Knee Joint.—Krida states that intermittent hydrarthrosis in general has heretofore been regarded as a medical curiosity of unknown pathogenesis and that treatment has been decidedly unsatisfactory. He reports two typical cases of intermittent hydrarthrosis of the knee joint, of diverse etiology, in which apparent cure was obtained following the operative removal of the synovial membrane. The

etiology in one of the cases was definitely traumatic and the condition was associated with a fibrous tissue mass in the calf muscle, the probable origin of this mass being a hematoma of that region. The attacks were of nine months' duration, came on five weeks after the traumatism, and persisted despite aspiration, rest in bed and autoserotherapy. No clinical hypersensitiveness could be demonstrated in the history or by exhaustive tests. The etiology in the other case was obscure but definitely related to menstruation. The semilunar cartilages had been removed at another hospital. The patient had had repeated aspirations without effect. Despite the fact that recurrences of this disorder rarely take place, the author believes that, on the basis of his observations, synovial excision offers the best prospect for the cure of this condition.

Icterus Neonatorum.—Snelling carried out an investigation to determine the part played by the liver in the production of icterus neonatorum. He observed that the red blood count and hemoglobin fall gradually during the first two weeks of life. The icteric index is above the normal excretory threshold at birth. It rises for a period; then it falls rapidly at first and later gradually to a normal level. The icteric index curve bears no relation to the change in erythrocytes and hemoglobin either individually or collectively. The excretion of urobilin and bilirubin in the stools for the first three days of life is at a minimum and then rises rapidly. This rise is concurrent with the fall in the icteric index observed in the blood. Bilirubin excretion is minimal by the liver in utero, and there is a period following birth during which pigment excretion is gradually assumed up to the normal physiologic level. The closure of the ductus venosus with increase of portal circulation and the discontinuance of hematopoietic activity in the liver occur during this period of liver insufficiency and may be related to the production of icterus neonatorum. The morphology of the endothelium of the liver sinuses indicates that it has been engaged in growth and hematopoiesis until birth. The endothelium of the liver sinuses probably does not assume the bilirubin removing function immediately at birth, but coincident with the morphologic change to the usual Kupffer cell this function increases.

Ephedrine in Narcolepsy.—Jacobsen reports that he treated three children, subject to recurring attacks of sleep, with ephedrine sulphate. One of the children was also subject to attacks of temporary loss of tone in the voluntary muscles. In each case the onset of the symptoms was sudden. In none was there any discoverable etiologic factor. The rapid gain in weight in two of the patients following the onset is similar to that which occurs in certain cases of encephalitis, but no symptoms suggestive of an acute infectious disease or of encephalitis could

be elicited. The attacks of sleepiness were at their height before any gain in weight had been observed. Prolonged treatment with large doses of thyroid in two of these patients produced no amelioration of the symptoms, but ephedrine sulphate promptly relieved them almost completely in all three cases. The effectiveness of the drug in controlling attacks was not diminished after prolonged use. The frequency of sleep attacks when ephedrine was omitted remained essentially at a level; the somnolent tendencies gradually decreased until all three children are now free from symptoms and are no longer receiving medication. Duration of the symptoms in the three cases was thirty, eighteen and fourteen months, respectively. That ephedrine provided only symptomatic relief and should not be credited with effecting the final cure is indicated by the fact that its sudden withdrawal at any time during the period of treatment plunged the patient into a series of sleep attacks as severe as those occurring before the drug was started. The use of ephedrine makes it possible for these children to resume immediately their normal lives.

Bacteriologic Study of Pyelitis.—From a study of 109 cases of pyelitis, Summerfeldt and her associates observed that the micro-organisms isolated from the urine were chiefly species of gram-negative bacilli. Similar bacterial species were isolated from the stool and urine in forty cases of pyelitis and, biologically and serologically, similar cultures were obtained from seven. Agglutinins for the homologous urine species were demonstrated in the serums of twenty-three cases of pyelitis, and none in the serums of twenty-five cases.

Infant Nutrition.—Gerslley states that the danger of lactose fermentation in the intestine is no longer tenable in infant nutrition. Unquestionably the addition of lactose to the diet increases the hydrogen ion concentration of the intestinal contents, but this does not lead to clinical diarrhea. The large quantity of acid found in the stools in clinical diarrhea is related to some abnormality in the mechanism of absorption and of peristalsis leading to the sweeping out of the acids and is independent of the amount of lactose in the diet. The question

has been obscured in the past by: 1. The failure to realize the importance of the effect of parenteral infections on digestion and intestinal peristalsis; and ascribing the abnormal stools to unsatisfactory diets. 2. An insufficient ratio of lactose to protein in the diet permitting the growth of a mixed flora with, unquestionably, a great variety of end products. 3. The giving of a diet with a favorable lactose-protein ratio but not waiting the two weeks required for the establishment of a uniform gram-positive flora. 4. The giving of a diet in the proper proportions but not realizing the dangers of overfeeding. The author raises the question whether these intestinal reactions are of significance as to the general body health and development, and whether the proper ratio of carbohydrate to protein in the diet, besides establishing favorable conditions in the intestine, is also favorable to the general body metabolism.

Treatment of Hyperthyroidism.—Snowden points out that the treatment of hyperthyroidism should never be haphazard but should be carried out according to a consistent plan adapted to the aspects of each individual case. If the symptoms are of recent onset and the physical condition of the patient is good, a trial period of complete rest, sedatives and forced feeding should be instituted. During this medical treatment the use of compound solution of iodine should be avoided if possible, for its benefits are transitory and therefore confusing. Moreover, since the effectiveness of iodine tends to diminish with use, it should be reserved for preoperative administration. If radical treatment is necessary, surgery is to be preferred, because the desired result is obtained much more quickly and the incidence of permanent cures is somewhat higher. If roentgen treatment is undertaken, compound solution of iodine should be used advisedly, for there is a possibility that it reduces the destructive action of the x-rays on the secreting cells of the thyroid. In a thyroid crisis, the basis of treatment is to replace the tissue fluid and carbohydrate, and large doses of compound solution of iodine should be given. In the presence of persistent vomiting at least 1,000 cc. of a 10 per cent solution of dextrose should be given intravenously every twenty-four hours, and 1,000 cc. of physiologic solution of sodium chloride subpectorally. With the 1,000 cc. of dextrose solution injected intravenously should be incorporated 30 grains (2 Gm.) of sodium iodide. In a severe case, on two occasions, the author dissolved from 5 to 7 minims (0.3 to 0.4 cc.) of compound solution of iodine in the 1,000 cc. of dextrose solution injected intravenously, with no evident untoward effects and with apparently beneficial results.

Hormone Test for Pregnancy.—Navarro and de Leon describe a modification of the Aschheim-Zondek test for pregnancy which makes possible the unlimited application of the test in this and in other countries in which a handicap as regards the supply of animals obtains. A female rabbit of any age is prepared for laparotomy under aseptic conditions. Under ether anesthesia, a median line incision is made. The abdominal cavity is exposed and the ovaries are inspected and compared. One of them is removed and placed in a preservative

to serve as a normal control for that particular rabbit. The stump is ligated to avoid bleeding. Ripe, unruptured graafian follicles are always found in the ovaries of adult female rabbits. If in the examination the two ovaries are found to be dissimilar in appearance, the one with the greatest change is removed for control purposes. The abdominal wall is closed in two layers of peritoneum-muscle and skin, plain catgut number 00 being used for the first and abaca for the second layer. The wound is covered with a small dressing sutured to the skin at the extremities of the wound. The rabbit is allowed forty-eight hours in which to recuperate from the operation, then from 6 to 12 cc. of freshly catheterized urine is injected into the marginal ear vein of the rabbit. Forty-eight hours after the injection, another laparotomy is performed, the line of incision being made on the side of the ovary left at the first operation. The two ovaries are then compared and the results noted and, after proper identification, both are placed in solutions for histologic preparation. When the reaction is positive, the ovary is enlarged from two to four times the size of that of the normal control ovary, and "blood points" or corpora hemorrhagica appear with distinctness on or bulging out of the surface. In the case of young female rabbits from 3 to 4 months old, the authors noted that the changes in the ovary are more pronounced, both in the general increase of the size of the ovary and in the production of hemorrhagic spots. The presence of "blood points" and the definite enlargement of the ovary exposed to the action of the anterior pituitary hormone are the criteria for a positive diagnosis.

Significance of Renal and Ureteral Pain.—Culver states that any pain of renal origin originates within the kidney and ureter. The possibility of painful sensations due to renal torsion, traction of the main vessels and pressure on the external surface of the adjacent parietal peritoneum should be kept in mind. Abnormal impulses from the renal pelvis, ureter, renal capsule or blood vessels under certain unknown and little understood conditions may eventually be referred to some superficial area supplied by spinal nerves from the corresponding cord segment. Any condition that causes renal enlargement with rapid distention of the capsule may cause pain, and pelvic distention or any intrapelvic condition that causes irritation and subsequent spastic contractions of the pelvic musculature may result in painful sensations. Physiologic ureteral peristalsis produces no sensation, but any condition generating abnormal contractions results in pain of a radiating type along the course of the ureter. It is quite generally understood that this type of radiating pain is only the result of the downward passage of some foreign substance such as stone, clots or inflammatory or neoplastic debris, but other local pathologic processes may start these spasmodic ureteral contractions with similar clinical manifestations. Such symptoms, while not common, may result from ureteritis, ureteral kinks, strictures, or extra-ureteral pressure sufficient to produce partial obstruction. It is apparent, therefore, that the search for the cause of ureteral colic should not cease, in all instances, with negative roentgen and urine studies.

Acute Infective Osteomyelitis.—Pyrah and Pain report the results of operation in a series of 262 consecutive cases of acute infective osteomyelitis. Seventy-one patients died, a mortality of 27.1 per cent. Of sixty-four patients treated by primary incision of the periosteum, sixteen died, a mortality of 25 per cent. Some of these needed a secondary operation later. The average results of this form of treatment are much better than those of the gutter operation. The amount of sequestrum formation is much less than the area of compact bone from which the periosteum has been stripped. The gutter operation was performed in the 176 cases of average severity. There were fifty-two deaths (29.5 per cent). Primary partial diaphysectomy was performed in twenty cases with one death, and H. Winnett Orr's method was used in two cases, both proving fatal. The authors believe that the results of their series of cases and the arguments they put forward give support to what is definitely a strong tendency among most surgeons who have recently written on acute osteomyelitis; namely, the more conservative treatment of the disease. In a case of average severity the subperiosteal abscess should be incised for approximately its full length, and particular care should be taken to see that the incision reaches the epiphyseal cartilage, since it is in the region of the epiphyseal line that pus escapes from the cancellous tissue by one of the vascular foramina. The region of the metaphysis should then be explored either by a small trephine or by a drill. If pus is found, compact bone should be removed only so far as to uncover the zone occupied by the pus. Provision should be made for drainage and for irrigation. If no pus is found, no further opening of the bone should be done. If the patient is severely ill or if the case is one of the acute type in which a subperiosteal abscess of considerable size has formed within two or three days and in which the toxemia is profound, only periosteal incision should be done; in surviving patients it will probably be necessary to open the bone some days later.

Treatment of Acute Empyema in Childhood.—McEachern used the following method in applying closed drainage in seventy-five consecutive cases of acute empyema in children: The operation is performed under local anesthesia and a number 16 or 18 (French) catheter is used. Artery forceps clamped on the catheter near the end prevent the entrance of air through its lumen. The trocar with cannula is introduced between the ribs at the most convenient point. The trocar is withdrawn and the index finger is placed over the end of the cannula to exclude air until the catheter is inserted. The catheter, which has a lateral eye of half an inch above the terminal one, is allowed to project into the cavity 1½ inches and the cannula is removed. Before the clamp on the end of the catheter is removed to take off the cannula, a clamp is placed on the proximal side of the catheter. The opening about the catheter is sealed by successive layers of absorbent cotton and collodion until a collar, 5 inches in diameter and half an inch thick, is built up about the tube. In order that

this dressing may adhere firmly to the skin and the adjacent catheter, these parts must be thoroughly clean and dry. The dressing will remain tight longer if the catheter is held immovable in the chest wall. To ensure that the dressing will not be disturbed in moving the child back to bed, it is fanned for twenty minutes. The child is then returned to bed with the clamp still on the end of the catheter. To allow the dressing to set more firmly, this clamp is left in position for three hours longer; then the catheter is connected with the drainage apparatus, the clamp is removed and the pus is allowed to drain off. The apparatus consists of three ordinary Winchester bottles with tight-fitting rubber stoppers pierced with two holes, some glass tubing, a container for surgical solution of chlorinated soda, and some rubber tubing of suitable size. If the effusion is large and slow decompression of the lung is desired, it can be accomplished by removing and applying the clamp at intervals as desired. Irrigation of the cavity is begun twenty-four hours after the catheter has been inserted. These irrigations are carried out every two hours during the day and three times at night. The top of the fluid in the container for surgical solution of chlorinated soda is never allowed to be more than 18 inches above the opening in the chest, as too much pressure tends to force the fluid out around the tube and under the dressing, thus loosening it from the skin. To irrigate, a clamp is placed on the rubber tube leading to the bottle used as a trap to prevent the washings from the empyema cavity to become mixed with the water from the siphon; then the clamp is removed from the tube leading from the bottle containing the solution and the solution is allowed to run into the chest until it causes pain or stops from the equalization of pressure. This clamp is then replaced and the one on the tube leading to the suction apparatus removed, when the contents of the cavity drain off into the bottle used as a trap. In forty-six of the seventy-five cases the organism was the pneumococcus, in nine the streptococcus, in six the staphylococcus, in one a mixed infection of pneumococcus and streptococcus, in one a mixed infection of pneumococcus and staphylococcus, in six "no growth" was reported and in six no report was made. The age of the patients was from 4 months to 11 years. There were two deaths, both in children under 2 years of age, giving a mortality of 2.66 per cent for the series, and a mortality for those under 2 years of age of 9.52 per cent.

Antigametocyte Treatment.—During the malaria season, Clemesha carried out three carefully controlled experiments on the labor population of three estates (total, 825). The results show that it is possible to control entirely the spread of malaria by careful antigametocyte work. This appears to be quite easy in cases in which the prophylactic doses are given over long periods, as a regular procedure. When given over a short period of time, that is, during great danger, they are equally successful, provided certain conditions are rigidly adhered to. If a high degree of success is wished for, a thorough elimination of gametocyte carriers in the labor population must be

undertaken. This usually means examining the blood of all children and adults in bad health, while babies in arms should receive particular attention, because of the likelihood of these missing the biweekly dose. The search for and cure of gametocyte carriers should always be undertaken at least a month before the onset of the dangerous period. In a community receiving two doses of quinine with plasmochin a week, those who do contract malaria show extraordinarily few malarial parasites (trophozoites or schizonts) in the peripheral circulation. Malignant tertian and benign tertian gametocytes would not have been found if the dose had been taken regularly. Quartan parasites and gametocytes were much more frequently encountered and were much less acted on by the plasmochin than the other two. Two doses of quinine with plasmochin a week cause the attack, even of the malignant tertian form, to be mild in character. The duration of the fever is usually from two to four days instead of from eight to twelve days, and profound disturbance in health is only observed in susceptible newcomers to the district. The cost for a whole year for the regular treatment of the entire labor force is much less than that occasioned by a severe outbreak of malaria.

Cereal Food Poisoning.—The experiments of Stockman and Johnston show that all the cereal grains (rice, rye, wheat, oats and corn) examined proved to be poisonous to monkeys when they constituted the bulk of their diet, even when relatively large amounts of fruit, milk and butter were consumed along with them. They were poisonous also to rabbits and guinea-pigs. Also acids isolated from the various grains and given as sodium salts, hypodermically and orally, to healthy animals with their ordinary diet, were poisonous and produced similar symptoms. The pathologic changes were the same in the two tests and implicated chiefly the nervous system, but the bones and viscera also were more or less involved. The pathologic changes fully accounted for the various symptoms. The poisonous substance is in all an acid or acids but possibly not the same in all. The most probable explanation of their action is that they not only are irritant and poisonous in themselves but also have a secondary effect of gradually or suddenly withdrawing alkalis and especially calcium from the blood and tissues. It is not, therefore, a question of vitamins or of any kind of deficiency in the grains, for all the animals were getting vitamin-containing foods in abundance. The larger the quantity of cereal food consumed and the larger the dose of acid given orally or hypodermically, the more severe were the symptoms, facts which militate against any idea of a deficiency. As regards pellagra, there is evidence that it is occasionally caused by cereals and diets other than maize, and therefore there must be a factor common to them all. This, the authors think, is explained by the presence of a positive poison and by their acidity, with consequent injury to the nervous and other tissues of the body and a disturbance of the calcium and alkali balance. However, pellagra exists as a maize disease with its symptoms dependent on functional disturbances and organic lesions of the nervous system. The prominent skin lesion is probably due to a trophoneurosis which renders the skin unduly sensitive to any

irritant, such as sun rays, or merely to pressure as it occurs in persons lying in bed and not exposed to the sun. The monkeys and rabbits in the authors' studies reproduced, probably as nearly as they can be reproduced in animals, the symptoms and lesions of pellagra, and the pathologic changes in the nervous system were identical with those described by numerous investigators as occurring in pellagra. The rabbits showed marked skin lesions and a thinning of the bones. The incidence of pellagra in maize eaters is essentially a question of the quantity eaten. It occurs only when maize bulks preponderantly in the dietary and it has been demonstrated repeatedly and convincingly that the disease can be abolished or prevented by lessening the quantity of maize and substituting other articles of food.

Antitoxin Treatment of Scarlet Fever.—During a period of four and a half years, Banks administered intravenously scarlatinal antitoxin in 1,204 cases of scarlet fever. The results obtained confirm his tentative conclusions reached in 1928 that the acute stage of the disease can generally be arrested in from twelve to twenty-four hours, complications almost wholly prevented, and the period of morbidity reduced to a little more than two weeks. These effects were obtained in hospital wards in which more than 50 per cent of the cases, generally about 75 per cent and including all the worst, were so treated, and it is possible that the reduction of mass infection obtained in the wards by this means is an essential condition for obtaining such results. Under such conditions, relapses and cross infections were rare. Some evidence was obtained that antitoxin administered intravenously in the acute stage of scarlet fever largely prevents the onset of septic complications, including the late septic type itself, scarlatina anginosa, and that it may be of striking benefit in the treatment of the septic type, even at a late stage. The author states that it is important that the clinical potency and freedom from dangerous reactions of each individual batch of serum be proved. The indications for the intravenous injection of antitoxin in scarlet fever are toxic and septic scarlet fever, the severer forms of scarlatina simplex and definite cases of scarlet fever with faucial inflammation, rash and pyrexia. Its use is contraindicated in all cases with a history of asthma, eczema, hay fever, frequent urticaria or other manifestation of allergy; in all cases with a history of a previous injection of serum, especially within the previous two years, except when serum is urgently indicated; in cases in which any test for serum sensitiveness is positive, and in mild cases presenting little or no faucial inflammation and little or no rash.

Serous Meningitis.—Sheldon reports a case in which an attack of acute tonsillitis was followed, after an interval of about eight days, by a generalized scarlatiniform rash and by two groups of symptoms, which developed concurrently: (1) a series of disturbances of the larger joints, characterized by pain and effusion, the latter being especially prominent in the knees, and (2) a serous meningitis, of sufficient severity to give rise to 4 diopeters of papilledema. Both these groups of symptoms subsided as a peritoneal abscess due to a hemolytic streptococcus developed. Its drainage led to complete recovery. The diagnosis of hydrocephalus, due to a serous meningitis, was

established by the normal character of the cerebrospinal fluid, its increased pressure and the subsidence of symptoms, including the papilledema, after two lumbar punctures. The patient would not allow her tonsils to be removed; therefore a culture could not be obtained. The degree of leukocytosis when the patient was first seen suggested that the peritoneal abscess may have been developing even then, and it may well have been the focus from which was derived the streptococcus toxin that gave rise to the allergic symptoms. These may have been due merely to a direct toxic action on the synovia and the choroid plexus, but, if so, it is not a common association, and the demonstration of the possibility of serous hydrocephalus resulting from such an allergic state as serum sickness justifies one in extending this conception to cover the events of the present case. The author suggests that, as a result of previous attacks of tonsillitis, the patient had become sensitized to a streptococcus toxin and that the rash, joint effusions and serous hydrocephalus, which followed after the usual period of about eight days, were in the nature of an allergic reaction.

Note on Use of Steam for Providing Suction. G. V. Doyle.—p. 432.
*Note on Vaccine Treatment of Pneumonia. V. Davies.—p. 433.

Vaccine Treatment of Pneumonia.—Davies used pneumococcus vaccine (mixed), B strength, in treating twenty-two patients suffering from pneumonia, eight of whom received their injection on the first day. Four of these had normal temperatures within twenty-four hours and all eight had temperatures below 37.8 C. (100 F.) within thirty-six hours, with no subsequent rise. There was at the same time a corresponding improvement in both the general condition and the lung signs. In all the other patients, that is, those receiving treatment between the second and the fourth day of the illness, there was some sign of improvement following the administration of the vaccine, and all patients' illnesses ran a mild and uncomplicated course to recovery. In all these patients, the pneumonia was either the primary disease or secondary to influenza and bronchitis, except in one case of typhoid. The twenty-two patients include a variety of types, such as a baby of 1 year with double lobar pneumonia, a woman of 55 who had had asthma for twenty years, a man of 76 with glycosuria, and a woman of 82 who was almost bedridden. It is, of course, well known that the virulence of the organisms that cause pneumonia varies greatly from year to year. Consequently a vaccine that gave good results in one epidemic might possibly not be so effective in another. The other important point is the diagnosis, which would have to be confirmed in a large number of cases before the treatment could be absolutely assessed.

*Epituberculosis. H. A. V. Loots.—p. 214.
Hypophyseal Cachexia. L. D. Adler.—p. 216.

Epituberculosis.—Loots states that the points of interest in epituberculosis are the length of time the condition endures, varying from several months to more than a year, and the fact that recovery invariably occurs in these cases. The age at which the condition occurs is the first three years of life. There is little or no fever. The child is out of sorts. There are no bacilli in the sputum or the stool. The fact that these cases do not come to necropsy makes it difficult to prove that they are tuberculous in nature. The following facts, however, taken together, prove that they are tuberculous: (1) The Mantoux reaction is always positive, and a positive Mantoux, though by itself not of much value in later childhood, carries more weight when encountered in a child of 3 or less; (2) there is frequently a history of open tuberculosis in another member of the household, and (3) tubercle bacilli can be demonstrated in aspirated material. The author has had under observation two cases of epituberculosis for a period of nine months. These were slowly clearing up, but unfortunately on lung puncture no organisms were recovered. If allergic manifestations like erythema nodosum in tuberculosis and rheumatic fever are kept in mind, as well as the skin tests with tuberculin

which are dependent on allergic reactions, such an explanation is feasible and probable. Goldberg and Gasul reported cases of this nature in which the consolidation cleared up after a period of a year but promptly reappeared on the application of the Mantoux intradermal tuberculin test reaction. Quite different would be the progress if the condition were a tuberculous bronchopneumonia. The other condition likely to cause confusion would be unresolved pneumonia, which is quite common in children, but the history gives no evidence of a sudden onset, nor does fibrosis or bronchiectasis follow, which so often happens in unresolved pneumonia.

Segregation in Leprosy.—Hasselmann states that compulsory segregation has utterly failed in the Philippine Islands to result in any noticeable decrease in the incidence of leprosy as well as in the number of annual admissions of new cases. It inspires fear and keeps patients in the early stages of the disease from seeking medical advice, until they have had a chance to pass into a more advanced stage. The control of leprosy must have as its foremost object the discovery of as many early incipient cases as possible and the periodic examination of household members and others exposed to infection. With this aim, the establishment of skin policlinics and treatment dispensaries seems to achieve much more than less liberal, costly segregation methods. The establishment of attractive segregation settlements for the mutilated and for the supposedly highly infectious patients, without any too rigid enforcement and not too far away from the home districts of the patients, and with enough tillable land provided for the patients and their dependents, promises to lower the cost of leprosy control. In the individual treatment of a case of leprosy, a proper and sufficient, well balanced diet and the careful treatment of any intercurrent disease are imperative. The treatment of the disease must not lose sight of the more important goal: the treatment of the patient. The high incidence of true relapses (46.4 per cent) among paroled negative cases demands continued reexamination of the patient and his family over a long period. One cannot avoid the question whether the last acid fast bacilli of Hansen ever disappear entirely in perhaps even the majority of persons once infected, regardless of medicinal, so-called specific therapy. Therefore, in the arrested, negative cases the prevention of relapses lies rather in the diligent preservation of a high general resistance by proper and sufficient food, occupational and physical exercise and high morale.

Pellagra or Pellagroid in Leper Settlements.—For the past six or seven years Wilson noted among the inmates of the institutions at Soonchun and Fusan a condition similar to pellagra which might be termed pellagroid. It is evidently a food deficiency problem, possibly of the fat soluble vitamin A, from the fact that it responds quickly to treatment with pork or cod liver oil. In the early spring a series of cases appear showing stomatitis and a skin eruption. On the skin of the back of the hands, the neck, the ankles and occasionally the face there appears a dermatitis as a reddish or brown condition quite like a sunburn. After a few days or weeks the condition becomes darker, the skin cracks and later desquamation takes place. With treatment about 80 per cent of the skin trouble disappears entirely; a little remains over to the next season, showing a roughened skin. The gastro-intestinal tract shows disturbance, sore tongue and mouth, gas and distention; constipation and diarrhea in the later stages, though not in al

presence retards the healing of the pulmonary lesion, while their removal exerts a beneficial effect. The authors emphasize the value of Benedek's method of skull percussion with the aid of which correct localization of the tumor was made possible. In contradistinction to the value of the percussion method, encephalography demonstrated minimal lateral deviation of the ventricle. The authors point out that the results of operation on the meningeal tuberculosis are quite favorable even in the presence of severe pulmonary involvement. The occurrence of postoperative sensory disturbances of the opposite arm in the area of innervation of the nervus cutaneus antibrachii lateralis as well as of the median nerve is the result of operative trauma to the cortex.

Stomach Contents After Alcohol Test Meal.—Vogels investigated the value of microscopic study of gastric sediment after an alcohol test meal. The contents were secured by the fractional method. Seventy-one patients, including those with gastroduodenal ulceration, acute and chronic gastritis, gastric carcinoma and gastric complications resulting from diseases of other organs, were subjected to the study. Gastric ulcer, especially the callous variety, was characterized by pronounced epithelial desquamations. In acute gastritis, the increase in leukocytes was a characteristic feature. Gastritis accompanying certain general disease states showed the same result. The stomach, after a resection, presented a cytologic picture similar to that of a stomach which had not been operated on; namely, a preponderance of epithelium in the sediment. The bacterial flora of the stomach was found to be quite rich and was little influenced by the degree of acidity. Admixture of particles of food indicate motor disturbance occasioned by organic or functional pyloric stenosis. The oxydase reaction was found to be of value in differential diagnosis because of its ability to preserve the leukocytes in the sediment, especially in the presence of marked fermentation, and because it enables one to differentiate the leukocytes into myeloid and lymphocytic types.

Etiology of Diarrheal Disturbances in Nurslings.—In her study on the bacteriology of diarrheal disturbances of nurslings, Goldschmidt pays particular attention to a type first isolated by Adam and designated by him as the dyspepsia colon bacillus. This type is serologically well characterized and can be differentiated from other types of *Bacillus coli* and from the bacteria of the typhoid-paratyphoid-dysentery group. Demonstration by means of the culture method alone does not produce optimal results, but agglutination is required for a reliable identification. With few exceptions, the dyspepsia colon bacillus occurs only in the intestinal tract of nurslings. It can be demonstrated in approximately 50 per cent of the children having dyspepsia, and it is also occasionally demonstrable in nurslings who are free from intestinal disturbances. The bacillus is only rarely demonstrable in the gastric contents, the urine and the heart blood of dyspeptic nurslings, and it is extremely rare in healthy adults. It has never been found in nurslings having a parenteral *Bacillus coli* infection with healthy intestine, and it has not been detectable among numerous types of *Bacillus coli* from cow's milk. The symptomatology of diarrheal disturbances in which the dyspepsia colon bacillus is present does not differ from other dyspepsias. Moreover, the occurrence of the dyspepsia colon bacillus is by no means confined to the syndrome of intoxication of nurslings. This is demonstrated by the fact that only a small number of the children having diarrhea, in whom the dyspepsia colon bacillus was detected, reached the stage of intoxication. There were signs indicating that the diarrheal disturbances in which dyspepsia colon bacilli were found are contagious. They appear in large numbers at a time, and epidemiologic studies

could be made in several stations of the clinic. Bacillary dysentery, one of the most frequent house epidemics, could be excluded in these cases. The author reaches the conclusion that the dyspepsia colon bacillus is one of the many etiologic factors of the diarrheal disturbances in nurslings.

Subendocardial Hemorrhages.—In their studies on heart and trauma, Külls and Strauss frequently observed subendocardial hemorrhages in the left ventricle. They think that the mechanical theory of the pathogenesis of these hemorrhages is the most convincing. It is based on the fact that the anatomic structure of the endocardium around the conduction system is different from that of the other portions of the heart. Here is found an extremely loose subendocardial connective tissue and an abundance of vessels that evidently serve the special purpose of the conduction system. The authors had an opportunity to examine the hearts of 235 large slaughtered animals about half an hour after death. Of this number, 125 had been killed according to the Jewish ritual (the complete severance of the neck by three or more deep cuts into the trachea and carotids to effect great loss of blood). Subendocardial hemorrhages were found in all of these animals, while of the 110 animals who had been shot only 10 per cent showed subendocardial hemorrhages. In cats that had been killed by means of carbon dioxide, the subendocardial hemorrhages were found in only 2 per cent. These observations indicate that the mode of death is the determining factor and that the defense movements are of minor significance. The sudden cessation of the fine and autonomically regulated coronary circulation, the interruption of the central nervous regulation and the mechanical injury, particularly of the vagus, which all take place in killing according to the Jewish ritual, must be the causes of the subendocardial hemorrhages.

Functional Significance of Quantity of Blood.—Plesch shows that the regulation of the quantity of blood is largely determined by the venous pressure. The connection between the quantity of blood and the venous pressure produces an approximation of the beat volume of the two sides of the heart, and this process can be entirely mechanical without any nervous regulation whatever. But there are regulatory mechanisms helping the two sides of the heart to adapt themselves to the functional requirements, such as the active contraction of the auricle and the contraction or increase in tonus of other venous organs; for instance, the spleen. These regulatory mechanisms suffice under physiologic conditions, but in pathologic conditions, such as throttling at the atrioventricular ostium, stiffening of the ventricular wall, or lack of tonus in large areas of the venous system, the functionally produced beat volume may not be adequate for the maintenance of the circulation. In this case, new blood must be formed in order to increase the auricular pressure. The author shows that venous stasis in decompensation is a compensation for the insufficiency of the volume. He considers edema a compensatory mechanism in that it gives outside support to the venous vessels and is probably a factor in the maintenance of the beat volume. However, the two sides of the heart are not equivalent in regard to the problem of edema. A decompensation of the right heart and of the venous vessels of the systemic circulation produces stasis and edema in the venous organs of the systemic circulation but leaves the lesser circulation unimpaired; however, if the left heart or the venous regulation of the lesser circulation are damaged, the blood vessels of the lungs become enlarged

according to the method of Sawyer, Kitchen and Lloyd. It may now be used in place of convalescent serum for the vaccination of human beings against yellow fever. The method of the foregoing authors makes use of anti-yellow fever serum and yellow fever virus. The serum taken from a convalescent or recently vaccinated person must have an immunizing power of 100. Anti-yellow fever horse serum may be substituted for the convalescent serum in the proportion of 1:5. The yellow fever virus employed is originally obtained from monkeys and attenuated by repeated passage through mice. It is emulsified in nine times its volume of human serum, filtered, put in ampules and desiccated in the congealed state. For vaccination, 0.5 cc. of the antiserum per kilogram of body weight is injected subcutaneously; six hours later from 0.3 to 0.5 cc. of the emulsion of the virus (distilled water is added to make up the original volume) is injected subcutaneously in the arm. Sixteen persons were vaccinated by this method by Sawyer, Kitchen and Lloyd and twenty-five by Findlay without serious mishaps. The reactions usually consisted of tenderness at the site of the serum reactions, a slight rise in temperature about thirty hours after injection of the virus, and headache and slight photophobia. While the problem of vaccination against yellow fever is not entirely solved, recent experiences permit the hope of a solution. From now on the danger of vaccination is less to be feared than the risk incurred by laboratory workers and inhabitants of infected areas.

Exudative Contralateral Pleuritis in Course of Therapeutic Pneumothorax. C. Tiengo.—p. 379.

Pleuritis in Therapeutic Pneumothorax.—Tiengo treated two tuberculous patients with artificial pneumothorax in which pleuritis arose as a complication. Examination of the first patient revealed a participation of the right pleura through exudative reaction in a grave bronchopneumonic process of the right upper lobe, a contralateral pleuritis due to a gradual rise of the contralateral exudative phenomenon and its benign course, a rapid local and general improvement of the patient after abandonment of the pneumothorax, and a favorable outcome three years after interruption of pneumothoracic treatment. The second patient showed improvement due to the pneumothorax during the first month of treatment. Contralateral pleuritis set in suddenly after thirty days of treatment with aggravation of the symptoms. The author does not doubt the tuberculous origin of the pleuritides; in both cases Rivalta's reaction was positive and the leukocytic formula was lymphocytic. In the second case there was invasion of the underlying parenchyma leading to death from a bilateral pulmonary tuberculosis. The process spread to the contralateral lung immediately after the appearance of the pleuritis. In one case, the contralateral pleuritis was established a few hours after insufflation of air and, in the second case, one month from the beginning of the treatment when it had not yet created a sufficient collapse of the diseased lung. The author states that the pneumothorax can act at a distance on organs and viscera which have no relation to the diseased lung. In the case of one author, every refilling was followed by hematuria due to a tuberculous kidney. The febrile attacks and cutaneous manifestations following the first refillings appear to be anaphylactic; they include the focal reactions observed in the course of tuberculin therapy. Some authors found that the hemoclastic tuberculous patients after tuberculin treatment of tuberculin or albumose-free tuberculin, according to the person and remain in a state of tuberculin administered, with the number of foci, which are often undiagnosed in various organs. This

allergic phenomenon as the effective cause of contralateral pleuritis. If antigen material passes into the circulation and can produce such reactions, it seems logical that old localizations should receive sufficient stimulus from this allergizing material to renew their exudative activity. There also is the possibility that the contralateral pleuritis may occur independent of collapse therapy. The author advocates the application of pneumothoracocentesis in cases presenting considerable contralateral effusions and serious circulatory and respiratory disturbances.

Renal Decapsulation in Hematuric Nephritis.—Cirio states that there is a great disparity in the reports on decapsulation treatment for nephritis. He holds that in less cases, when the life of the patient is not in danger, decapsulation is the most preferable operation. In cases in which there is evident inflammatory history and pain accompanies the hematuria there has been a high percentage of successful decapsulations. The hematuria depends on a chronic inflammatory factor, which involves a small portion of the kidney, is particularly persistent and usually does not respond to prolonged medical treatment. In these cases, decapsulation causes a hyperemia leading to improvement of the circulation of the organ and of its trophic condition and favoring resolution of the inflammation. According to Stropeni, decapsulation has a soothing effect on pain, an attenuated microbicidal action, a reabsorbing effect on the exudates, dissolvent effects through which fungosities disappear, nutritive effects and favorable influence on the regeneration of the tissues. The author states that decapsulation or even partial enervation, if the capsule destroys the sensitive nerve fibers, reduces the intensity of the stimulus transmitted to the center so that it no longer arrives at the specific spinal-thalamic centers of the pain. He reports three cases of painful hematuric nephritis in which decapsulation was the operation of choice. Two of the patients were continually treated for from two to three years after operation but, eventually, were completely cured. The other patient was treated until three months after operation and showed satisfactory results.

Treatment in Severe Ulcerous Colitis.—Bensaude and his associates think that the treatment of severe ulcerative colitis must take into account both etiologic factors involved; that is, infection and predisposition. They employed auto-hemotherapy in five cases of severe rectocolitis, with an evolution varying from two months to five years. This treatment produced a rapid improvement in four cases in which all the customary methods of treatment had failed. The fifth patient was improved but had incessant recurrences, which were stopped each time by this therapy. The hemorrhages disappeared after several days even in the most hemorrhagic forms. The mucus and the number of stools returned to normal in from ten to fifteen days, and the change in their consistency was the most pronounced sign. The general condition was improved gradually and the four patients were dismissed, cured. Improvement of the functional symptoms was markedly in advance of the improvement of physical signs. It is too early to draw conclusions as to a permanent cure, but none of the four patients have had a recurrence after the lapse of several months. The results resemble those obtained by Kalk, who cured several cases of ulcerative colitis by giving the patients serum sickness by injections of horse serum. The cures obtained by anti-dysenteric serum in colitis of nondysenteric origin may also be explained by the mechanism of shock. The same may be true of Bargen's serum.

- Osteo-Articular and Infantile Surgery. A. Mouchet and C. Røderer.—p. 521.
Treatment of Dorsolumbar Fractures Without Paralytic Symptoms. P. Mathieu.—p. 538.
*Painful Syndromes of Sacrolumbar Region. G. Roudil.—p. 542.
*Vertebral Angioma. C. Røderer.—p. 544.

Painful Syndromes of Sacrolumbar Region.—Roudil was consulted by a woman, aged 26, with pain in the lower part of the spine, which had come on gradually two days after a violent hyperextensive movement of the spine when sitting down. The pain, which was aggravated by walking and relieved by decubitus, radiated into the pelvic girdle and upper part of the buttocks. Roentgenography disclosed a congenital malformation consisting of an unusual type of bilateral and total sacralization of the fifth lumbar vertebra. The body of the fifth lumbar vertebra was in synostosis with the first sacral vertebra, and the two transverse processes were joined in like manner to the iliac bones, but there was an osseous fissure completely separating the transverse processes from the rest of the vertebra and creating a veritable articulation between the vertebral portion comprising the body, the lamina and the superior articular processes and the two transverse processes. The width of the fissure, the regularity of its borders and the absence of a violent trauma ruled out the idea of a fracture. The author thinks that the hyperextensive movement of the spine made by the patient caused a distention of the fibroligamentous tissue at the level of the nearthrosis. This was followed by arthritic manifestations, the nearthrosis being probably more sensitive

to a slight trauma. A small celluloid girdle molded to the sacrolumbar region made the pain and muscular contraction disappear.

Vertebral Angioma.—Røderer reports a case discovered by chance during examination of the roentgenograms of the spine of a young woman who complained of a persistent, diffuse pain in the dorsolumbar region of the spine which had appeared after a fall on the back. She had a slight scoliosis with right dorsal and left lumbar convexity of long duration. Roentgenography disclosed a typical image of angioma involving the fifth dorsal and first lumbar vertebrae. The disks and bodies of the intervening vertebrae appeared absolutely normal. The fifth dorsal vertebra was more transparent than its neighbors; it had a border but the central portion had a speckled appearance caused by many irregularly scattered light spots. The trabeculation was much enlarged and in general in a vertical direction, one side being eroded, the other slightly swollen. The first lumbar vertebra was of approximately normal size, but the lesions were more developed, giving the appearance of a pumice-stone. The direction of the trabeculae could not be distinguished. The porous aspect was seen best in the profile view. It was not limited to the body but extended to the spinous and articular processes. The author says that the characteristic appearance of this roentgenographic image permits it to be differentiated from cancer, which spares the disks, and from various forms of spondylitis, which resorb them more or less. Its recognition is important, as the angioma is sensitive to roentgen rays. In this case the two vertebrae of transition in a double scoliosis were affected; the author suggests that the porous condition of the angiomatous vertebra may have caused the scoliosis.

*Anti-Yellow Fever Vaccination. G. J. Stefanopoulo.—p. 1016.

Hepatitis of Elimination.—In experiments on dogs, Fiessinger and Cattani found that the intravenous injection of bacteria is followed by the rapid production of lesions of the hepatic parenchyma, which seem to be linked with the elimination of the bacteria by the biliary tract. Hepatic lesions were produced by the nonpathogenic *Bacillus mesentericus* and by the pathogenic *Bacillus paratyphosus A* and *Bacillus paratyphosus B*. In the case of *B. mesentericus* the bacteria appeared in the bile three quarters of an hour after intravenous injection. The hepatitis of elimination appeared almost immediately after the injection of the bacteria and attained its maximum at the end of twenty-four hours; no trace of it could be found fifteen days later. When the experiment was repeated on one of the dogs one month later under identical conditions, no hepatic lesions were produced. It appears as though the first injection created an active immunity. These facts indicate that there are no bacteria devoid of toxicity. Even if the massive introduction of a strain of bacteria into an organism leaves it unaffected, this does not mean that the passage of the bacteria through the hepatic cells is innocuous. Besides the general pathogenicity there is a local pathogenicity manifesting itself by cellular lesions of slight intensity and rapid regression. These lesions do not appear if the organism is protected against the injected bacteria by vaccination or serum therapy. Killed bacteria (*B. mesentericus*) also produced discrete but distinct hepatic lesions. This indicates the danger of vaccination in a person with a diseased liver. The elimination of bacteria by the excretory organs appears to be one of the chief means of defense of the organism against infection, but it cannot take place without the production of lesions in the organ traversed, which, in case of massive or prolonged infection with highly virulent bacteria, may be severe and irreparable. The frequency of hepatic and renal lesions in the course of septicemias appear to result from the elimination of the bacteria by way of these organs.

Vaccination Against Yellow Fever.—Stefanopoulo reports that the anti-yellow fever serum produced by Pettit and himself in horses or large monkeys has been successfully substituted for human convalescent serum in the vaccination of monkeys.

according to the method of Sawyer, Kitchen and Lloyd. It may now be used in place of convalescent serum for the vaccination of human beings against yellow fever. The method of the foregoing authors makes use of anti-yellow fever serum and yellow fever virus. The serum taken from a convalescent or recently vaccinated person must have an immunizing power of 100. Anti-yellow fever horse serum may be substituted for the convalescent serum in the proportion of 1:5. The yellow fever virus employed is originally obtained from monkeys and attenuated by repeated passage through mice. It is emulsified in nine times its volume of human serum, filtered, put in ampules and desiccated in the congealed state. For vaccination, 0.5 cc. of the antiserum per kilogram of body weight is injected subcutaneously; six hours later from 0.3 to 0.5 cc. of the emulsion of the virus (distilled water is added to make up the original volume) is injected subcutaneously in the arm. Sixteen persons were vaccinated by this method by Sawyer, Kitchen and Lloyd and twenty-five by Findlay without serious mishaps. The reactions usually consisted of tenderness at the site of the serum reactions, a slight rise in temperature about thirty hours after injection of the virus, and headache and slight photophobia. While the problem of vaccination against yellow fever is not entirely solved, recent experiences permit the hope of a solution. From now on the danger of vaccination is less to be feared than the risk incurred by laboratory workers and inhabitants of infected areas.

Anatomopathologic and Clinical Contribution to Constitutional Pathogenesis of Atrophic Hepatic Cirrhosis. S. de Candia.—p. 972.
Contribution to Acute Peritonitis Due to Appendicitis. P. Bastianelli.—p. 975.

Calcemia and Calcipexy in Pulmonary Tuberculosis.—Starna declares that the meager knowledge of calcium metabolism does not justify the usage of calcium as a specific treatment of tuberculosis. The author reviews the research of others in which calcium therapy offered most favorable results but still maintains that the action of calcium in tuberculosis is not definite. In the treatment of tuberculosis he attributes great importance to vitamin D in any form from cod liver oil to Gerson's diet. The easy administration of viosterol has induced many authors to experiment with it in the treatment of tuberculosis and many have successfully combined calcium and viosterol. According to György, hypercalcemia is the proof of intoxication due to hypervitaminosis and is accompanied by serious general decline. The author cites six of a number of patients with pulmonary tuberculosis treated with intravenous injections of 10 cc. of a 10 per cent solution of calcium chloride on alternating days together with daily oral administration of 1 Gm. of tribasic calcium phosphate and 20 drops of viosterol before lunch. After from thirty-five to forty-five days, treatment was suspended and metabolic clinical and roentgenologic examination was made. Four patients showed improvement in their general condition and weight and considerable decrease of their calcemia. The two remaining patients showed an

Contribution to Acute Peritonitis Due to Appendicitis. P. Bastianelli.—p. 975.

Calcemia and Calcipecty in Pulmonary Tuberculosis.—Starna declares that the meager knowledge of calcium metabolism does not justify the usage of calcium as a specific treatment of tuberculosis. The author reviews the research of others in which calcium therapy offered most favorable results but still maintains that the action of calcium in tuberculosis is not definite. In the treatment of tuberculosis he attributes great importance to vitamin D in any form from cod liver oil to Gerson's diet. The easy administration of viosterol has induced many authors to experiment with it in the treatment of tuberculosis and many have successfully combined calcium and viosterol. According to György, hypercalcemia is the proof of intoxication due to hypervitaminosis and is accompanied by serious general decline. The author cites six of a number of patients with pulmonary tuberculosis treated with intravenous injections of 10 cc. of a 10 per cent solution of calcium chloride on alternating days together with daily oral administration of 1 Gm. of tribasic calcium phosphate and 20 drops of viosterol before lunch. After from thirty-five to forty-five days, treatment was suspended and metabolic clinical and roentgenologic examination was made. Four patients showed improvement in their general condition and weight and considerable decrease of their calcemia. The two remaining patients showed

increase in the calcemia and cachexia; one lost in weight while the other gained slightly. The author states that in all patients manifesting an improvement in the general condition together with a decrease of the calcium content of the blood the tissues draw from and absorb more of the circulating calcium than normally. The author concludes that viosterol, like calcium, does not decrease the calcium content of the blood by itself but that, when the two are administered together, they tend to modify the calcemia.

Therapy of Poliomyelitis.—Pette says that, in spite of the extensive involvement of the spinal cord and of the brain, the symptoms of poliomyelitis consist almost exclusively in the abolishment of the motor functions, whereas other manifestations, such as parkinsonism, are never observed, although the pallidum and the substantia nigra are nearly always involved. The essential nature of poliomyelitis is reflected in the impairment of the ganglion cells. Severe parenchymal damage is found only in the motor portions of the spinal cord, whereas in the other regions of the central organ the gliogenous and the mesodermal reactions predominate. It could be proved in animal experiments that the segments of the spinal cord are not involved all at once but become so one after the other. This factor is the anatomic foundation of a successful treatment at the time of the first appearance of the paralytic manifestations. The fact that the virus of poliomyelitis is neurotropic and causes symptoms only within the central nervous system and never in the mucous membranes seems to indicate that the catarrhal manifestations that precede the paralytic stage of poliomyelitis are not caused by the virus of poliomyelitis but by other infections. The author considers the frequent occurrence of catarrhs in close proximity to occasional poliomyelitis as an indication that the nonspecific infection is a predisposing factor for the paralytic stage. At first the cells show changes during the preparalytic stage. The significance of these changes lies in the fact that the stage of the process can thus be determined. The author states that serum therapy is the method of choice. The earlier it is started the better are its prospects, although success may still be expected even if it is not begun until the first paralytic symptoms appear.

Large Doses of Iron in Treatment of Anemia.—Buresch describes six cases of severe anemia caused by gastric hemorrhages, which in turn were produced by gastric or duodenal ulcers. Large doses of reduced iron, that is, from 3 to 4 Gm. daily, effected rapid improvement. Not only was the blood status favorably influenced, but the general condition also improved. The author discusses the various theories concerning the mode of action of iron therapy. Observations on a patient with achlorhydria convinced her that the theory, which considers the presence of free hydrochloric acid as an absolute requirement for the efficacy of iron therapy, does not necessarily apply to all cases. She calls attention to a phenomenon of which she found no record in the available literature on iron therapy; namely, a pronounced eosinophilia, which in one patient reached 41 per cent. So far this phenomenon had been observed only in the stage of regeneration in pernicious anemia undergoing liver therapy.

in an old Egyptian papyrus, according to which the sex of a fetus can be determined from the action of the urine of a pregnant woman on germinating grains of barley and of wheat. He found that more rapid growth of barley compared to that of wheat speaks for the female sex of the fetus, whereas a non-accelerated or a retarded growth of barley indicates that the fetus is male. The author made such tests on the urine of 100 pregnant women. The majority of them were in the last stage of pregnancy. The observations enabled the author to make a correct diagnosis of the sex of the fetus in eighty of the women; in the other twenty, the diagnosis was erroneous.

Freund-Kaminer Intracutaneous Cancer Reaction.—Kotnretz and Weber state that the Freund-Kaminer cancer test is based on the difference in the behavior of normal serum and that obtained from cancer patients toward cancer cells. Normal serum dissolves cancer cells, whereas serum of patients having carcinoma does not and, when mixed in equal amounts with normal serum, the serum of cancer patients will protect cancer cells against destruction. It was further established that the intestinal contents acted in the same way as the serum and that the addition of animal fatty acids enhanced the destructive power against cancer cells. It was likewise shown that *Bacillus coli* has the power of destroying cancer cells, but if grown on an acid medium it develops a protective power for the same cells. According to Freund and Kaminer, the cell-destructive substance is contained in normal fatty acid and can be extracted from it by ether. The "destructive" substance is presumably bound up in some other combination with the fatty acids. This last acid, designated as the "carcinoma acid," is utilized in the test. The technic consists in injection of 0.05 or 0.03 cc. of the acid intracutaneously into the flexor surface of the forearm. Below this a 0.03 cc. control injection of physiologic solution of sodium chloride or of tricesol is made. A positive reaction manifests itself in from twenty-four to forty-eight hours by the appearance of a nodule surrounded by an area of redness. Inflammatory redness alone is regarded as a negative reaction. Observations were made on four groups of patients: (1) proved cases of cancer; (2) a control group of patients suffering from other than malignant disease; (3) clinically uncertain conditions; (4) tumors other than cancer. In the first group the test was correct in 86.4 per cent. There were fourteen negative and ten doubtful reactions. In the control group of 118 patients there were 58 negative, 36 uncertain and 24 positive reactions. In the fourth group of seven mesenchymal tumors there were one negative, four doubtful and two positive reactions. The authors conclude that a positive reaction is of value when signs suggesting a malignant condition are present. A positive reaction alone does not establish the diagnosis of a malignant condition in the absence of other evidence. The negative reaction is of a greater value than the positive one. The reaction is of value in differential

presence retards the healing of the pulmonary lesion, while their removal exerts a beneficial effect. The authors emphasize the value of Benedek's method of skull percussion with the aid of which correct localization of the tumor was made possible. In contradistinction to the value of the percussion method, encephalography demonstrated minimal lateral deviation of the ventricle. The authors point out that the results of operation on the meningeal tuberculosis are quite favorable even in the presence of severe pulmonary involvement. The occurrence of postoperative sensory disturbances of the opposite arm in the area of innervation of the nervus cutaneus antibrachii lateralis as well as of the median nerve is the result of operative trauma to the cortex.

Stomach Contents After Alcohol Test Meal.—Vogels investigated the value of microscopic study of gastric sediment after an alcohol test meal. The contents were secured by the fractional method. Seventy-one patients, including those with gastroduodenal ulceration, acute and chronic gastritis, gastric carcinoma and gastric complications resulting from diseases of other organs, were subjected to the study. Gastric ulcer, especially the callous variety, was characterized by pronounced epithelial desquamations. In acute gastritis, the increase in leukocytes was a characteristic feature. Gastritis accompanying certain general disease states showed the same result. The stomach, after a resection, presented a cytologic picture similar to that of a stomach which had not been operated on; namely, a preponderance of epithelium in the sediment. The bacterial flora of the stomach was found to be quite rich and was little influenced by the degree of acidity. Admixture of particles of food indicate motor disturbance occasioned by organic or functional pyloric stenosis. The oxydase reaction was found to be of value in differential diagnosis because of its ability to preserve the leukocytes in the sediment, especially in the presence of marked fermentation, and because it enables one to differentiate the leukocytes into myeloid and lymphocytic types.

Etiology of Diarrheal Disturbances in Nurslings.—In her study on the bacteriology of diarrheal disturbances of nurslings, Goldschmidt pays particular attention to a type first isolated by Adam and designated by him as the dyspepsia colon bacillus. This type is serologically well characterized and can be differentiated from other types of *Bacillus coli* and from the bacteria of the typhoid-paratyphoid-dysentery group. Demonstration by means of the culture method alone does not produce optimal results, but agglutination is required for a reliable identification. With few exceptions, the dyspepsia colon bacillus occurs only in the intestinal tract of nurslings. It can be demonstrated in approximately 50 per cent of the children having dyspepsia, and it is also occasionally demonstrable in nurslings who are free from intestinal disturbances. The bacillus is only rarely demonstrable in the gastric contents, the urine and the heart blood of dyspeptic nurslings, and it is extremely rare in healthy adults. It has never been found in nurslings having a parenteral *Bacillus coli* infection with healthy intestine, and it has not been detectable among numerous types of *Bacillus coli* from cow's milk. The symptomatology of diarrheal disturbances in which the dyspepsia colon bacillus is present does not differ from other dyspepsias. Moreover, the occurrence of the dyspepsia colon bacillus is by no means confined to the syndrome of intoxication of nurslings. This is demonstrated by the fact that only a small number of the children having diarrhea, in whom the dyspepsia colon bacillus was detected, reached the stage of intoxication. There were signs indicating that the diarrheal disturbances in which the dyspepsia colon bacilli were found are contagious. They occurred in large numbers at a time, and epidemiologic studies

could be made in several stations of the clinic. Bacillary dysentery, one of the most frequent house epidemics, could be excluded in these cases. The author reaches the conclusion that the dyspepsia colon bacillus is one of the many etiologic factors of the diarrheal disturbances in nurslings.

Subendocardial Hemorrhages.—In their studies on heart and trauma, Küls and Strauss frequently observed subendocardial hemorrhages in the left ventricle. They think that the mechanical theory of the pathogenesis of these hemorrhages is the most convincing. It is based on the fact that the anatomic structure of the endocardium around the conduction system is different from that of the other portions of the heart. Here is found an extremely loose subendocardial connective tissue and an abundance of vessels that evidently serve the special purpose of the conduction system. The authors had an opportunity to examine the hearts of 235 large slaughtered animals about half an hour after death. Of this number, 125 had been killed according to the Jewish ritual (the complete severance of the neck by three or more deep cuts into the trachea and carotids to effect great loss of blood). Subendocardial hemorrhages were found in all of these animals, while of the 110 animals who had been shot only 10 per cent showed subendocardial hemorrhages. In cats that had been killed by means of carbon dioxide, the subendocardial hemorrhages were found in only 2 per cent. These observations indicate that the mode of death is the determining factor and that the defense movements are of minor significance. The sudden cessation of the fine and autonomically regulated coronary circulation, the interruption of the central nervous regulation and the mechanical injury, particularly of the vagus, which all take place in killing according to the Jewish ritual, must be the causes of the subendocardial hemorrhages.

Functional Significance of Quantity of Blood.—Plesch shows that the regulation of the quantity of blood is largely determined by the venous pressure. The connection between the quantity of blood and the venous pressure produces an approximation of the beat volume of the two sides of the heart, and this process can be entirely mechanical without any nervous regulation whatever. But there are regulatory mechanisms helping the two sides of the heart to adapt themselves to the functional requirements, such as the active contraction of the auricle and the contraction or increase in tonus of other venous organs; for instance, the spleen. These regulatory mechanisms suffice under physiologic conditions, but in pathologic conditions, such as throttling at the atrioventricular ostium, stiffening of the ventricular wall, or lack of tonus in large areas of the venous system, the functionally produced beat volume may not be adequate for the maintenance of the circulation. In this case, new blood must be formed in order to increase the auricular pressure. The author shows that venous stasis in decompensation is a compensation for the insufficiency of the volume. He considers edema a compensatory mechanism in that it gives outside support to the venous vessels and is probably a factor in the maintenance of the beat volume. However, the two sides of the heart are not equivalent in regard to the problem of edema. A decompensation of the right heart and of the venous vessels of the systemic circulation produces stasis and edema in the venous organs of the systemic circulation but leaves the lesser circulation unimpaired; however, if the left heart or the venous regulation of the lesser circulation are damaged, the blood vessels of the lungs become enlarged

and produce dyspnea and pulmonary edema. In this case the compensation is as dangerous as the disorder itself, whereas in the systemic circulation the conditions are reversed.

Periodic Fertility and Sterility in Women.—Knaus contends that, in women with a regular menstrual cycle of twenty-eight days, conception can take place only from the eleventh to the seventeenth day of the menstrual cycle. The factors are as follows: 1. The ovum remains fertilizable only a few hours after it is discharged by the follicle. 2. The spermatozoa lose their fertilizing capacity in the female genitalia in less than forty-eight hours. 3. The autonomous function of the corpus luteum spurium lasts fourteen days. 4. The rupture of the follicle takes place regularly and spontaneously fourteen days before the next menstruation, irrespective of the length of the menstrual cycle. 5. The impulse for the persistence of the function of the corpus luteum at the beginning of pregnancy comes from the hormones of the implanted ovum. The author emphasizes that in women ovulation is spontaneous and is not, as in some animals, produced by coitus. On the basis of three case reports, he shows that failures in the application of his theory can always be traced to the fact that the menstrual cycle was not of the assumed length. It is necessary for a woman to keep an exact record of the onset of her menstrual periods. If this is done for at least a year, the term of ovulation can readily be determined by subtracting fourteen days from the length of the cycle. In women in whom the length of the menstrual period varies, the date of ovulation varies too. For instance, in a woman in whom the length of the period varies between twenty-eight and thirty-two days, ovulation can take place from the fourteenth to the eighteenth day after the onset of the last menstruation, and conception can take place between the eleventh and the nineteenth day. The author mentions Ogina's studies on this subject (abstracted in THE JOURNAL, June 18, 1932, p. 2257), whom he credits with priority in the discovery of the physiologic sterility of women and with whom he largely agrees. However, he thinks that Ogina extends the period of conception capacity too far and thereby shortens the period of physiologic sterility more than is necessary.

Salpingographic Examinations After Sterilization.—Eydung reports his observations made in the course of the last five years on eighty women who underwent sterilization: Sterilization has been done according to Madlener's method in sixty-three, according to Alfieri's method in nine, and the inguinal incision was made in eight. The only failure in the eighty sterilizations was observed in a woman in whom Alfieri's method had been employed. In the first group, not a single failure became evident and the salpingographic control examinations revealed in only two roentgenograms a visibility of the oviducts with closed ostium abdominale. The author considers tubal sterilization according to Madlener the most suitable method, particularly if it is done in the course of a laparotomy. In cases in which a laparotomy is not required for other reasons, he advises transplantation of the oviducts into the inguinal canal as the preferable method.

Puerperal Inversion of Uterus Caused by Fatigue.—Schultze gives the history of a primipara, aged 21, in whom the spontaneous delivery of the child and the placenta was followed by collapse. Palpation gave the impression that the posterior wall of the uterus presented a hole and, because of the somewhat large size of the fetus and a rather narrow pelvis, a rupture of the uterus was suspected, but in the course of palpation a change became noticeable. On the right side the uterus could not be felt, whereas on the left side it was still palpable, proving the existence of an inversion. The fundus of the inverted uterus could be felt directly behind the

vulva. It had been forced through the external os. Reposition by pressure on the fundus failed, although there was no constriction at the os, but it was possible to press the muscular bag gradually backward by beginning at the right side. The uterus was now extremely flaccid, there was considerable bleeding in spite of the intravenous administration of ergotamine tartrate and, as soon as the hand was withdrawn, the inversion returned. A tampon was introduced, the uterus contracted well around it and the hemorrhage ceased. In discussing the causes of the inversion, the author points out that it is especially frequent in young primiparas and that the weakened and asthenic condition of the patient was probably a contributing factor. Moreover, the labor pains had lasted a considerable time when they ceased, and several injections of hypophyseal extract became necessary. It has been asserted that an overdosage of hypophyseal extract may cause inversion, but, since only the entirely flaccid uterus can become inverted and the hypophyseal extract produces an increased tonus and a spastic contraction of the muscles, the author considers this cause unlikely. As certain conditions and manipulations during the placental period, which generally play an important rôle in uterine inversion, were also absent in this case, he is of the opinion that the weakness of the labor pains resulting from fatigue, noticeable during the entire process of delivery, was the cause of the inversion. He sees in this condition a parallelism to the severe atonic hemorrhages occasionally observed following prolonged and difficult labor. The author does not fear greatly the danger of shock, which is considered by some a contraindication to immediate reposition, but he is convinced that an expectant attitude involves danger of infection.

Combined Form of Lipoid-Amyloid Nephrosis.—Zeman presents a study of six cases of lipoid-amyloid nephrosis. The two fundamental changes are the lipoidosis of the cortical tubular epithelium and the amyloidosis of the tufts and the arterioles. He regards the demonstration of a certain amount of amyloid infiltration of the tufts as a secondary complication of the lipoid dystrophy brought about by the albuminous component. He observed in a patient with acute amyloidosis in a contracted kidney extensive anisotropic lipoidosis of the tubules. This observation contradicts Fahr's dictum that secondary lipoidosis of an amyloid kidney is never extensive. On the basis of his observations the author regards lipoid nephrosis, contrary to the prevalent idea, not as an independent morbid entity but as a symptomatic manifestation of a general disturbance of the metabolism affecting both the lipoid and the albuminous elements.
